Fractures of the Lower Extremity of the Humerus.—These fractures are spoken of as fractures in, or in the neighborhood of, the elbow-joint, and they include: (*a*) fractures of the external condyle; (*b*) fractures of the internal condyle; (*c*) fractures of the internal epicondyle; (*d*) fractures at the base of the condyles; (*e*) T- or Y-shaped fractures; (*f*) epiphyseal separation, and (*g*) fractures of the capitellum and trochlea. There may be more than one fracture, or there may be also a dislocation of the humerus, of the ulna, or of both bones. Rarely the fracture is compound. These fractures are frequent injuries in childhood, and are not uncommon in adults.

Method of Examination.—A fracture of the elbow is rapidly followed by great swelling, and the diagnosis is often very difficult. In most cases, when possible, the *x*-rays should be used in arriving at a diagnosis. In every case in which the *x*-rays are not used, and in most cases in which they are, the surgeon examines the parts carefully while the patient is under ether. If swelling is very great, it is necessary to abate it in order to reach any conclusion as to the condition. We can bandage the arm, rest it semiflexed on a pillow, and apply evaporating lotions or even an ice-bag for a day or two, or, what is better, temporarily diminish the swelling by Gerster's plan, which is as follows: Apply an Esmarch bandage from the hand to well above the seat of fracture; this will drive away extra-articular swelling and permit of thorough examination. It is a great advantage to have the patient anesthetized, for then not only can we make an accurate diagnosis, but we can reduce the fracture satisfactorily and apply a careful first dressing.

Compare the injured with the sound elbow. Note swelling and local ecchymosis. Feel the radial pulse. Note the "carrying angle" (Fig. 308). Measure each arm from the tip of the acromion process of the scapula to the tip of the external condyle of the humerus. Feel each prominent bony point and note if it is mobile (condyles, olecranon, head of ulna). Feel the shaft just above the condyles. Mark with ink on each elbow the tip of the external condyle, the tip of the internal condyle, and the tip of the olecranon, and observe the relation between these points of each elbow in flexion and in extension. In an uninjured elbow a straight line transverse to the long axis of the limb with the joint in extension will pass through the condyles and leave the tip of the olecranon just a shade above it. "When the elbow is at a right angle, these three points will be found in the same plane with the back of the upper arm" (Scudder, in "The Treatment of Fractures"). Rotate the radius while a thumb is held against the head of the bone. Make flexion and extension of the elbow and determine if there is any lateral motion. Test for mobility just above the condyles. The above maneuvers will determine the presence or absence of crepitus, preternatural mobility, deformity, etc.

Fractures of the External Condyle of the Humerus.—A fracture of the external condyle runs into the joint and the capitellum is usually broken off. Such an injury occurs oftenest in children, being due to falling on the hand; but it may occur from direct force, and may happen to adults.

The *symptoms* of fracture of the external condyle are severe pain, great swelling, and crepitus (found on pressing or moving the condyle and on rotating the radius). Mobility may also be discovered. A projection is felt on the outer and posterior surface of the elbow. The forearm is semiflexed and supinated. The patient cannot use the joint.

Fractures of the Inner Epicondyle of the Humerus.—The inner epicondyle is an epiphysis which unites during the seventeenth year. It not infrequently breaks from muscular action or from direct violence, and the fracture does not involve the joint. Crepitus and mobility can be detected. Displacement is slight. The *outer epicondyle* is never fractured alone.

Fractures of the Internal Condyle of the Humerus.—The line of fracture after a break of the internal condyle runs into the joint, to the trochlear surface of the humerus. The *cause* is nearly always direct violence. Packard, of Philadelphia, observed a case in which the condyle had been torn off while lifting a tub.

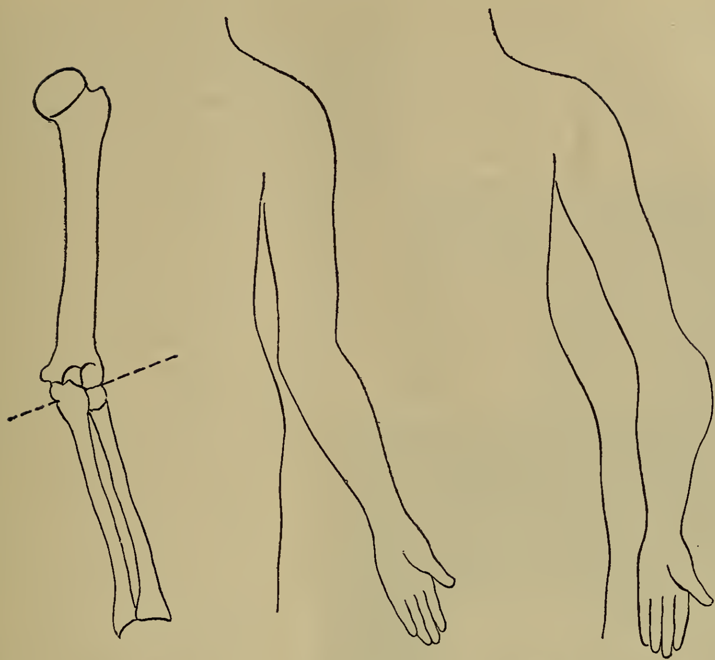
Symptoms.—In fracture of the internal condyle the fragment, accompanied by the ulna, goes upward and backward, and when the forearm is extended the ulna projects posteriorly, the lower end of the humerus being felt in front. The fragment forms a projection back of the elbow. Crepitus and preternatural mobility can be found if swelling is not too great. Crepitus is detected by flexing and extending the forearm. The space between the condyles is broader than normal, and the forearm takes a bend toward the ulnar side, the "carrying function" of the forearm being lost (Fig. 307). When a person carries a heavy object, such as a bucket of coal, he instinctively rests the inner condyle upon the pelvis, and the normal deviation of the forearm outward keeps the bucket from striking the leg. This deviation outward when the inner condyle rests against the ilium gives us the carrying function. In fracture of the inner condyle the broken condyle ascends and the "carrying function" is lost (Fig. 308). This deformity is known as *gunstock deformity.*

Fig. 307.—Loss of "carrying function" after fracture of inner condyle of the humerus.

Fractures at the Base of the Condyles of the Humerus (Figs. 309 and 310).—A fracture in this region is just above the level of the tip of the olecranon and is on a higher level behind than in front. The *cause* is direct force acting upon the olecranon.

The *symptoms* are loss of function, and pain from injury to the median or ulnar nerve. Crepitus and mobility are readily found. The lower fragment is drawn backward and upward by the action of the triceps, biceps, and brachialis anticus muscles. The lower end of the upper fragment projects in front of the joint. This lesion may be mistaken for dislocation of the bones of the forearm backward. In fracture the limb is mobile; in dislocation, it is rigid. In fracture the deformity is easily reduced and strongly tends to recur; in dislocation the deformity is reduced with difficulty and does not tend to recur. In dislocation there is shortening of the forearm, but not of the arm; in fracture there is shortening of the arm, but not of the forearm. In dislocation there is a smooth, large projection below the crease in front of the elbow; in fracture there is a sharp projection above the crease. In fracture there is crepitus; in dislocation there is no crepitus.

The *diagnosis* can be settled by the x-rays.



a *b* *c*

Fig. 308.—Diagram to exhibit the "carrying function" of the forearm, and the loss of this function in fracture of the inner condyle of the humerus: *a* and *b* show the normal relation of the parts when carrying; *c* shows the alteration of axis of the forearm when the inner condyle is fractured, what is known as gunstock deformity resulting (after Allis).

T-fractures of the Humerus.—A T-fracture consists of a transverse fracture above the condyles plus a vertical fracture between them. The *cause* is violent direct force applied posteriorly.

The *symptoms* are increase in breadth of the joint (Fig. 311), preternatural mobility, crepitus, pain and swelling, mounting up of the inner condyle back of the elbow on the inner side, and of the outer condyle back of the elbow on the outer side. The forearm is semiflexed and supinated, and the carrying function is lost.

Fig. 309.—Supracondylar fracture of the humerus.

Fig. 310.—Fracture of the humerus above the condyles.

Prognosis of Fractures In or Near the Elbow-joint.—In many fractures it is difficult or impossible to obtain reduction, and in some it is impossible to maintain reduction. Stimson is undoubtedly right when he says that "in intercondyloid fracture with marked separation there is no practicable means merely to maintain reduction."[1] In fracture in or about the elbow-joint I have regarded the prognosis for complete restoration of function as poor, and believed that in most of these fractures some deformity and considerable stiffness are inevitable. Of late, however, influenced largely by Astley P. C. Ashhurst's study of "Fractures of the Lower End of the Humerus" ("Samuel D. Gross Prize Essay of Phila. Acad. of Surgery," 1910), I have been studying this question anew, and as a result take a less gloomy view of the situation, and am disposed to agree with Ashhurst that "in the vast majority of cases the ultimate results will be perfectly satisfactory." Nevertheless I am still cautious as to what I can safely predict to the patient and the patient's family. Ankylosis, partial or complete, is always a possible sequence. Ankylosis may result from prolonged immobilization, the muscles contracting and becoming fibrous, the fascia and ligaments about the joint shortening, the capsule shrinking and thickening, some of the cartilages becoming fibrous, and the joint being partly obliterated. It may result from extravasation of blood into the joint and tendon-sheaths with subsequent formation of fibrous tissue. It may arise from organization of inflammatory exudate within and about the joint and in the sheaths of muscles and tendons. It may arise from the formation of an excess of callus. Bruns claims that in fracture in the joint excess of callus rarely forms, and that masses of callus form chiefly in the line of fracture near but not in a joint.[2] Excessive callus formation is sure to take place if reduction is not thoroughly accomplished or if the fragments are not well immobilized, but move upon each other. A mass of callus in or about a joint limits or prevents motion. The two greatest causes of impaired function are blocking by callus and stiffness from traumatic arthritis (Jones, of Liverpool).

Fig. 311.—Deformity following fracture of the humerus between the condyles.

Treatment of Fractures In or Near the Elbow-joint.—Thoroughly set the fracture while the patient is under ether. It is advisable, when it can be done conveniently, to use the *x*-rays to confirm the diagnosis and to use them again after dressings have been applied, to be sure that the bones remain in good position. If swelling is very great, it may be necessary to delay setting for two or even three days, the arm being bandaged and laid upon a pillow or lightly supported on an anterior angular splint during the waiting period.

In all cases except transverse fracture above the condyles and fracture of the olecranon reduction is best effected by drawing upon the forearm, supinating it, extending it, and then bending it slowly into a position of acute flexion, the degree of flexion being in inverse ratio to the amount of swelling.

[1] "Transactions American Surgical Association," vol. ix.
[2] Max Oberst, in Volkmann's "Sammlung Vorträge."

In transverse fracture above the condyles reduction is effected by drawing the forearm and the lower fragment downward and forward and at the same time pushing the upper fragment back.

Some surgeons advocate dressing the fracture on an anterior angular splint, the forearm being fully supinated (Fig. 312). The advantage claimed for this splint is that if ankylosis occurs the joint is in a position to be useful, which it is not if ankylosed in extension. Some deformity is usually apparent after treating a case with this splint; the deformity following fracture of the inner condyle is not corrected by it, but if the splint is carefully applied the result is usually a useful extremity in all cases except fracture of the inner condyle. In transverse fracture of the shaft of the humerus above the condyles the anterior angular splint is the best method of treatment, as it prevents displacement. The splint must not be applied when there is great swelling, and swelling must be removed by resting the extremity on a pillow, the elbow being semiflexed, applying evaporating lotions or even an ice-bag, employing massage, and gently compressing by bandaging. In some cases the joint should be aspirated. In order to apply this dressing, take a right-angled splint and pad its outer surface, being careful to place thick, soft pads over the convexity which will press in front of the elbow and over each end of the splint. Fasten the upper end to the arm, then make extension of the forearm, and if the fracture is found to be well reduced, fasten the hand and forearm to the splint (Fig. 312). If the hand and forearm are first fixed to the splint, there will be no extension from the elbow and deformity will result. If posterior projection exists, a pasteboard cup is molded over the elbow. The extremity is hung in a triangular sling. At night the extremity is kept in the sling or laid on a pillow. Every third or fourth day, while the extremity is carefully steadied, the splint is removed, the arm and forearm well rubbed with alcohol, massaged, and the splint reapplied. The splint is worn between five and six weeks. At the end of the third week, after removing the dressings, slightly flex, slightly extend, and slightly pronate the forearm, and reapply the splint. At the end of the fourth week repeat this maneuver, making movements of greater range. In the middle of the fifth week and at the end of the fifth week do it again, and flex and extend as much as possibe. Very early and very frequent passive motion is objectionable, as it leads to overproduction of callus and ankylosis, but passive motion as above described is imperatively necessary. Many surgeons at the end of the second week apply a Stromeyer splint, which permits the patient and the surgeon to make some motion by means of the screw without removing the dressings. In very stout persons an anterior angular splint will not stay in place. In such a case the forearm may be placed at a right angle to the arm and plaster of Paris be used. After the dressings are removed employ passive motion, massage, hot and cold douches, baking, inunctions of ichthyol or mercurial ointment, iodin locally, corrosive sublimate and iodid of potassium internally, and direct the patient to systematically use the arm. If in any case after four weeks non-union exists, put up the arm in a plaster splint for three or four weeks more. Some surgeons use a posterior right-angled trough instead of an anterior angular splint (Fig. 304).

Fig. 312.—Anterior angular splint for fractures in or near the elbow-joint.

Allis warmly advocates treating fractures in and about the joint in extension. He holds that the extended position secures the best circulation, and if either condyle is unbroken secures the benefit derivable from a natural splint. Furthermore, in fractures of the inner condyle it restores the carrying function, which the flexed position does not do. For one week after the accident the patient stays in bed, with his arm extended upon a pillow. After swelling subsides the limb is wrapped firmly in a spiral flannel bandage and plaster of Paris is rubbed in or the bandage is covered with plaster.

Some surgeons extend the limb and apply an ordinary plaster bandage, and in about three weeks substitute an anterior angular splint. The trouble with treatment in extension is that if ankylosis ensues the limb is nearly useless. Furthermore, treatment in extension requires confinement to bed.

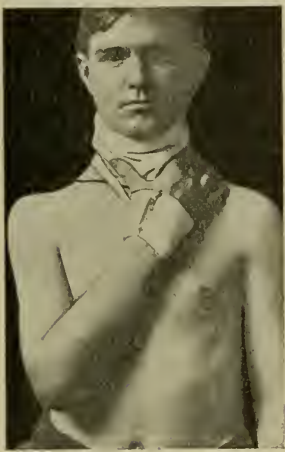


Fig. 313.—Jones's dressing for injuries of the elbow-joint.

Jones, of Liverpool, thinks that splints and bandages are largely responsible for the stiffness which so commonly ensues upon an elbow injury. He advocates treatment by supination and acute flexion in all elbow injuries except fracture of the olecranon. It has been demonstated that the position of acute flexion forces the fragments into place and holds them firmly between the coronoid process of the ulna, the trochlear surface of the ulna, the fascia, and the triceps tendon. The surgeon must be certain that the radial pulse is perceptible *after* the elbow has been flexed. Flexion is maintained by fastening a bandage around the wrist and neck. The bandage around the neck passes through a rubber tube, which serves to protect the neck. The ball of the thumb should rest against the neck. The bandage is fastened to a leather band around the wrist or to a glove, the fingers of which have been cut off. The most convenient dressing to maintain Jones's position is shown in Fig. 313.

After the dressing has been applied certain precautions are to be observed. For the first week or ten days look at the arm daily. If the swelling grows worse, diminish the degree of flexion, and do the same if there is severe pain. If the radial pulse disappears, diminish the flexion until free circulation is obtained. This position is maintained from three to six weeks.[1] After the first two weeks lower the wrist an inch or two. At the end of three weeks make a little passive motion (just one movement in each direction). Passive motion and massage are applied as if an anterior splint were being used. The author has treated many cases by Jones's method, and now prefers it to any other plan in all fractures of the elbow except fracture of the olecranon, transverse fracture above the condyles, fracture of the inner condyle near the line of the ulnar nerve, and fracture between the condyles in which the coronoid process gets between the fragments in flexion. The first-mentioned injury must be dressed in extension, the transverse fracture above the condyles requires an anterior angular splint, and the other two injuries should be treated in extension. If a fracture near the line of the ulnar nerve is treated in acute flexion, the callus poured out will be apt to entangle and press upon the nerve.

If it is found impossible to reduce the fragments or to maintain reduction we should make an incision and nail or screw the fragments in place. A comminuted fracture requires operation.

In *young children* the anterior angular splint must not be used. It will

[1] "Provincial Medical Jour.," Dec., 1894, and Jan., 1895.

become loosened, and motion will inevitably take place at the seat of fracture. Such cases can be treated satisfactorily in Jones's position, the arm being held to the chest by plaster-of-Paris bandages, or they can be treated in extension. Bertomier's plan is very useful in young children.[1] The extremity is dressed without pressure in extension and supination. This can be effected by flannel bandages. In from four to eight days a silicate of sodium bandage is applied in order to prevent pronation. About the sixteenth day the bandage is cut so as to form two troughs. From this period every third day the splints are removed and gentle passive motion is made. The splints are removed permanently at the end of four weeks.

If *false ankylosis* follows fracture of the elbow, the adhesions should be broken up under ether, and for some time the hot-air apparatus should be used daily, and massage, passive motion, and the hot and cold douche should be employed. In *true ankylosis* an operation should be performed and the interlocking callus or the interposed tissue or fragment be removed, if a skiagraph shows that operation promises success. If gunstock deformity results and produces marked disablement, it should be operated upon. An osteotomy is performed on the inner condyle. The arm is set in the extended position, plaster of Paris applied, and is not removed for six weeks.[2]

Fig. 314.—Fracture between the condyles treated by Jones's position. Degree of voluntary flexion obtained.

Separation of the lower epiphysis of the humerus is a not unusual accident. The inferior extremity of the humerus may be separated, or the condyles may be separated from each other and from the shaft of the bone.

The *symptoms* are prominence in front of the joint, caused by the lower end of the shaft of the humerus; projection backward of the olecranon; the forearm rests midway between pronation and supination. Epiphyseal separation may retard growth and produce deformity.

Treatment.—Jones's position or an anterior splint as above directed.

Fractures of the ulna comprise the following varieties: (1) fracture of the coronoid process; (2) fracture of the olecranon process; (3) fracture of the shaft, and (4) fracture of the styloid process.

Fractures of the coronoid process of the ulna (Fig. 316) are rarely observed, and practically occur only as a complication of backward dislocation of the ulna or in association with other fractures.

Symptoms.—When fracture of the coronoid process is associated with a dislocation, crepitus is appreciated on reduction, and it is found that the deformity of the dislocation promptly returns on cessation of extension. The upper fragment may be pulled upward by the brachialis anticus muscle, and there exists an inability to flex the forearm completely. The position is one of extension with posterior projection of the olecranon. The broken piece is felt in front of the joint.

The *treatment* is by an anterior splint the angle of which is less than a right angle. Jones's position may be used in treating such a case. A stiff joint may follow.

[1] "Révue de Chir.," vol. viii, 1888. [2] G. G. Davis, "Phila. Med. Jour.," May 13, 1889.

Fractures of the olecranon process of the ulna occur not uncommonly in adults. Hulke states that such a fracture never occurs before the age of fifteen, but the writer has seen in the Jefferson Medical College Hospital a girl aged fourteen with a fractured olecranon. The *cause* is direct violence or muscular action. Only a small fragment may be torn away, or the entire

Fig. 315.—Fracture between the condyles treated by Jones's position. Degree of voluntary extension obtained.

olecranon may be broken off, and the break may be comminuted or may even be compound.

The *symptoms* of most fractures of the olecranon are: swelling; partial flexion of the forearm; separation of the fragments, the upper piece being pulled up from ½ inch to 2 inches by the triceps; the space between the fragments is

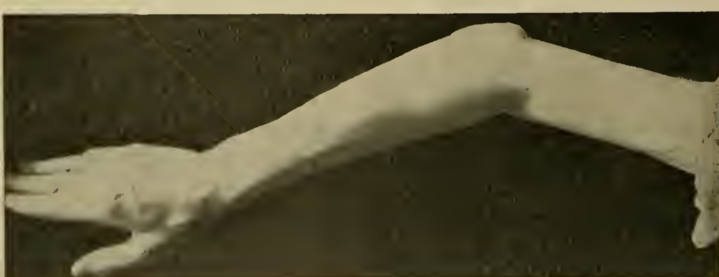

Fig. 316.—Fracture of coronoid process.

increased by flexion at the elbow, and lessened by extension at the elbow; and there is inability to extend the arm. Bulging of the triceps and crepitus on approximating the fragments are observed. In some few cases there is no separation, the periosteum being untorn or the fascial expansions from the triceps holding the fragments in apposition. In such cases crepitus can be elicited by rocking the upper fragment from side to side.

When treated by non-operative methods the *prognosis* is usually fair, fibrous union being the rule. Some joint stiffness usually occurs, and much ankylosis may be unavoidable. The prospect of a freely movable joint is better when extra-articular wiring is practised.

Treatment.—Fracture of the olecranon is usually treated with a well-padded anterior splint almost, but not quite, straight. A perfectly straight splint is uncomfortable, and by opening a retiring angle between the fragments and into the joint favors non-union and ankylosis. The splint should reach from a level with the axillary margin to below the fingers. If the upper fragment does not come in contact with the lower, pull it down by adhesive plaster and fasten the strips to the splint. The author in 1 case employed a glove to which strings from the adhesive plaster were attached. After applying the splint keep the patient in bed for three weeks. The danger of ankylosis in this fracture is very great, and, in case it occurs in the position of extension, an almost useless arm results. Follow the rule of T. Pickering Pick, and at the end of three weeks anesthetize the patient, press the thumb firmly down upon the top of the olecranon, carry the forearm slowly to a right angle, and apply an anterior angular splint and direct it to be worn for two weeks. When the anterior splint has been applied, passive motion should be made every other day, or every third day, and massage should be used at the same time. When the splint is removed, try to increase the range of motion as previously directed. Surgeons usually incise and apply wires only when it is found impossible to secure apposition of the fragments after fracture of the olecranon. Such a course is, I am persuaded, injudicious conservatism. I do not advise that the rule should be to treat fractures of the olecranon as a routine by opening and wiring, but I do advise that we should treat them by extra-articular operation and wiring as advocated by John B. Murphy ("Jour. Am. Med. Assoc.," Jan. 27, 1906). The conservative non-operative treatment

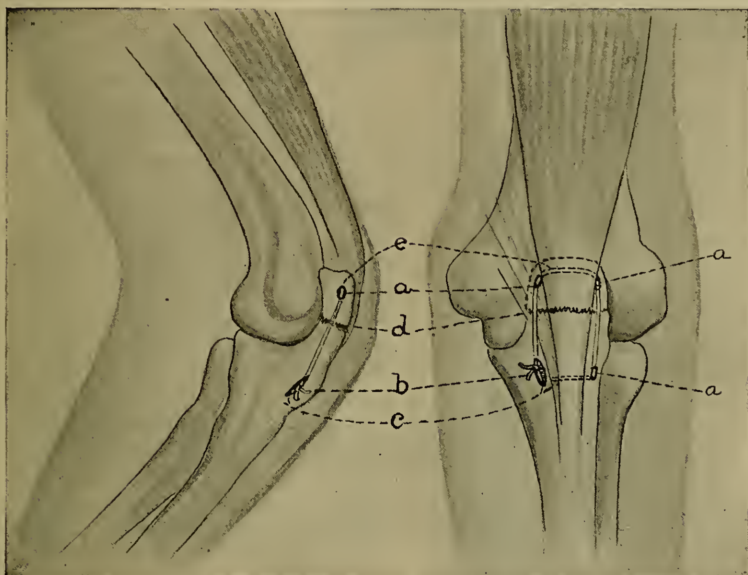

Fig. 317.—Murphy's method of treating fracture of the olecranon by subcutaneous exarticular wiring. Lateral view and posterior view. Wiring the fragments of the olecranon together: *a*, Incision; *b*, twist or tie of wire; *c*, hole drilled in bone for passage of wire; *d*, fracture; *e*, passage of wire through tendon of triceps (Murphy).

often fails. Sometimes the fragments cannot be approximated, frequently they cannot be maintained in approximation, not unusually a stiff or actually ankylosed joint results. Murphy thus describes the operation which should be done ("Jour. Am. Med. Assoc.," Jan. 27, 1906) (Fig. 317): "A longitudinal incision $\frac{1}{3}$ inch long was made on the external aspect of the ulna, $\frac{1}{2}$ inch from its articular surface, and tissues were divided to the bone. A smaller incision was made on the corresponding inner side. I perforated the base of the olecranon with an eyelet drill, which ran transversely from outward inward. I threaded the drill with a fine aluminum-bronze wire, drawing it through this transverse canal. The wire was carried upward under the skin on the inner surface of the elbow and then drawn out through another small incision, $\frac{1}{16}$ inch, made at the level of the apex of the olecranon. The wire was then reinserted and directed transversely from inward outward, passing it through the tendon of the triceps above the olecranon, and then drawn out to corresponding outward point through a very small incision similar to that made on the inner side. The wire was again reinserted and pushed downward under the skin until it was finally brought out through the initial external incision. The circle once completed, traction was exerted on the wire until I was sure that the two fragments were in perfect coaptation, the latter being easily and satisfactorily accomplished. The ends of the wire were twisted several times and then divided by scissors close to the bone. By this procedure the skin was incised at four points, the largest incision being $\frac{1}{3}$ inch in length." The extremity is placed in flexion upon an anterior splint, which is worn for four weeks. Passive motion is begun on the third day. A compound fracture and a comminuted fracture always require operation, in which the joint is freely opened. Non-union requires opening of the joint and wiring of the fragments.

Fig. 318.—Fracture of the shaft of the ulna (case in the Pennsylvania Hospital; skiagraphed by Dr. Gaston Torrance).

Fractures of the shaft of the ulna alone are most usual near the middle of the bone, are always due to direct violence, and are not infrequently compound. An injury which breaks the ulna is very apt to break the radius also.

Symptoms.—By running the finger along the inner surface of the bone there are detected inequality and depression; crepitus and mobility are easily developed; there are pain and the evidence of direct violence. The long axis of the hand is not on a line with the long axis of the forearm, but is internal to it. If deformity exists, it is due to the lower fragment passing into the interosseous space because of the action of the pronator quadratus; the upper fragment, acted on by the brachialis anticus, passes a little forward (Fig. 318). The

forearm at and below the seat of fracture is narrower and thicker than normal.

Treatment.—In treating fracture of the shaft of the ulna place the forearm midway between pronation and supination, so as to bring the fragments together and to obtain the widest possible interosseous space, and thus limit the danger of union taking place between the radius and ulna. The position midway between pronation and supination is obtained by flexing the forearm to a right angle with the arm and pointing the thumb to the nose. Take two well-padded straight splints, one long enough to reach from the inner condyle to below the fingers, the other from the outer condyle to below the wrist; place a long pad of lint over the interosseous space on the flexor side of the limb, and another on the extensor side; apply the splints and hang the forearm in a triangular sling (Fig. 319). Passive motion is to be begun in the third week, and the splints are to be worn for four weeks. Fractures of the ulna can be treated very efficiently by plaster of Paris. The best results are secured by wiring or plating.

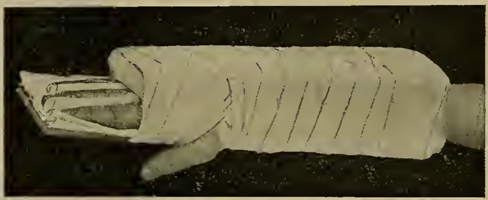

Fig. 319.—Two straight splints in fracture of both bones of the forearm.

Fractures of the styloid process of the ulna are due to direct force. The displacement is obvious.

Treatment.—In treating fracture of the styloid process push the fragment back into place and use a Bond splint with a compress for four weeks, or apply a plaster-of-Paris dressing.

Fractures of the radius include the following varieties: (*a*) Fractures of the head; (*b*) fractures of the neck; (*c*) fractures of the shaft, and (*d*) fractures of the lower extremity.

Fracture of the head of the radius has been studied by Dr. T. Turner Thomas ("University of Penna. Med. Bulletin," Oct., 1905; and "Annals of Surgery," August, 1907). He has furnished me with the following résumé of his views, with which I entirely agree:

"Fracture of the head of the radius is not infrequent, and is usually the result of a fall on the hand with the elbow in extension and the forearm in pronation. In extension of the elbow the capitellum of the humerus is in contact with only the anterior part of the radial head. Since the carpus articulates almost entirely with the radius, the force of the usual fall on the hand is transmitted almost entirely through this bone, and at the elbow is received by only the anterior part of the radial head. According to the degree of violence applied more or less damage may be done to the head, or head and neck. The anterior portion of the rim may be split off, the intact ulna preventing the humerus from pursuing the detached fragment and pushing it away from its fellow, and the intact orbicular ligament holding the two in close apposition. This uncomplicated fracture is the most common, but the least troublesome. Union with ultimately good function is the rule, even though the fracture go unrecognized and untreated, because of the close splinting of the untorn orbicular ligament. Since it is the same accident, a fall on the outstretched hand, which usually produces Colles's fracture, fracture of the external condyle of the humerus, fracture of the neck of the radius, fracture of the coronoid process, and posterior dislocation of both bones of the forearm, any one or several of these injuries may complicate the fracture of the radial head. When the anterior part of the head breaks off the bony resistance to the descent of the capitellum by the radius is lost, so that if the force of the accident

is severe enough, lateral bending of the elbow to the radial side with further descent of the capitellum may result with greater separation of the fragments, tearing of the orbicular ligament, and more damage to the head. The descent of the condyle in a posterior dislocation may carry before it the detached fragment of the head, and this fragment be left buried in the tissues of the forearm several inches below its normal position after the dislocation has been reduced.

"*Prognosis.*—In the vertical or oblique fissured fracture of the head with close approximation of the fragments, after union takes place, limitation of all movements of the elbow results from adhesions and slight irregularities in the bone. The function rapidly returns in the succeeding weeks, although some limitation of extension will continue for months. More marked irregularity in the circumference of the head may last much longer and may produce permanent limitation of rotation. Bony union between the head and corresponding surface of the ulna will prevent all rotation of the forearm. In either case flexion and extension usually return almost if not completely. Non-union of the fragments may induce pain and limitation of movement, especially rotation; but with close approximation of the fragments and an untorn orbicular ligament, an apparently perfect return of function may follow, the fragments moving smoothly as one piece within the ligament. The prognosis will depend chiefly upon the degree of damage done to the head and the separation of the fragments.

"*Symptoms.*—The most characteristic feature of this fracture is its obscurity. The thick muscular covering of the radial head, except posteriorly, the splinting effect of the orbicular ligament, and the close contact of the head with the humerus and ulna, make the diagnosis of the small intra-articular fracture particularly difficult. In the uncomplicated vertical fracture there will usually be no movements of the fragments on each other, and, therefore, no crepitus, and there will be no deformity. A history of a fall on the hand; some swelling of the elbow, particularly on the radial side; severe pain and limitation in all movements of the elbow, particularly in rotation; pain and tenderness distinctly localized to the head of the radius; and the exclusion of fracture of the humerus, ulna, and the shaft of the radius, will point strongly to a fracture of the head of the radius. If the injury is treated as a fracture, and two or three weeks later, when fixation is removed, there is marked limitation of all movements of the elbow, the diagnosis will be more than reasonably assured. The x-ray may be misleading unless directed in the line of the fracture, and this is not easy to accomplish, since the position of the fragments in their relation to the humerus vary with every change in rotation of the forearm. In most cases an exposure to the x-ray in the transverse plane of the humeral condyles, with the forearm in pronation, will give a successful skiagraph. If the x-ray is directed at right angles to the line of fracture the skiagraph will usually be negative. If the fragments are freely separated and if crepitus is elicited, the diagnosis will be more easily determined.

"*Treatment.*—In the uncomplicated fracture without crepitus or deformity, Jones's position or a right-angled splint for three weeks will be sufficient. The resulting fibrous ankylosis will largely disappear from forced use in the following weeks, but several months will be necessary before extension is complete. If crepitus is present, four or five weeks' fixation will be better, and in this case the return of function will probably take longer. As a rule, if union is obtained function will return. If pain on movement persists for many months, a detached fragment or the whole head should be excised. Marked limitation of movement from enlargement of the head or bony union between it and the ulna calls for excision of the head."

Fracture of the neck of the radius (Fig. 320) is by no means so rare an accident as was thought before the discovery of the x-rays. It seldom occurs

alone and is usually associated with fracture of the radial head. These fractures are transverse and frequently impacted. The cause is a fall upon the pronated hand when the forearm is extended.

Symptoms.—In this fracture the forearm is pronated and the patient is found to have the lost power of voluntary pronation and supination. Under forced pronation and supination it will be noted that the head of the radius does not move unless there is impaction. Crepitus is sometimes absent because of impaction. Thomas points out that there is angulation of the neck due to driving of the radial head downward and forward ("Annals of Surgery," August, 1907). Reduction is always difficult and may be impossible.

The *treatment* for fracture of the neck of the radius is the same as for other fractures of the elbow-joint—namely, an anterior angular splint or Jones's position.

Fracture of the shaft of the radius (Fig. 321) is far commoner than fracture of the shaft of the ulna. It may occur above or below the insertion of the

Fig. 320.—Fracture of the neck of the radius.

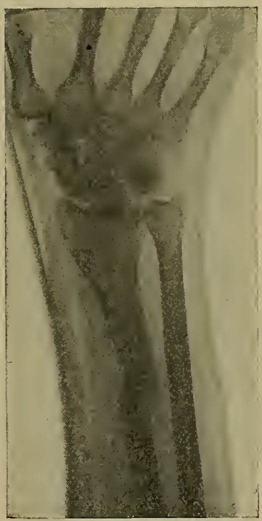

Fig. 321.—Fracture of radius alone.

pronator radii teres muscle. It may arise from either direct or indirect force. Fracture of the shaft of the ulna may coexist as a result of the same accident.

Fracture of the Shaft of the Radius Above the Insertion of the Pronator Radii Teres Muscle.—*Symptoms.*—The upper fragment is drawn forward by the biceps and is fully supinated by the biceps and the supinator brevis. The lower fragment is fully pronated by the pronator quadratus and pronator radii teres, and its upper end is pulled into the interosseous space. There are crepitus, mobility, pain, narrowing and thickening of the forearm below the seat of fracture, and loss of the power of pronation and supination. The head of the bone is motionless during passive pronation and supination. The hand is prone.

Treatment.—In treating this fracture do not put the forearm midway between pronation and supination, as this position will not bring the fragments into contact, the upper fragment remaining flexed and supinated. To bring the lower fragment in contact with the upper, flex and fully supinate the forearm. Apply an anterior angular splint to the extremity for four weeks, and begin passive motion in the third week.

Fracture of the Shaft of the Radius Below the Insertion of the Pronator Radii Teres Muscle (Fig. 321).—In this variety of fracture the upper fragment is acted on by the biceps, the supinator brevis, and the pronator radii teres, and it remains about midway between pronation and supination, passing forward and also into the interosseous space. The lower fragment is acted on by the supinator longus and the pronator quadratus, the latter being the more powerful of the two, hence the lower fragment is moderately pronated, its upper extremity being drawn into the interosseous space. Other symptoms are identical with those of fracture above the insertion of the pronator radii teres.

Treatment.—In treating fracture below the pronator radii teres the forearm is flexed and is placed midway between pronation and supination; two interosseous pads and two straight splints are applied as for fracture of the ulna (see Fig. 319). The splints are worn for four weeks, and passive

Fig. 322.

Fig. 323.

Figs. 322, 323.—Fracture of both bones of the forearm.

motion is begun in the third week. Plaster of Paris is a most satisfactory dressing. Loss of function is best obviated in this fracture by incision and fixation.

Fracture of the shafts of both bones of the forearm (Figs. 322–326) is not frequently seen. It is caused either by direct or indirect force. If due to indirect force the radius breaks first.

Symptoms.—After fracture of both bones of the forearm the hand is pronated, and the two lower fragments come together and are drawn upward and backward or upward and forward by the combined force of flexor and extensor muscles, shortening being manifest and the projection of the lower fragments being detected on either the dorsal or the flexor surface of the forearm. The upper fragment of the ulna is somewhat flexed by the brachialis anticus; the

upper fragment of the radius is flexed by the biceps and is pronated and drawn toward the ulna by the pronator radii teres. The forearm is narrower than it should be (the ends of the fragments having passed into the interosseous space) and is thicker than normal from front to back (the contents of the interosseous space having been forced out). Crepitus, mobility, pain, and inequality exist, the power of rotation is lost, and on passive rotation the head of the radius does not move. The forearm is prone and semiflexed.

Treatment of this fracture usually consists in the application of two straight splints and two interosseous pads, the forearm being flexed to a right angle and placed midway between pronation and supination (see Fig. 319). The splints are worn for four weeks, and passive motion is

Fig. 324.—Fracture of both bones in the lower third of the forearm.

Fig. 325.

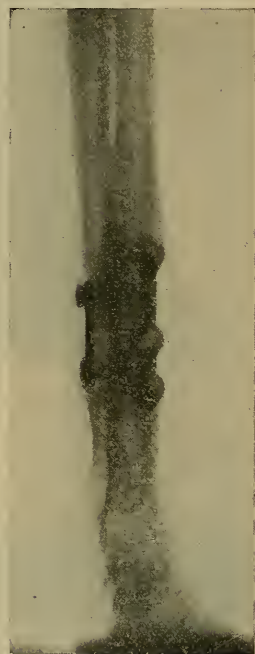

Fig. 326.

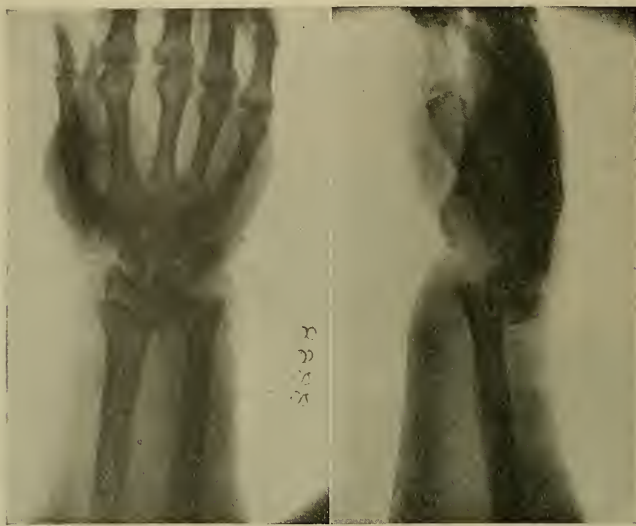
Figs. 325, 326.—Ununited compound comminuted fracture of both bones of forearm (*x*-ray by Dr. Senders).

begun in the third week. Instead of these splints a plaster-of-Paris dressing can be used. I am persuaded that pronation and supination are best preserved by incision and fixation (Figs. 325 and 326).

Fractures of the Lower Extremity of the Radius.—*Colles's fracture* is a transverse or nearly transverse fracture of the lower end of the radius, between the limits of $\frac{1}{4}$ inch and $1\frac{1}{2}$ inches above the wrist-joint, the lower fragment sometimes mounting upon the dorsum of the upper fragment (Fig. 327), the two fragments sometimes impacting (Fig. 328). An oblique fracture beginning within $\frac{1}{2}$ inch of the joint and passing into the joint is known as *Barton's fracture* (Fig. 329). Colles's fracture was first recognized as a fracture by Colles, of Dublin, in 1814. Before this time the injury was called backward dislocation of the wrist. It is a very common injury, is met with most frequently in those beyond the age of forty, and oftener in women than in men. It is due to transmitted force (a fall upon the palm of the pronated hand). Some think that the force is received by the ball of the thumb and passes to the carpal bones and the edge of the radius; a fracture beginning posteriorly rather than anteriorly and the force driving the lower fragment upon the dorsal surface of

the radius, the carpus and lower fragment moving upward and outward. It is much more likely that this fracture is due to cross-strain on the bone. There



A B

Fig. 327.—Colles's fracture before reduction: A, Anteroposterior; B, lateral views.

is sudden traction upon the anterior ligaments, which drag upon the bone and break it at a point where the cancellous end of the radius joins the compact shaft (Fig. 330). The fragments are not unusually impacted (Fig. 328). In the author's experience dislocation of the lower end of the ulna is not a very unusual complication. It arises from a fracture of the ulnar styloid or tearing off of the internal lateral ligament of the wrist.

Fig. 328.—Impacted Colles's fracture.

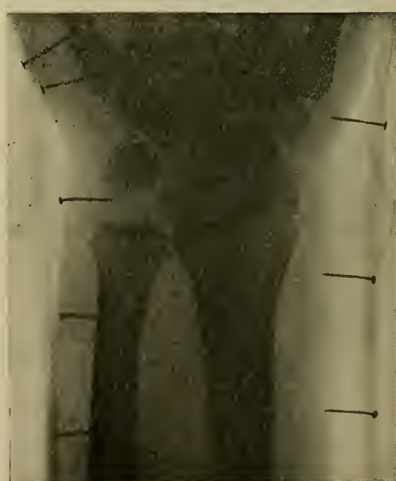


Fig. 329.—Barton's fracture.

Symptoms.—In Colles's fracture the hand is abducted (drawn to the radial side of the forearm) and pronated, the head of the ulna is prominent, the styloid process of the radius is raised, and the lower fragment may mount on the back of the lower end of the upper fragment, causing a dorsal projection, termed by Liston the "silver-fork deformity" (Figs. 331, 332). The lower end of the upper fragment can be felt beneath the flexor tendons above the wrist. The position in deformity is produced by the force. Some consider it is maintained by the action of the supinator longus and the flexor and extensor muscles, but particularly by the extensors of the thumb. Pilcher has demonstrated the fact that in this fracture a portion of the dorsal periosteum is untorn, and this untorn portion acts as a binding band to hold the fragments in deformity. Pronation and supination are lost. In this fracture the hand can be greatly hyperextended (*Maisonneuve's symptom*). Crepitus, which is best obtained by alternate hyperextension and flexion, can be secured unless swelling is great or impaction exists. Crepitus on side movements is rarely obtainable. Impaction may greatly modify the deformity, though displacement generally exists to some extent, and the fragments do not ride

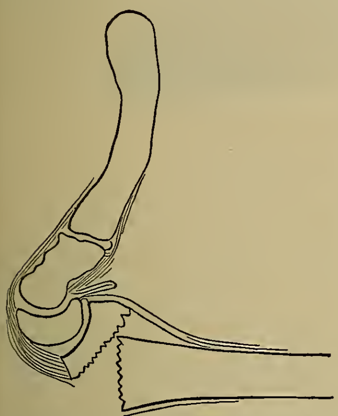

Fig. 330.—Effect upon the lower end of the radius of the cross-breaking strain produced by extreme backward flexion of the hand (Pilcher).

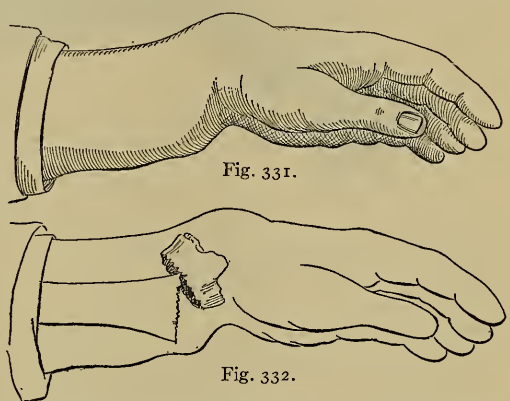

Figs. 331, 332.—Deformity at the wrist consequent upon displacement backward of the lower fragment of the radius after fracture at its lower extremity (Levis).

easily on each other. The styloid process of the ulna may be broken, or the inferior radio-ulnar articulation may be separated (dislocation of the lower end of the ulna). This latter complication allows the lower fragment to roll freely upon the upper, and the characteristic silver-fork deformity does not appear. If the styloid process of the ulna is broken, pressure over it causes great pain. If a person in falling strikes the back of the hand and a fracture of the radius occurs, the lower fragment is driven upon the front surface of the upper fragment and is felt under the flexor tendons at the wrist (*reversed deformity*). An elaborate study of fracture of the radius with forward displacement of the lower fragment has been published by John B. Roberts.[1]

Treatment.—In treating an ordinary Colles's fracture reduce the deformity by hyperextension to unlock the fragments and relax the dorsal periosteum, follow by longitudinal traction to separate the fragments, and forced flexion to force them into position. This formula was introduced many years ago by the late R. J. Levis. It is of the first importance to thoroughly reduce this fracture, and very often it is not thoroughly reduced. Imperfect reduction means permanent deformity, stiffness of the tendons and wrist, and possibly an almost useless

[1] "Am. Jour. Med. Sci.," Jan., 1897.

hand. The extremity can be placed upon a Levis splint (Fig. 333), the position maintaining reduction and the tense extensor tendons giving dorsal support. Some surgeons use Gordon's pistol-shaped splint. The favorite splint in Philadelphia practice in the past has been Bond's (Pl. 7, Fig. 7). It places the hand in a natural position of rest (semiflexion of the fingers, semi-extension of the wrist, and deviation of the hand toward the ulna). Two pads are used: a dorsal pad which overlies the lower fragment, and a pad for the flexor surface which overlies the lower end of the upper fragment. A bandage is applied,

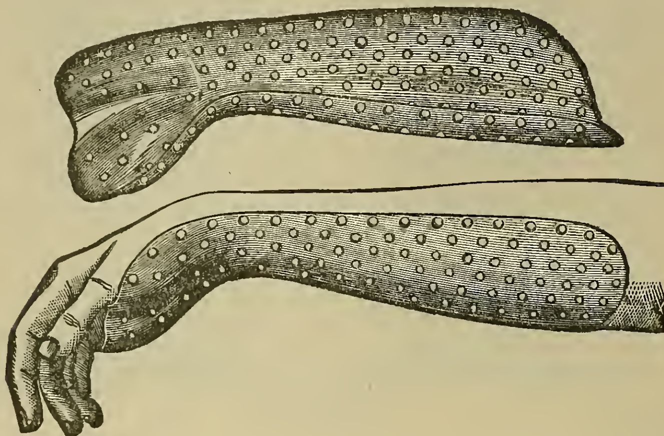

Fig. 333.—Levis's radius-splints, right and left, for fracture of the lower end of the radius.

the thumb and fingers being left free (Fig. 334). Passive motion is begun upon the fingers in three or four days, and upon the wrist during the second week. The splint is removed in three weeks, and a bandage is worn for a week or two more because of the swelling. In applying the Bond splint, do not pull the hand too much up on the block, or the fracture will unite with a projection upon the flexor surface of the extremity and the tendons of the wrist will be apt to be caught in the callus. The most satisfactory dressing is the straight dorsal splint advised by Roberts (Fig. 335). It runs from just below the external condyle to the beginning of the fingers. I use it almost invariably. It prevents the recurrence of deformity and is mechanically the proper mode of treatment. It should be worn for three weeks. Undoubtedly more or less stiffness often follows Colles's fracture, and some very able surgeons have been so impressed with the frequency of crippling stiffness that they have dispensed with the use of a splint. Sir Astley Cooper long ago spoke of simply placing the arm in a sling as proper treatment for fracture of the radius. Moore, of Rochester, applied a cylindrical compress over the ulna, held in place for six hours by adhesive plaster, then cut the plaster, placed the forearm in a sling, and let the hand hang over the edge of the sling. Pilcher applies a band of adhesive plaster around the wrist and supports the wrist in a sling, but, as Storp says, dispensary patients are apt to disarrange this dressing. Storp wraps a piece of rubber plaster 4 inches wide around the wrist, and places a second piece around the first so arranged

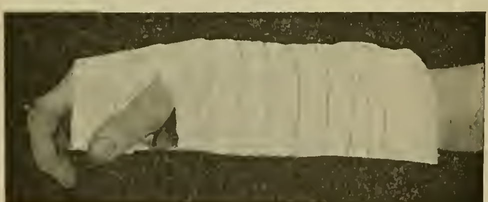

Fig. 334.—Bond's splint in Colles's fracture.

as to form a fold over the radius; an opening is made through the fold for the passage of a sling. In ten days the plaster is removed and the forearm is carried in a sling. Massage is begun in the third week. Impaired function follows in about 40 per cent. of these fractures. If a stiff joint and limited tendon motion eventuate from the fracture, use massage, frictions, sorbefacient ointments, tincture of iodin, electricity, hot and cold douches, and the hot-air apparatus, or give ether and forcibly break up adhesions. If reduction was not thoroughly effected and too great a length of time has not elapsed, and the hand is helpless and painful, the bone should be refractured. In a young or middle-aged person, in whom a useless hand has folowed an ill-reduced fracture, osteotomy is justifiable.

Fracture of Both the Radius and Ulna Near the Wrist.—Colles's fracture may be complicated by a fracture of the ulna other than of its styloid process.

Symptoms.—In fracture of the radius and ulna near the wrist the lower ends of the upper fragments come together, the upper fragment of the radius is pronated, and the lower fragment of the radius is drawn up. Pain, crepitus, mobility, shortening, and loss of function exist.

Treatment.—Fracture of the radius and ulna near the wrist should be treated by the straight dorsal splint, as is Colles's fracture.

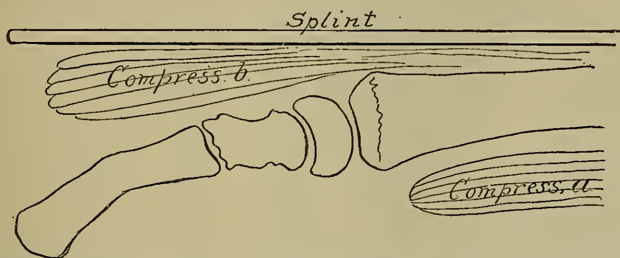

Fig. 335.—Diagram showing the arrangement of compresses and splint best adapted to retain fragments in proper position after reduction (Pilcher).

Separation of the Lower Radial Epiphysis.—This accident occurs in children from falling upon the palm of the hand. It never happens after the twentieth year.

Symptoms.—In separation of the lower radial epiphysis the lower fragment mounts upon the upper and produces a dorsal projection like that found in Colles's fracture, but the hand does not deviate to the radial side. The deformity resembles that of a backward carpal dislocation, but is differentiated from dislocation by the unaltered relation in the fracture between the styloid processes and the carpal bones.

The *treatment* in separation of the lower radial epiphysis is the same as for Colles's fracture.

Fractures of the carpus were until recently thought to be infrequent, but the *x*-rays have taught us differently, and we now know that many supposed sprains of the wrist are, in reality, simple fractures of the carpus. Ernest Amory Codman and Henry Melville Chase show that a majority of carpal injuries "are either simple fractures of the scaphoid or anterior dislocations of the semilunar bone," the two injuries being frequently combined ("The Diagnosis and Treatment of Fracture of the Carpal Scaphoid and Dislocation of the Semilunar Bone," in "Annals of Surgery," March and June, 1905). The *cause* of carpal fracture may be violent direct force or a fall upon the extended palm.

Symptoms.—Fractures of the carpus in general are indicated by pain,

tenderness, swelling, evidences of the infliction of direct force, sometimes crepitus, loss of power in the hand, and a very little displacement.

Treatment.—Many compound comminuted fractures of the carpus require amputation. In an ordinary compound fracture asepticize, drain, dress with antiseptic gauze and a plaster-of-Paris bandage, cutting trap-doors in the plaster over the ends of the drainage-tube. In a simple fracture dress the hand upon a well-padded straight palmar splint (Pl. 7, Fig. 10) reaching from beyond the fingers to the middle of the forearm, and place the hand and forearm in a sling. The splint is worn for four weeks, and passive motion of the wrist is begun in the second week.

Fracture of the carpal scaphoid (see previously quoted article by Codman and Chase) usually results from falls upon the palm of the extended hand and is most common in males between the ages of twenty-five and thirty-five. It is rarely recognized at the time of the accident; the patient complains of severe pain, tenderness, and disability and is thought to have a sprain. According to Codman and Chase, the symptoms improve up to a certain point, but not beyond it, and the joint remains in a condition of irritation and weakness. After months or, perhaps, years the diagnosis is made. In one case of my own, a locomotive engineer, the injury resulted from a blow on the palm with the reverse lever. He came to me three years after the injury, when I recognized the condition as the one described by Codman and Chase. These writers say that the fingers are normally flexible, active and passive movements of the wrist are restricted to one-half or more of the normal excursion, and movements of flexion or extension beyond this are limited by muscular spasm, resembling the spasm occurring in a tuberculous joint. Any attempt to forcibly evercome the spasm produces violent pain. Crepitus is absent. The radial side of the wrist-joint exhibits some swelling, which obscures somewhat the flexor tendons of the thumb. There is tenderness on pressure over the scaphoid and it is most acute in the anatomical snuff-box. The *x*-ray shows a transverse fracture of the scaphoid bone ("Annals of Surgery," March and June, 1905). Professor Dwight considers the above-described injury to be due to the two portions of the bone (there are two centers of ossification) having never formed a bony union and having been wrenched apart by violence. Codman believes the injury is the result of violence acting on a normal bone, the resulting non-union being due to lack of fixation and the presence of synovial fluid between the fragments.

The fracture may be accompanied by forward dislocation of the semilunar bone. If for several weeks after an accident causing fracture of the scaphoid the wrist is immobilized, union may occur, otherwise non-union will surely result.

Treatment.—This injury should be thought of when violence has been applied to the carpus. It may be treated by a straight palmar splint if the case is seen early. If seen when there is non-union, the proximal half of the scaphoid should be excised (the incision being posterior and external to the extensor communis digitorum tendons) and passive motion should be begun within one week (Codman and Chase, Ibid.).

Fractures of the Metacarpal Bones.—Fracture of the metacarpus is very common. One or more bones may be broken. The first metacarpal bone is oftenest broken; the third is seldom broken (Hulke). The *cause* is direct or indirect force. Fracture at the base of the first metacarpal bone was described by E. H. Bennett in 1881. It is called *Bennett's fracture*, or, as its discoverer named it, *stave of the thumb*. The fracture may be transverse at the neck or longitudinal, "the anterior basal projection being broken off" (Raymond Russ, in "Jour. Amer. Med. Assoc.," June 16, 1906). This injury results from violent force applied to the distal end of the metacarpal (as in striking with

the fist) or to the end of the extended thumb, and Russ regards it as the most common metacarpal fracture. It is usually mistaken for a sprain of the thumb and is sometimes regarded as subluxation backward of the first metacarpal.

Symptoms.—The signs of a metacarpal fracture are: dorsal projection of the upper end of the lower fragment or the lower end of the upper fragment; pain, crepitus; and often evidences of direct violence. In fracture of the first metacarpal (Bennett's fracture) there is swelling, particularly evident in the flexor tendon sheaths on the thenar eminence (Russ), disability, pain, tenderness near the base of the metacarpal, and deformity, apparent shortening of the thumb, and crepitus on reduction. The *x*-rays solve a doubtful case.

Treatment.—To treat a fracture of a metacarpal bone reduce by extension; place a large ball of oakum, cotton, or lint in the palm to maintain the natural rotundity, and apply a straight palmar splint like that used for fracture of the carpus. It may be necessary to apply a compress over the dorsal projection. The duration of treatment is three weeks, and passive motion is begun after two weeks. A plaster-of-Paris dressing is often used. Raymond Russ ("Jour. Amer. Med. Assoc.," June 16, 1906) describes the following splint as successfully used in a case of Bennett's fracture (Fig. 336). I have used it in a case with much satisfaction. "The thumb was put in strong abduction and three wooden butcher's skewers neatly padded were placed about the metacarpal, one posteriorly in the interosseous space, one along the outer border, and the third over the thenar eminence. These extended from well above the metacarpal bone to the first phalangeal joint. They were fastened tightly in place by two strips of adhesive plaster. Traction was then exerted on the thumb and maintained by strips of adhesive plaster passing about the first phalanx and the projecting ends of the three skewers. This dressing was reinforced by a rectangular cardboard splint. Accurate coaptation and sufficient traction to overcome the deformity and muscular action are most necessary in the treatment of this fracture. Slate pencils or small lead pencils can be used in place of the wooden skewers. The soapstone slate pencils are less brittle than the ordinary kind."

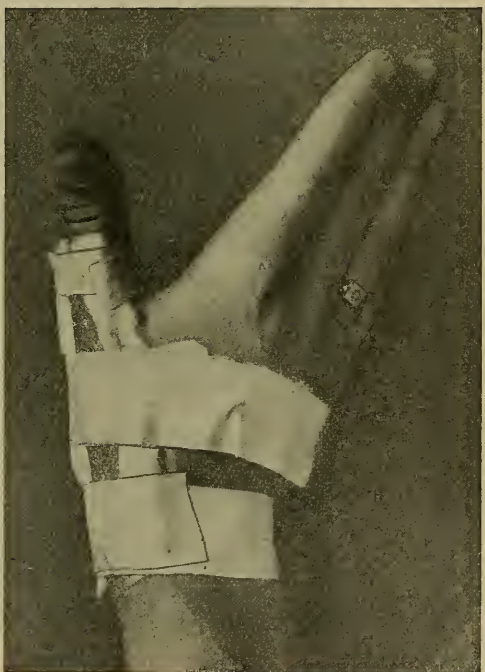

Fig. 336.—Coaptation traction splint of Russ.

Fractures of the Phalanges.—The phalanges are often broken. The fracture may be compound. The *cause* usually is direct force.

Symptoms.—Fracture of a phalangeal bone is indicated by pain, tenderness, bruising, crepitus, and mobility, with very little or no displacement.

Treatment.—If the middle or distal phalanx is broken, mold on a trough-like splint of gutta-percha or of pasteboard, which splint need not reach into the palm. If the proximal phalanx is broken, carry the splint into the

palm of the hand. Make the splint of gutta-percha, pasteboard, wood, or leather. The splint is worn three weeks. A sling must be worn, otherwise the finger will be knocked and hurt. Some cases require a dorsal as well as a palmar splint. These cases may be treated very satisfactorily with a silicate of sodium or plaster-of-Paris bandage.

Fracture of the femur is a very common injury. The divisions of the femur are: (1) the upper extremity; (2) the shaft; (3) the lower extremity.

Fractures of the upper extremity of the femur are divided into: (*a*) intracapsular; (*b*) extracapsular; (*c*) of the great trochanter, and (*d*) epiphyseal separation (either of the great trochanter or the head).

Examination of the Hip.—It is sometimes though seldom necessary to give ether. Remove all the patient's clothing and place him recumbent upon a

Fig. 337.—Intracapsular fracture of the hip (author's case).

table. Note the position of the extremity. Feel with care the great trochanter and femoral neck. Very gradually and gently make movements to determine if there is impairment, undue mobility, or crepitus. Never make sudden or violent movements in looking for crepitus. The diagnosis can be made even if crepitus is not obtained, and rapid or violent movements may tear apart an impaction. Measure the sound extremity and the injured extremity. The measurement is made from the anterior superior spine of the ilium to the inner malleolus. Other symptoms to be looked for are set forth on pages 583 and 584.

Intracapsular Fracture of the Femur.—Intracapsular fracture of the neck of the femur is transverse or only slightly oblique (Fig. 337), and is not unusually impacted (see Figs. 267, 268, 269). Stokes follows Gordon, of Belfast,

in classifying fractures of the femoral neck. He divides them into intracapsular and extracapsular, and subdivides intracapsular fractures into fracture with penetration of the cervix into the head; fracture with reciprocal penetration; intraperiosteal fracture at the junction of the cervix and head; intraperiosteal fracture of the center of the cervix; extraperiosteal fracture, with laceration of the cervical ligaments. The last-named fracture is the most common. The first four forms may unite by bone, the fifth form will not because of non-apposition, lack of nutrition, effusion of blood, synovitis, or interstitial absorption.[1] Stokes points out that we may have penetration without impaction. The *cause* is often slight indirect force, of the nature of a twist, acting upon a person of advanced years (more often a woman than a man), but not unusually a fall upon the great trochanter is the cause. A fall upon the knees, a trip, or an attempt to prevent a fall may produce this fracture. It often happens that the fall is due to the fracture rather than that the fracture arises from the fall. Intracapsular fracture is never caused by direct force unless it is due to gunshot violence. The aged are more liable to intracapsular fracture than the young or the middle-aged, because, first, the angle which the neck forms with the axis of the femur becomes less obtuse with advancing years, and may even become a right angle; this change is more pronounced in women than in men; second, the compact tissue becomes thinned by absorption, the cancelli diminish, the spaces between them enlarge, the bony portions of the cancellous structure are thinned and destroyed, and the cancellous structure becomes fatty and degenerated. The injury is not, however, limited to the aged. It has been positively shown that this fracture may occur in the young, even before the union of the epiphyses. In fact, fracture of the femoral neck is not very uncommon in children and in young and vigorous adults (Royal Whitman, "Med. Record," March 19, 1904). I have seen one case in a man of twenty-five, one in a man of twenty-eight, and several cases in those under forty-five. In the aged the fracture is, of course, complete, but in children and even in young adults it is usually incomplete, and for this reason the fracture is often not recognized in children and young adults.

Symptoms.—In intracapsular fracture there is usually *shortening* to the extent of from $\frac{1}{2}$ to 1 inch, but in some cases no shortening can be detected. Shortening of $\frac{1}{4}$ inch does not count in making a diagnosis, for one limb is often naturally a little shorter than the other. If the reflected portion of the capsule is not torn, the shortening is trivial in amount or is entirely absent. In some cases shortening gradually or suddenly increases some little time after the accident. This is due to separation of a penetration or of an impaction, tearing of the previously unlacerated fibrous synovial reflection, or restoration of muscular strength after traumatic paresis has passed away. A gradually increasing shortening arises from absorption of the head of the bone. Shortening is due chiefly to pulling upon the lower fragment by the hamstring, the glutei, and the rectus muscles.

Pain is usually present anteriorly, posteriorly, and to the side. The area of pain is localized, and motion or pressure greatly increases the suffering. Pain is not commonly severe except upon motion or from pressure, when it may be localized in the joint. In some cases the pain is violent.

Eversion exists and is spoken of as *helpless eversion*, though in a very few instances the patient can still invert the leg. The eversion is due to the force of gravity, the limb rolling outward because the line of gravity has moved externally. That eversion is not due to the action of the external rotator muscles, as was taught by Sir Astley Cooper, is proved by the fact that when a fracture happens in the shaft below the insertion of these muscles

[1] Stokes, in "Brit. Med. Jour.," Oct. 12, 1895.

the lower fragment still rotates outward. This is further demonstrated by the considerations that the internal rotators are more powerful than the external, that some patients can still invert the limb after a fracture, and that eversion persists during anesthesia.[1] In some unusual cases *inversion* attends the fracture. Inversion, if it exists, is due to the fact that the limb was adducted and inverted at the time of the accident, and after the accident it remains in this position (Stokes). Besides shortening and eversion, the leg is somewhat flexed on the thigh and the thigh on the pelvis, the extremity when rolled out resting upon its outer surface. *Abduction* is commonly present. Limited abduction suggests impaction.

Loss of power is a prominent symptom: the limb can seldom be raised or inverted; although in rare cases, when the fibrous synovial envelope is untorn, the patient may stand or even take steps. *Crepitus* often cannot be found, either because the fragments cannot be approximated, because there is impaction or penetration, or because the bone is greatly softened by fatty change. To obtain crepitus the front of the joint must be examined while the limb is extended and rotated inward. But why try to obtain crepitus? The diagnosis is readily made without it; in many cases it cannot be detected, and the endeavor to obtain it inflicts pain and may produce damage. These fractures in the aged have a not very flattering chance for repair, and efforts to find crepitus may produce serious damage.

Altered Arc of Rotation of the Great Trochanter (Desault's Sign).—The pivot on which the great trochanter revolves is no longer the acetabulum, and the great trochanter no longer describes the segment of a circle, but rotates only as the apex of the femur, which rotates around its own axis. It is needless to try to obtain this sign; to do so inflicts violence on the parts.

Relaxation of the fascia lata (Allis's sign) simply means *shortening.* The fascia lata is attached to the ilium and the tibia (iliotibial band), and when shortening brings the tibia nearer to the ilium, this band relaxes and permits the surgeon to push his fingers more deeply inward on the injured side, between the great trochanter and the iliac crest, and nearer the knee above the outer condyle, than on the sound side. In this examination each limb should be adducted. Allis has pointed out another sign: when the patient is recumbent the sound thigh cannot be lifted to the perpendicular without flexing the leg; the injured thigh can be.

Lagoria's sign is relaxation of the extensor muscles.

Ascent of the Great Trochanter Above Nélaton's Line.—This line is taken from the anterior superior iliac spine to the most prominent part of the ischial tuberosity (Fig. 338). In health the great trochanter is below, and in intracapsular fracture it is above, this line.

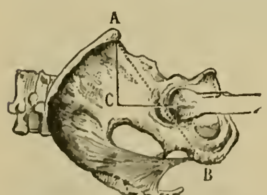

Fig. 338.—A-B, Nélaton's line; A-C-D, Bryant's iliofemoral triangle (Owen).

Relation of the Trochanter to Bryant's Triangle (Fig. 338).—Place the patient recumbent, carry a line around the body on a level with the anterior superior iliac spines, draw a line from the anterior iliac spine on each side to the summit of the corresponding great trochanter, and measure the base of the triangle from the great trochanter to the perpendicular line to determine the amount of ascent. The difference in measurement between the two sides shows the amount of ascent of the trochanter; that is, shows the extent of shortening.

Morris's measurement shows the extent of inward displacement. Measure from the median line of the body to a perpendicular line drawn through the trochanter on each side of the body.

[1] Edmund Owen, "A Manual of Anatomy."

Diagnosis.—The x-rays are a valuable aid to diagnosis (Fig. 339). Intracapsular fracture without separation of fragments may be mistaken for a mere contusion, and the diagnosis may continue obscure unless the fragments separate. Loss of function in contusion is rarely complete or prolonged, although occasionally the head of the bone undergoes absorption. Early after a contusion, and usually throughout the case, there is no alteration between the relation of the spine of the ilium and the trochanter, and no shortening. Some time *after* a severe contusion the head of the bone may be absorbed. Contusion of a rheumatic joint leads to much difficulty in diagnosis. Intracapsular fracture may be confused with *extracapsular* fracture or with dislocation of the hip-joint. Extracapsular fracture, which is common in ad-

Fig. 339.—Author's case of recent intracapsular fracture in a woman aged forty successfully nailed. Nail is still in place after five years.

vanced life, but is met with not unusually in middle life and even occasionally in the young, results usually from great violence over the great trochanter; if non-impacted, there are noted shortening of from $1\frac{1}{2}$ to 3 inches, crepitus over the great trochanter, and usually, but not invariably, eversion; if impacted, there is less eversion, crepitus is absent, and the shortening is limited to about an inch. The extensor muscles are relaxed. Great tenderness exists over the great trochanter in both impacted and non-impacted fractures. In dislocation on the dorsum of the ilium the patient is usually a strong young adult. There is a history of forcible internal rotation. There are inversion (the ball of the great toe resting on the instep of the sound foot), rigidity, ascent of the great trochanter above Nélaton's line, and shortening of from 1

to 3 inches. The head of the bone is felt on the dorsum of the ilium, and the trochanter mounts up toward the spine of the ilium, and pressure upon it causes no pain. In dislocation into the thyroid notch there is possibly eversion, but it is linked with lengthening.

In *fracture of the brim of the acetabulum* there is shortening, which occurs on the removal of extension, inversion, abduction, flexion of the knee, the head of bone is drawn upward and backward with the acetabular fragment, and there is retention of the power of eversion and of adduction (Stokes). Crepitus is most distinctly appreciated by a hand resting on the ilium.

In *fracture of the fundus of the acetabulum* (see Fig. 294) there is shortening, and the head of the bone enters the pelvis (Stokes).

The *prognosis* is not very favorable. Some aged patients die in a day or two from shock. Not a few perish later from hypostatic congestion of the lungs, kidney failure, or exhausion. The majority of cases recover with a little shortening, some stiffness, and a permanent limp. There is a much better chance for firm union if the fracture is impacted than if it is not. Even if non-union results after an intracapsular fracture, and it is not unusual, a patient may get about fairly well with a proper support. In some cases after intracapsular fracture rheumatoid arthritis develops. Many surgeons have maintained that bony union never occurs, but it certainly does sometimes take place. Stokes holds that bony union is possible in fractures with penetration, and even in fractures without penetration when the fracture is within the periosteum.[1]

Treatment.—In treating a very feeble old person for intracapsular fracture make no attempt to obtain union. Keep the patient in bed for two weeks; give lateral support by sand-bags; tie around the ankle a fillet, attach a weight of a few pounds to the fillet, and hang the weight over the foot-board of the bed. When pain and tenderness abate, order the patient to get into a reclining-chair, and permit him very soon to get about on crutches. If hypostatic congestion of the lungs sets in, if bed-sores appear, if the appetite and digestion utterly fail, or if diarrhea persists, abandon attempts at cure in any case, and get the patient up and take him into the sunshine and fresh air, simply immobilizing the fracture as thoroughly as possible by means of pasteboard splints or plaster of Paris. In the vast majority of cases, no matter how old the patient may be, undertake treatment. We may be forced to abandon it, but should at least attempt to obtain a cure. If it is determined to treat the case, place the patient on a hair mattress, several boards being laid transversely under the mattress in order to prevent unevenness and the formation of hollows. A fracture-bed is a valuable adjunct to treatment.

Treatment by the Extension Apparatus of Gurdon Buck.—Extend the knee and place the leg in a natural posture, and put a pillow beneath the knee. Combine extension with lateral support by means of sand-bags. The extension should be gentle, never forcible. It is not wise to pull apart an impaction in an old person, but it should always be done in a young or middle-aged person. Place the subject on a firm mattress or a fracture-bed. If the patient be a man, shave the leg. Cut a foot-piece out of a cigar-box, perforate it to admit the passage of a cord, wrap it with adhesive plaster as shown in Plate 7, Figs. 15 and 16, run the weight-cord through the opening in the wood, and fasten a piece of adhesive plaster on each side of the leg, from just below the seat of fracture to above the malleolus (Pl. 7, Fig. 14). The plaster is guarded from sticking to the malleoli by having another piece stuck to its under surface opposite each of these points. Apply an ascending spiral reversed bandage over the plaster to the groin (Fig. 340), and finish the bandage by a spica of the groin. Slightly abduct the extremity. Put a brick under each leg of the bed at its

[1] See the masterly paper by Stokes, before quoted.

foot, thus obtaining counterextension by the weight of the body. Run a cord over a pulley at the foot of the bed, and obtain extension by the use of weights. In an adult from 15 to 20 pounds will probably be necessary at first, but after a few days from 8 to 10 pounds will be found sufficient (remember that a brick weighs about 5 pounds). Dawbarn's rule as to the proper weight to be attached is 1 pound for every year up to twenty. When the foot of the bed is raised and the weight to make extension is applied, very gently rotate the extremity, put the foot at a right angle with the leg, and make a bird's-nest pad of cotton or oakum to save the heel from pressure. Take

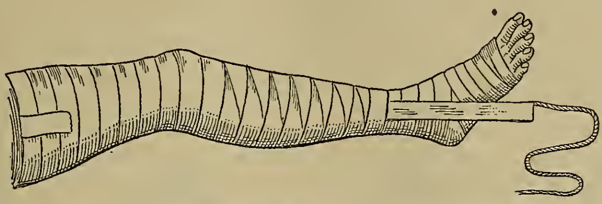

Fig. 340.—Adhesive plaster applied to make extension.

two canvas bags, one long enough to reach from the crest of the ilium to the outer malleolus, the other long enough to reach from the perineum to the inner malleolus. Fill the bags three-quarters full of dry sand, sew up their ends, cover the bags with slips, and put the bags in place in order to correct eversion. The slips may be changed every third or fourth day. Keep the bed-clothing from coming in contact with the extremity by means of a cradle (Figs. 341, 342). The bowels are to be emptied and the urine is to be voided in a bed-pan, unless using a fracture-bed. For two weeks the patient remains recumbent, after which time he can be propped up on pillows. Maintain extension for three

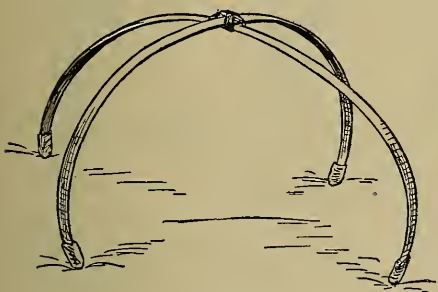

Fig. 341.

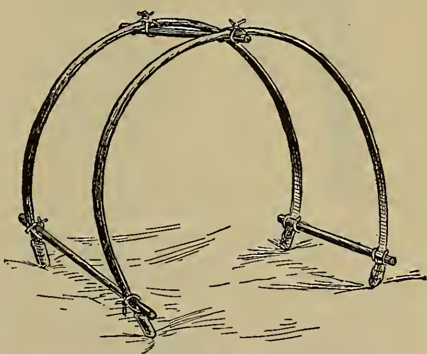

Fig. 342.

Figs. 341, 342.—Cradle to keep clothing from leg, made from two barrel-hoops (Scudder).

weeks, then simply maintain support by sand-bags or molded pasteboard splints upon the part, and keep up this support three to five weeks more. After removing the extension he can be transferred daily to a couch. In from six to eight weeks after the infliction of the injury he can be moved about in a wheeling-chair, the leg being extended or the knee flexed in accordance with the dictates of comfort. After a week or so of such movement a thick-soled shoe is placed on the sound foot and the patient is allowed to use crutches; but weight is not put upon the injured extremity until from ten to twelve weeks have elapsed from the time of the accident. For many months, at least, and possibly permanently, he walks with the aid of a cane. Union, if it takes place, is usually

cartilaginous, but is sometimes bony, and there will surely be some shortening and also some stiffness of the joint. Passive motion is not made until at least eight weeks have elapsed since the accident. Treatment by the extension apparatus is far from satisfactory, as it does not afford sufficient immobilization.

Senn's Method.—Senn claims that by this method of "immediate reduction and permanent fixation" bony union is obtained in fractures of the neck of the femur within the capsule. He "places the patient in the erect position, causing him to stand with his sound leg upon a stool or box about 2 feet in height; in this position he is supported by a person on each side until the dressing has been applied and the plaster has set.

"Another person takes care of the fractured limb, which in impacted fractures is gently supported and immovably held until permanent fixation has been secured by the dressing. In non-impacted fractures the weight of the fractured limb makes auto-extension, which is often quite sufficient to restore the normal length of the limb; if this is not the case, the person who has charge of the limb makes traction until all shortening has been overcome as far as possible, at the same time holding the limb in position, so that the great toe is on a straight line with the inner margin of the patella and the anterior superior spinous process of the ilium. In applying the plaster-of-Paris bandages over the seat of fracture a fenestrum, corresponding in size to the dimensions of the compress with which the lateral pressure is to be made, is left open over the great trochanter.

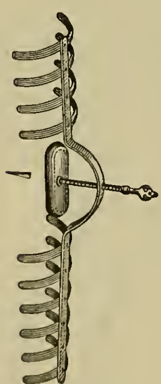

Fig. 343.—Senn's apparatus.

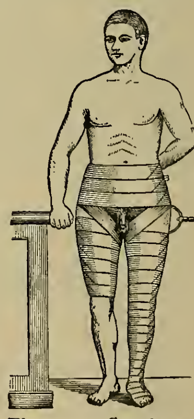

Fig. 344.—Senn's apparatus applied.

"To secure perfect immobility at the seat of fractures it is not only necessary to include in the dressing the fractured limb and the entire pelvis, but it is absolutely necessary to also include the opposite limb as far as the knee and to extend the dressing as far as the cartilage of the eighth rib.

"The splint (Fig. 343) is incorporated in the plaster-of-Paris dressing, and it must be carefully applied, so that the compress, composed of a well-cushioned pad with a stiff, unyielding back, rests directly upon the trochanter major, and the pressure, which is made by a set-screw, is directed in the axis of the femoral neck. Lateral pressure is not applied until the plaster has completely set. Syncope should be guarded against by the administration of stimulants.

"As soon as the plaster has sufficiently hardened to retain the limb in proper position the patient should be laid upon a smooth, even mattress, without pillows under the head, and in non-impacted fractures the foot is held in a straight position and extension is kept up until lateral pressure can be applied.

"No matter how snugly a plaster-of-Paris dressing is applied, as the result of shrinkage it becomes loose, and without some means of making lateral pressure it would become necessary to change it from time to time in order to render it efficient. But by incorporating a splint in the plaster dressing (Fig. 344) this is obviated, and the lateral pressure is regulated, day by day, by moving the screw, the proximal end of which rests on an oval depression in the center of the pad."

Treatment by Thomas's Splint.—Scudder, in his valuable treatise on "The Treatment of Fractures," advocates in intracapsular fracture the use of Thomas's hip splint. If the bones are unimpacted, the fragments are brought into apposition by extension, inversion, and pressure upon the great trochanter, and the Thomas splint is bent to fit, is padded, and is applied (Figs. 345, 346). When the bed-pan is to be used or the bed is to be smoothed, the patient can be lifted without disturbing the fracture. He can be turned on the sound side. If hypostatic congestion is developing, raise the head of the bed and tie the splint to the iron of the head of the bed. In addition to the use of the splint Scudder advocates the making of lateral pressure over the great trochanter by a graduated compress and a bandage. The splint is worn for six or eight weeks. It is then removed, the patient remaining in bed four weeks longer without any apparatus (Scudder, from Ridlon).

Jones, of Liverpool, treats fractures of the femoral neck by means of an extension frame (see Fig. 357).

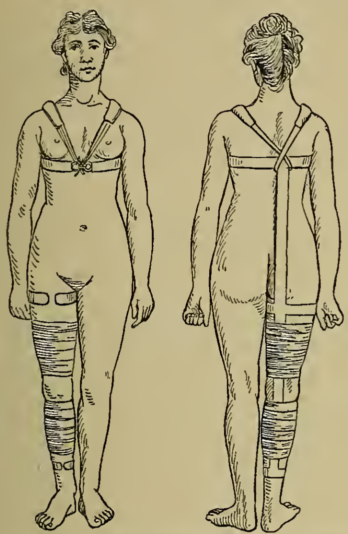

Fig. 345.—Thomas's single hip-splint in position (Ridlon).

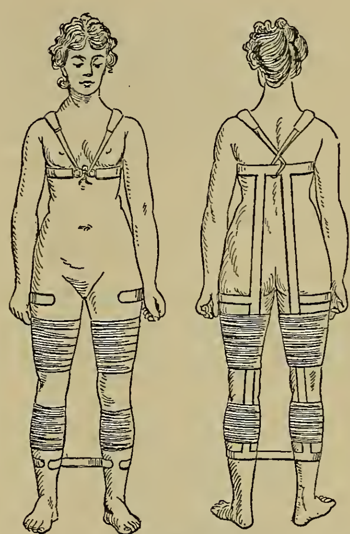

Fig. 346.—Thomas's double hip-splint in position (Ridlon).

Whitman's Treatment in Abduction.—The plan advocated by Royal Whitman ("Med. Record," March 19, 1904) is a most excellent one. It aims to abolish traumatic depression of the neck of the femur.

We can apply this plan in a young person to any fracture even if impacted. In an aged person we apply it only in a complete non-impacted fracture. In a young person we usually give ether and pull apart an impaction by abduction. In an aged person we should not do so.

In regard to impaction Jones says, if the shortening is trivial and there is no rotation an impaction is not to be pulled apart; if there is marked shortening and eversion, it is to be.

Make extension, counterextension, and internal rotation until the foot is at a right angle with the table and shortening is abolished, and then slowly abduct. The abduction relaxes the muscles which interfere with reduction and carries the outer fragment against the inner.

The extremity is set in extension and extreme abduction and plaster of Paris is applied. The tension of the capsule pushes the outer fragment against the inner and holds it; fixation is obtained by the neck of the femur being in

contact with the acetabulum and the great trochanter with the pelvis, deformity cannot be caused by muscular action, and the psoas helps pull the fragments together (Whitman).

The limb is kept fixed in abduction for six weeks and then a Thomas splint with extension is used.

Extracapsular Fracture (*Fracture of the Base of the Neck of the Femur*).—The line of extracapsular fracture is at the junction of the neck with the great trochanter, and is partly within and partly without the capsule, the fracture being generally comminuted and often impacted. The *cause* is violent force over the great trochanter (as by falling upon the side of the hip). This fracture is most usual in elderly people, but is met with in the middle aged and is not very uncommon in young adults. Stokes has described six forms of extracapsular fracture: extracapsular fracture with partial impaction posterior; fracture with complete impaction; fracture with partial impaction above; fracture with partial impaction below, the shaft being split; splitting of the neck longitudinally without impaction; comminuted non-impacted fracture.[1]

Symptoms.—When impaction is absent there is marked crepitus on motion, which is manifested most distinctly when the fingers are placed upon the great trochanter; there is severe pain, pressure upon the great trochanter is very painful, swelling and ecchymosis are marked; there is absolute inability on the part of the patient to move the limb, and passive movements cause violent pain; there is shortening to the extent of at least $1\frac{1}{2}$ inches, and sometimes to the extent of 3 inches, which shortening is made manifest by noting the ascent of the trochanter above Nélaton's line, by a comparison of measurements of the injured limb and the sound limb, and by measuring the base-line of Bryant's triangle on each side. Absolute eversion usually exists with slight flexion both of the leg and the thigh. In some rare cases there is inversion. This happens if at the time of the accident the limb was inverted and adducted (Stokes). Langoria's sign, Desault's sign, and Allis's sign are present. All these symptoms follow violent direct lateral force to the great trochanter. In the *impacted* form of extracapsular fracture, in addition to the aid given the surgeon by the history, there is severe pain, which is intensified by movement or pressure; shortening probably to the extent of 1 inch, which is not corrected by extension; limited abduction; great loss of function; and whereas the limb may be straight or even inverted, it is usually everted. The trochanter is above Nélaton's line, the base-line of Bryant's triangle is shortened, but not so much as in the unimpacted form; there is no crepitus unless the impaction is loose or is pulled apart, and the arc of rotation of the great trochanter is larger than in a non-impacted fracture.

Treatment.—In impacted extracapsular fracture it is best to pull apart the impaction if the patient is in good physical condition. Southam, of Manchester, in an impressive article has insisted on the absolute necessity of pulling apart an impaction. He gives ether, and when the patient is anesthetized unlocks the fragments.[2] This unlocking is best accomplished by abduction, the rim of the acetabulum acting as the fulcrum of the lever (Whitman). In treating extracapsular fracture we can use the extension apparatus with sand-bags (see page 586) for three weeks and then apply a plaster dressing. Get the patient on crutches after the plaster has been in place for two weeks. Remove the plaster at the end of four weeks. Thomas's splint may be used instead of Buck's extension or the treatment suggested by Whitman may be employed (see page 589).

Fractures of the Femoral Neck in Children.—Fracture of the femoral neck in children and in young adults can scarcely be regarded as very unusual, and is certainly more often encountered than separation of the upper epiph-

[1] "Brit. Med. Jour.," Oct. 12, 1895. [2] "Lancet," Dec. 21, 1895.

ysis. The accident results from a fall rather than, as so often in an adult, from a twist, and it is the product of considerable violence rather than of slight force. In children such fractures may be impacted, and most of those which are unimpacted are of the green-stick variety. The disability is not nearly so great as

Fig. 347.—The long spica as applied for fracture of the neck of the femur in the adult; illustrating the advantage of an appliance which permits movement without danger of displacing the fragments; an opening has been made to lessen the constriction of the abdomen (Whitman).

in an adult; in fact, it is not unusual for the victim of such an injury to be able to hobble about a few days afterward. The symptoms are shortening, some eversion, impairment of joint movements, and a limp when the patient gets about. Fractures of the hip in children are often unrecognized and lead frequently to permanent impairment because of the development of coxa vara. The x-rays should be used in making the diagnosis.

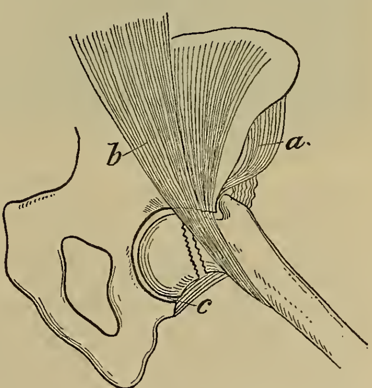

Fig. 348.—Reduction and fixation in abduction, showing security assured by direct bony contact of the neck and trochanter with the pelvis, also the effect of the attitude on muscular action: *a*, Abductor group; *b*, iliopsoas; *c*, capsule (Whitman).

A green-stick fracture may be treated with Thomas's splint, and after four weeks in bed "the child may be allowed up, wearing a traction hip-splint for several months until union is so firm that the danger from coxa vara is practically eliminated. A light plaster-of-Paris spica bandage from the calf to the axilla will maintain immobility after the splint is omitted" (Scudder, on "The Treatment of Fractures"). An impacted fracture, after the impaction has been pulled apart, is treated exactly as a green-stick fracture. Royal Whitman's plan for treating a green-stick fracture is very satisfactory. This surgeon ("Med. Record," March 19, 1904) dresses these cases by placing the limb in extreme abduction and holding it so by means of a plaster-of-Paris spica (Figs. 347, 348). In a case of acute disability of the hip-joint in a child, following some time after fracture of the femoral neck, make a careful differentiation from tuberculous disease of the joint and apply

a traction splint to support the body and give rest to the joint. If coxa vara becomes marked and causes great disability, osteotomy is justifiable.

Operative Treatment of Fracture of the Femoral Neck.—I have practised this but once. The patient was a woman forty years of age and the result was excellent (see Fig. 339). The operation is not indicated in elderly subjects. It is not indicated at all if the fragments can be coaptated and retained by extension and counterextension or by abduction. In a youth or a middle-aged person in whom retention in correct posture is impossible it is indicated.

Some advocate incision, suture of the torn capsule, and nailing. In my case I nailed through a very small skin incision and did not suture the capsule. It is held that suture of the capsule improves the circulation in the broken off head, but possible attainment of the object is not justification for the risk. The small cutaneous incision and nailing answers the purpose. It is not necessary to drill the trochanter as König did.

Fig. 349.—Comminuted fracture of upper third of femur.

Fig. 350.—Epiphyseal separation of head of the femur.

Before operating an x-ray picture is taken, while the fragments are brought into apposition by abduction or by extension and counterextension. From this picture the angle of the neck is noted and the length of nail required is determined. A silver nail is used. When ready to operate, the fragments are again brought into apposition by extension and counterextension or abduction. A small incision is made through the skin over the external aspect of the great trochanter, and the nail is driven through the trochanter and neck into the head. The wound is closed and dressed. The pelvis and extremity are then put up in plaster, a trap-door being cut over the seat of incision. The plaster dressing is retained for five or six weeks. Cure is obtained without shortening and with retention of joint mobility. This operation is also used for ununited fracture. Dr. G. G. Davis was the first to do a nailing operation for a recent intracapsular fracture of the femur.

Separation of the upper epiphysis of the femoral head (Fig. 350) is a very rare result of accident; it occurs most often from disease. It is met with in early youth, results in considerable permanent shortening, and perhaps in coxa vara.

Symptoms and Treatment.—The *symptoms* are like those of fracture of the neck, except that the crepitus is soft. The *treatment* is as for fracture of the neck.

Fractures of the Great Trochanter.—This is a very rare injury. There seem to be only 8 cases on record, but probably the diagnosis has been missed in some cases in which the fragment was held to the bone by periosteum. This process may be (1) broken off without any other injury. In some cases it is completely broken off; in some it remains attached by periosteum and fibrous tissue. (2) The line of fracture may run through the trochanter and leave one portion of the trochanter attached to the head and neck and the other part attached to the shaft of the femur. The *cause* is violent direct force over and behind the great trochanter or a fall (Armstrong, in "Annals of Surgery," August, 1907). Neck reported a case due to muscular action ("Zentralb. für Chir.," 1903).

Symptoms and Treatment.—The *symptoms* of the first form resemble those of epiphyseal separation and, of course, there is no shortening. The symptoms of the second form are similar to those of the extracapsular fracture. On rotating the femur the lower part of the trochanter moves with it, but not the upper. The lower fragment goes upward and backward and projects by the side of the sciatic notch. There are shortening, eversion, crepitus, and altered position of the trochanter. The *treatment* of the second form is like that in extracapsular fracture, and the first form is treated like separation of the epiphysis of the trochanter.

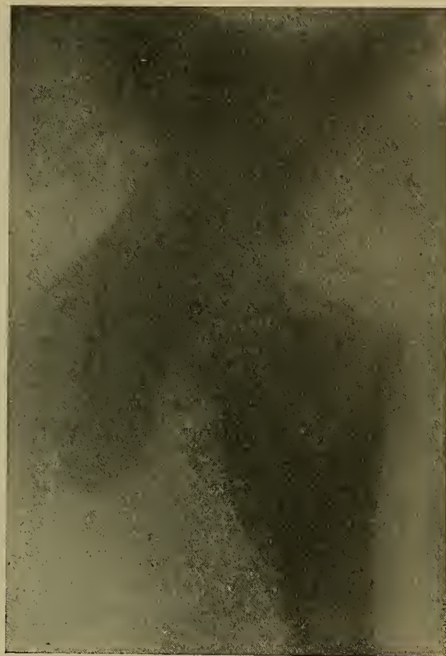

Fig. 351.—Intertrochanteric fracture.

Separation of the epiphysis of the great trochanter is a rare accident. The *cause* is direct violence and the injury occurs in those under eighteen years of age. Poland in 1898 collected 12 cases.

Symptoms.—The trochanter, if completely separated, is found to have ascended and passed posteriorly; there is no shortening of the thigh; all the motions of the hip-joint can be obtained; if the thigh is flexed, abducted, and rotated externally, and the fragment is pushed downward and forward, crepitus may be obtained—soft in epiphyseal separation, hard in fracture. There is no shortening. If the process is not completely separated, diagnosis is impossible without the *x*-rays.

Treatment.—If the epiphysis is not completely separated, immobilize the limb in the position of abduction. If it is completely separated, incise the soft parts and either suture or nail the fragment in place.

Fractures of the shaft of the femur may affect any portion of the shaft, but especially the middle third, and may occur at any age. Fracture of the upper third is a rare accident. Allis estimates that each year in Philadelphia there is 1 case of fracture of the upper third of the femur to every 100,000 inhabitants. Separation of the lower epiphysis occasionally occurs.

The *cause* of fractures in the upper third is usually indirect force; fractures in the lower third are due to direct force; and in fractures of the middle third these two causes are about equally potential. Fracture from muscular action occasionally occurs. Oblique fracture is the usual variety. In many cases the soft parts are badly lacerated and sometimes a great vessel is torn.

Symptoms.—The chief symptom in fracture of the shaft of the femur is great displacement, except when impaction occurs, when the break is due to direct force, or when the injury is in a child. In a child the line of fracture is often transverse and the periosteum may be untorn. Green-stick fractures occur in children. As a rule, in fracture of the shaft of the femur the lower fragment is drawn upward and the upper end of the lower fragment

Fig. 352.—Deformity following fracture of upper third of femur.

is found posterior and somewhat to the inside of the lower end of the upper fragment, and the lower fragment also undergoes external rotation (the drawing up is due to the rectus and hamstrings; the passing inward is due to the adductor muscles; the rotation outward arises from the weight of the limb). If a fracture of the lower two-thirds of the shaft is produced by direct force, there is usually but little deformity, because the line of fracture is nearly transverse. If produced by indirect force, there is often great deformity, the line of fracture being oblique. In fracture of the lower third of the shaft the gastrocnemius pulls upon the condyles and tilts the lower fragment, so that its upper end projects into the popliteal space and may damage the vessels. In fracture of the upper third the upper fragment is apt to be thrown strongly forward and outward (Fig. 352). Some attribute this to the action of the

psoas, iliacus, and external rotator muscles, but Allis thinks it is due chiefly to the lower fragment pushing the upper fragment into this position, a part of the tendon of the gluteus maximus acting as a hinge for the fragments.[1] In rare cases the angular deformity is backward. In fracture of the shaft of the femur there is complete loss of function, the thigh and leg are slightly flexed and usually everted. In some cases the leg and lower fragment are inverted. There are shortening to the extent of 2 or 3 inches, pain on movement, preternatural mobility, crepitus, and obvious deformity, and the ends of the fragments can be felt by the surgeon. In impaction there is alteration of the axis of the limb and some shortening. Always feel for the pulse below the fracture to learn if the artery is damaged.

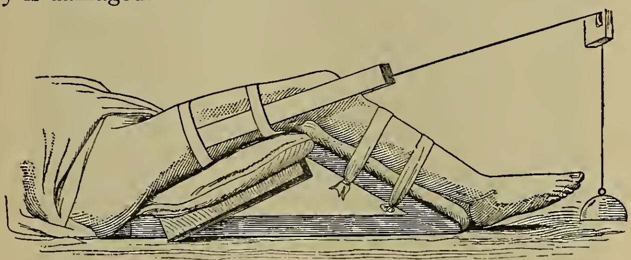

Fig. 353.—Dressing of fracture of the femur in the upper third with extension upon a double inclined plane (Agnew).

Treatment.—In setting and dressing a fracture of the thigh ether should be given and the parts must be handled with great care to prevent a sharp end of bone from tearing the soft parts and puncturing the skin. In fracture of the shaft of the femur, if impaction exists, the fragments must be pulled apart, when the case should be treated exactly as is a non-impacted fracture. After a fracture of the shaft of the femur some amount of permanent shortening is almost inevitable. In *fracture of the upper third* in an adult conservative treatment is usually unsatisfactory, and there is permanent shortening from angular union or from overlapping. In youths under fifteen a good result is obtained in over 90 per cent. of cases. Horizontal extension fails to correct the displacement of the upper fragment in fracture of the upper third. The double inclined plane will not correct the tilting of the upper fragment while shortening exists. Agnew used a double inclined plane and corrected shortening by the use of extension in the axis of the partly flexed thigh (Fig. 353). This plan is one of the most serviceable of those usually employed, but it too fails to completely correct the displacement. If, notwithstanding position and extension, the upper fragment projects, it should be pushed into place and be retained if possible by short splints bound upon the thigh. In many cases a Thomas knee-splint is the best apparatus. In fracture of the upper third with marked projection of the upper fragment the abduction frame may prove satisfactory. Extension should be continued for four weeks, a plaster-of-Paris

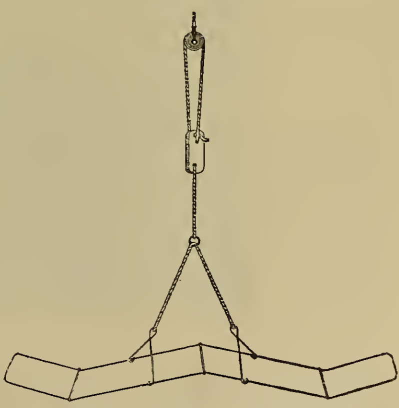

Fig. 354.—Smith's anterior splint.

[1] "Fracture in the Upper Third of the Femur Exclusive of the Neck," by Oscar H. Allis, "Medical News," Nov. 21, 1891.

bandage being used for four weeks more, the patient being then allowed to go about on crutches. Some surgeons, in fracture of the upper third, apply a plaster-of-Paris bandage to the leg, thigh, and pelvis, extension being made from the foot while the dressing is being applied. This method does not give good results because such extension will not correct the tilting of the upper fragment. The anterior splint of Nathan R. Smith is used by some in treating fractures of the upper third of the femur (Fig. 354). It is bent to the desired shape, fastened to the anterior surfaces of the leg and thigh, and hung to a gallows, the limb being suspended at the desired height. This splint is open to the same

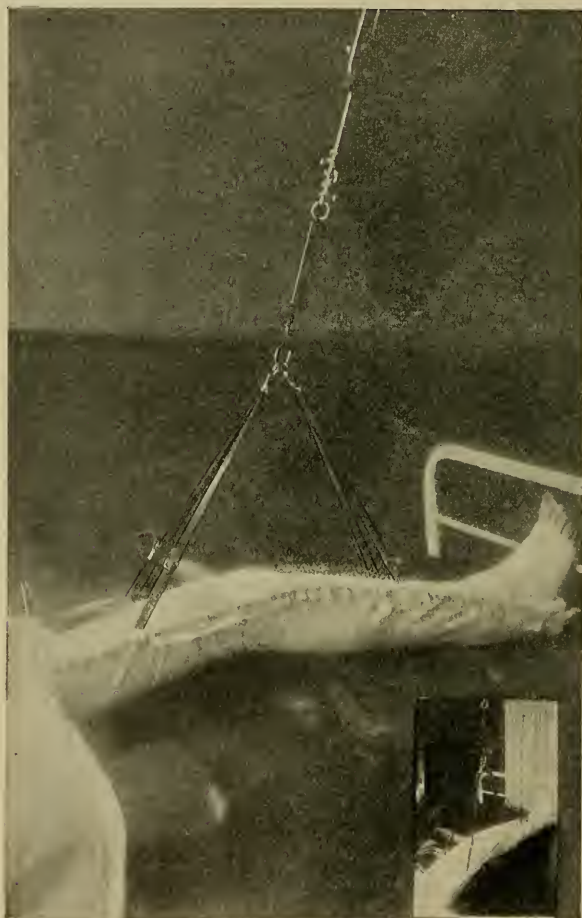

Fig. 355.—Hodgen's apparatus as applied by Dr. George S. Brown.

objection as the double inclined plane. In fact, in many fractures of the upper third of the shaft of the femur no apparatus will maintain reduction. In such cases it is advisable to incise, separate the muscles from between the fragments, and fasten the ends of the bone-fragments together with bone plates. This radical treatment has certain dangers of its own, but it is the plan which promises best to secure a thoroughly good limb. In *fracture of the middle third* or *upper part of the lower third* of the shaft of the femur the Thomas knee-splint is an excellent instrument. The extension apparatus and sand-bags will usually secure a satisfactory result (Pl. 7, Fig. 14). The

strips of adhesive plaster are carried to just below the seat of fracture, and the turns of the roller bandage should be taken to a little above this point. Extension should be continued for four weeks, when the plaster-of-Paris bandage ought to be applied. The plaster is kept in place for four weeks. Many surgeons use Hodgen's splint in treating fractures of the thigh. The limb is suspended in a cradle and extension is obtained by strapping the foot of the cross-bar of the frame and pulling upon the frame by cords (Fig. 355). Hodgen's apparatus as applied by Brown, of Birmingham, Ala., is one of the most satisfactory methods of treatment in fracture below the upper third. The extremity can be raised or lowered at will without disturbing the approximation of the fragments, extension to the required degree can be obtained, and the patient can be moved in bed. I consider this apparatus one of the most comfortable appliances which can be worn and excellent results are obtained by its use. In fracture of the middle third or upper part of the lower third of the shaft if the line of fracture is transverse and there is little deformity, as is seen often after a fracture by direct force, and often in children, immobilization in an immovable dressing may be all that is required; but if shortening exists, extension must be used. If extension is used, continue it for four weeks and then substitute a plaster-of-Paris dressing for four weeks. The amount of weight

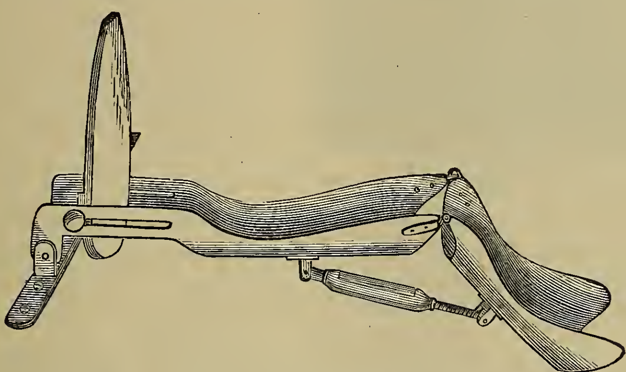

Fig. 356.—McIntyre's splint.

required is pointed out by Dawbarn—1 pound for each year up to twenty.[1] In *fracture near the knee-joint* (*lower part of the lower third* of the femur) it may be impossible to effect reduction by horizontal traction. In such a case make traction, and while it is being made gradually bring the leg to a right angle. Place the limb in a double inclined plane (Pl. 7, Fig. 2). A McIntyre splint (Fig. 356) is a useful form of double inclined plane. After four weeks of the use of a double inclined plane apply a plaster-of-Paris dressing, which is to be worn for four weeks.

Fractures of the Shaft of the Femur in Children.—In children under three years of age the extension apparatus will not satisfactorily immobilize the fragments. Fractures of the thigh in children are reduced by extension and counterextension; a well-padded splint reaching from the axilla to below the sole of the foot may be applied to the outer side of the limb and body. This splint is held in place by bandages which are overlaid by plaster of Paris. It is worn for four weeks, at which time it is removed and a plaster bandage, applied so as to include the entire limb, is worn for four weeks.

The abduction frame (Fig. 357) is a very useful plan of treatment.

Bryant's extension (Fig. 358) is very satisfactory in treating a child. Both

[1] "Annals of Surgery," Oct., 1897.

the injured limb and the sound limb should be flexed to a right angle with the pelvis, fixed by light splints, and fastened to a bar above the bed. The weight of the body produces counterextension and the child can be easily cleaned.[1]

Another plan is that of Theodore Dunham.[2] The child is placed upon a table, and the knee and hip are partly flexed. After first applying flannel rollers, plaster-of-Paris bandages are applied from the roots of the toes to the spine of the tibia, and as a spica about the upper part of the thigh and pelvis. Two pieces of iron, suitably bent, are used to anchor the two plaster bandages together. One end of one iron is attached to the plaster over the groin and one end of the other iron is attached to the plaster over the front of the leg. The free ends of the irons overlap. At the points over the joints and the front of the leg where the irons are to rest masses of plaster are placed. The iron is sunk into the plaster and supported at each spot by several turns of a plaster bandage. While the irons are being adjusted the thigh is so held as to prevent bending or rotation, and the hip and knees are semiflexed. When the plaster has set an assistant makes extension on the leg and another assistant makes counterextension by pressing on the pelvis. Any shortening is thus reduced and the two irons are lashed together by strong cord (Fig. 359).

Fig. 357.—Jones's abduction frame, showing continued traction and counterextension (courtesy of Mr. Robert Jones, Liverpool, England).

Van Arsdale's triangular splint is a very useful appliance. It is made of binders' board. A. Ernest Gallant[3] describes its preparation and application as follows: Measure the length of the sound thigh from the middle of the groin to the end of the femur. Draw upon cardboard an outline of a double spade (playing-card spade) (Fig. 360). Each of the four sections (*A*, *B*, *C*, *D*) must be equal to the length of the child's thigh, the flanged portions being equal to the widest part of the thigh. The figure is then cut out. The cardboard is moistened on one side and folded on the dotted line, section *A* being lapped over *D*, so as to form a triangle. It is fastened together by adhesive plaster. The thigh is flexed and the triangle is applied so that one flanged portion embraces the thigh and the other flanged portion rests upon the abdomen (Fig. 361). The triangle is fixed in position by bandages, figure-of-8 turns being made around the knee and around the thigh and body. Plaster or starch bandages are then applied to fix the splint firmly. The leg should be bandaged from the toe to the knee to prevent swelling (Fig. 361). This splint

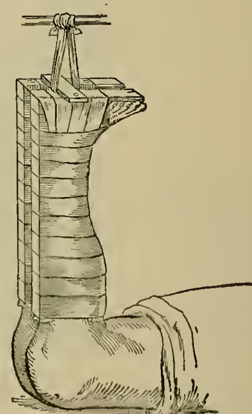

Fig. 358.—Bryant's extension for fracture of the thigh in a child.

[2] "Phila. Med. Jour.," April 23, 1898.
[3] "Jour. Amer. Med. Assoc., Dec. 18, 1897.

is worn for three weeks. A child wearing this splint can sit on a chair, nurse, play on the floor and crawl about, may sleep on either side, and the dressing is not soiled by the evacuations.

If a thigh is fractured during parturition, or during the first few weeks of life, *Wyeth's dressing* may be very serviceable. It is applied as follows: The leg is flexed on the thigh and the thigh on the abdomen. A flannel bandage is applied so as to include the leg, the thigh, and the body from the axilla to the pelvis. Plaster of Paris is applied over this; the dressing is worn for four weeks. A better dressing than the above is *Ware's*, a modification of *Van Arsdale's splint* ("Annals of Surg.," August, 1905) (Fig. 362). It is lighter, the patient can be moved about with ease, the child's toilet can be easily carried out, and breathing is not embarrassed. A right-angled triangle is

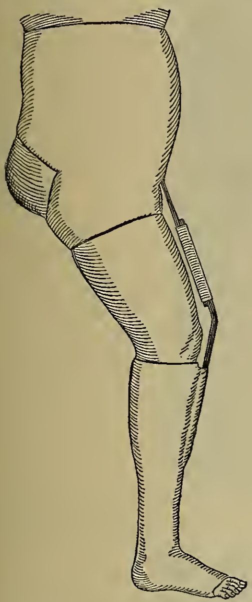

Fig. 359.—Dunham's apparatus for treating fractures of the thigh in infants and children.

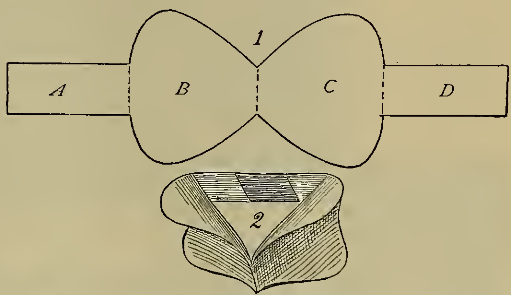

Fig. 360.—*1*, Diagram showing outline of Van Arsdale's splint; the end band to be folded on the dotted lines; each section to equal the length of the child's thigh. *2*, Diagram, splint folded, fastened by rubber plaster, flanges bent to embrace the thigh and abdomen, ready for adjustment (Gallant).

made of bookbinders' board. The length of one side is the distance from the trunk at the level of the lower angle of the scapula to the inguinal fold. The length of the other side is the length of the thigh. The hypotenuse is, of course, longer than the sides. The cardboard is marked, bent into the triangle, and the overlapping edges are secured by means of

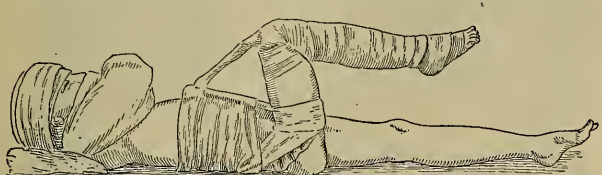

Fig. 361.—Showing Van Arsdale's triangular splint in position. Note the wide space between the dressings and the excretory passages (Gallant).

adhesive plaster. The thigh is flexed and abducted, the inner surface of the splint is padded, the apparatus is applied and retained by a muslin spica about the trunk and thigh. Several turns of a dextrin bandage are applied over this to give strength. The leg hangs free. The dressing is worn for three or four weeks. Figure 362 shows this dressing applied for fracture of the right femur, and Fig. 363 shows it applied when both bones are broken.

Fig. 362.—Ware's combined pasteboard triangle and plaster-of-Paris spica apparatus for fracture of the femur in infancy (Ware, in "Annals of Surgery," August, 1905).

Fig. 363.—Ware's apparatus for treatment of fracture of both femora (Ware, in "Annals of Surgery," August, 1905).

Fractures Just Above the Condyles of the Femur.—The *line* of fracture above the condyles is well above the epiphyseal line. The popliteal artery is in danger from the fragments. The *cause* of the break, as a rule, is direct violence. Indirect force is sometimes responsible (falls upon the feet). The knee-joint may be opened. The fracture is sometimes compound.

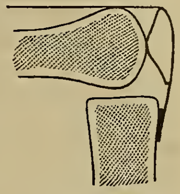

Fig. 364.—Mechanism of fracture of the patella by muscular action (after Treves).

Symptoms.—The upper end of the lower fragment is drawn upward and backward, because of the action of the rectus, hamstrings, gastrocnemius, and popliteus. The upper fragment passes inward, and the deformity is very manifest. There are pain, tenderness, shortening, crepitus, and mobility. The ends of the fragments can be felt by the surgeon. If the force has been very great, a T-fracture results. In T-fracture the knee is broadened and crepitus is obtained by moving the condyles, one up and the other down. The popliteal vessels may be torn. Always feel for the pulse below the fracture.

Treatment.—In treating fracture above the condyles, reduce the deformity by horizontal extension. If this fails, make traction at the same time, gradually bringing the leg to a right angle with the thigh. Place the limb on a double inclined plane for five weeks, then begin passive motion once every other day, reapplying the splint after the movements are completed. At the end of eight weeks after the accident remove the dressings, and, if the knee-joint be stiff, use for some time massage, passive motion, hot air, hot and cold douches, ichthyol inunctions, etc. Bryant treats this fracture in extension, cutting the tendo Achillis, if necessary, to amend deformity. It is occasionally necessary to plate the fragments. Some cases demand amputation because of injury to the structures in the popliteal space.

Fig. 365.—Fracture of the patella.

Fracture Separating Either Condyle.—The *cause* is direct force.

Symptoms and Treatment.—The broken piece is drawn upward, the leg bends toward the injury, crepitus exists, the knee is much broadened, there is no shortening, and considerable swelling is sure to arise. In treating a fracture separating either condyle, use a double inclined plane as directed above. If there is great displacement, the condyle should be nailed in place.

Longitudinal fractures run upward from the knee-joint. The *cause* is a fall upon the feet or the knees.

Symptoms and Treatment.—The *symptoms* of longitudinal fracture are often obscure. The femur is broadened when the knee is flexed. The split may be detected between the condyles. The *treatment* is the straight position in plaster for eight weeks.

Separation of the lower epiphysis occurs only before the twenty-first year. It is not a very rare accident in children.

The *symptoms* in separation of the lower epiphysis are like those of transverse fracture, but crepitus is moist. The lower fragment is tilted, so that the articular surface looks forward. The lower end of the upper fragment pro-

jects into the popliteal space. There is danger to the structures in the popliteal space. The growth of bone may be stunted. Feel for the pulse in the leg or foot.

Treatment.—Reduction may be effected in some cases by horizontal extension. Occasionally this is impossible.[1] In such a case adopt the plan of Hutchinson and Barnard, make extension, and while it is being made gradually place the leg at a right angle to the thigh. This is effected by an assistant making traction on the leg, while the surgeon clasps his hands beneath the lower part of the thigh and draws upward. The treatment for separation of the lower epiphysis is the use of a double inclined plane as above directed. In some cases replacement is impossible without incision. In a case of my own amputation was performed because of laceration of the popliteal vessels.

Fig. 366.—Fracture of the patella, showing wide separation of the fragments (author's case).

Fracture of the patella is a very common accident. The *cause* is direct force (often producing vertical, star-shaped, or oblique lines of fracture, but not uncommonly transverse) or muscular action (producing a transverse line of fracture).

Transverse Fractures of the Patella.—The knee-cap is more often broken by muscular action than is any other bone. When the knee is partly flexed the middle third of the patella rests upon the condyles of the femur and the upper third of the knee-cap projects above them; when in this position a contraction of the quadriceps may easily cause a fracture near the center of the bone (Fig. 364). The accident may be caused by sudden flexion of the knee when the quadriceps is contracting. The most usual cause is a fall or an

[1] See the case reported by Jonathan Hutchinson, Jr., and Howard L. Barnard, "Lancet," May 13, 1899.

attempt of the patient to save himself from a fall backward. Both patellæ may be broken at once. In fracture of the patella the joint, and often the prepatellar bursa, is opened. Fractures by muscular action and many fractures from direct force are transverse. The injury is more common in males than in females, and is extremely rare in the very young and the old. It is usually an injury of active manhood and middle life, but I have seen a woman of eighty-six with fracture of the patella.

Symptoms.—When the accident happens there is often an audible crack. As a rule, the patient will not try to use the limb, although it is possible for him to stand, to walk backward, and to move slowly forward when the extremity is kept straight. After the accident there is rapid and enormous swelling, due to the effusion first of blood and then of synovia and inflamma-

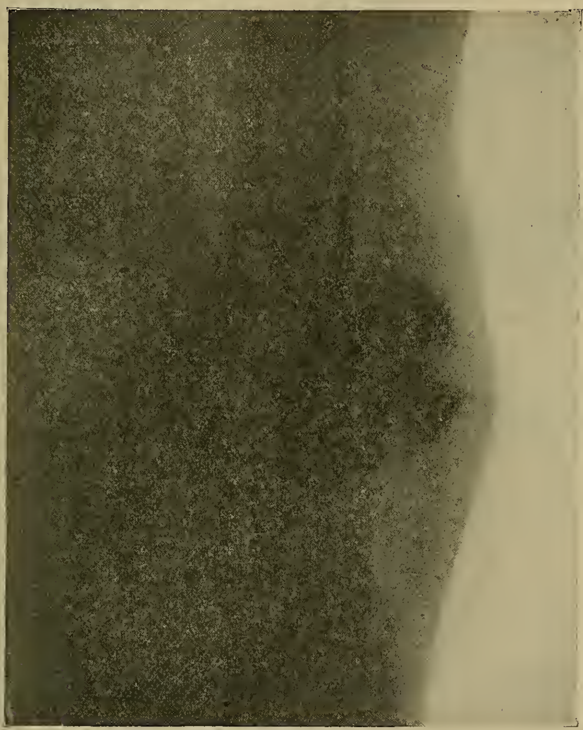

Fig. 367.—Fracture of the patella (Pennsylvania Hospital case; skiagraphed by Dr. Gaston Torrance).

tory products into and around the joint. The patient is absolutely unable to raise the limb from the bed. The fragments are movable and usually widely separated (Fig. 366), this separation being distinctly manifest to the touch unless swelling is great. The separation is accentuated by flexion of the leg. The separation may be to the extent of 1 inch or even more. In cases in which the lateral fibrous expansions and periosteum are but slightly torn, there may be slight separation or no separation. Separation is due in part "to the retraction of the quadriceps and the tension of the fascia lata, and in part to distention of the joint by blood and exudate.[1] If fragments are not approximated and union does not occur, the separation becomes gradually greater because of the progressive shortening of the muscle and the retraction of the

[1] Stimson's "Treatise on Fractures and Dislocations."

ligamentum patellæ (Stimson). In some cases an anterior angular displacement occurs because of the intra-articular distention (Fig. 367). It may be produced by the pressure of bandages or strips of plaster when the fragments have been brought together. Crepitus is detected if the upper fragment can be pushed down until it touches the lower piece; but if swelling is great, or if fibrous tissue is interposed between the bones, crepitus cannot be elicited. It is not necessary to obtain crepitus in order to make the diagnosis: the condition is usually obvious without this sign. The anterior fibroperiosteal layer is torn, and the tear does not correspond exactly with the line of fracture. A portion of this torn fibroperiosteal layer may, as Macewan pointed out, drop between the fragments and prevent union (Fig. 368). The lateral expansions of the capsule are usually extensively torn. If union occurs after a transverse fracture, it will probably be ligamentous, and if the patient gets about too soon, even apparently well-united fragments will by degrees stretch far asunder.

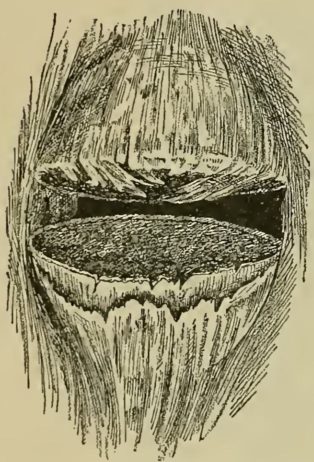

Fig. 368.—Transverse fracture of the patella; fractured surface partially covered by irregular flaps of torn aponeurosis (Hoffa).

Treatment of Transverse Fractures of the Patella.—*The Conservative Plan.*—If the swelling is so great as to prevent approximation of the fragments, reduce it by bandaging for a day or two, by using ice-bags, or by aspirating the joint. As a rule, the blood does not coagulate for several days. After it coagulates it cannot be withdrawn by aspiration, but only by incision. When the swelling diminishes, bring the two fragments into apposition, pull them together by adhesive plaster, and put on a well-padded posterior splint. Carry a piece of adhesive plaster over the upper end of the upper fragment, draw the bone down, and fasten the plaster to the splint behind and below the level of the joint. Carry another piece of plaster over the lower end of the lower fragment, draw the bone up, and fasten the plaster to the splint behind and above the joint. Carry a third piece over the junction of the fragments to prevent tilting. Agnew's splint enables us to satisfactorily accomplish this approximation (Pl. 7, Figs. 11, 12). A bandage holds the splint in place, and may be carried around the knee by figure-of-8 turns. The heel is sometimes raised upon a pillow so as to extend the leg and to semiflex the thigh, but this is not essential. Remove and reapply the dressing every few days, as it inevitably becomes loose. At each removal employ massage. At the end of three weeks remove the splint permanently and apply a plaster-of-Paris dressing from just above the ankle to the middle of the thigh, and get the patient about on crutches. Have the plaster cut so that it may be easily removed and every day employ massage and gentle passive movements, the surgeon fixing the upper end of the upper fragment by his thumb during the movements. The dressing is to be worn for five weeks. After eight weeks of treatment allow the patient to walk about on crutches, the joint being left free at night, but kept fixed during the day by pasteboard splints or by a light plaster-of-Paris bandage. After four weeks more he gets about with canes or a cane. For months after removing the splints and plaster a lacing knee-cap of leather should be worn in the daytime to support the joint. The plan of prolonged immobilization render more or less muscular atrophy and joint-stiffness certainties, but there are less serious impediments

than the wide separation of the fragments that inevitably attends an early use of the joint. Bryant, of New York, has devised an ambulatory dressing.

Operative Treatment.—Malgaigne's hooks are obsolete.

It is said that John Rhea Barton wired an ununited fracture of the patella in 1843. In 1877 Hector Cameron wired an ununited fracture of the patella, and a few months later Lord Lister operated on a fracture of the knee-cap two weeks after the accident. The question of the advisability of suturing a recent fracture has been very much disputed. The ordinary non-operative plans of treatment do not endanger life and generally give a fairly good functional result, although the joint remains insecure on extension, the patient is apt to fall, and a fall may refracture the bone. The operative method will usually succeed, and is capable of obtaining a better functional result and of obtaining it more rapidly. There is some danger of infection, and if infection should occur, the results may be most disastrous. Some cases obviously cannot be treated by the conservative method with any chance of success; cases, for instance, in which a flap of fibroperiosteum intervenes between the fragments, or cases in which from some other cause the bones cannot be approximated. Such cases should, of course, be operated upon. But in the great majority of cases a good result will follow conservative treatment, and conservative treatment should be trusted unless the case is in the hands of a surgeon and in a place where every antiseptic precaution can be taken. We agree with Stimson when he says that operative methods can be used with confidence when surrounded by every protection; he habitually uses them, but he never teaches

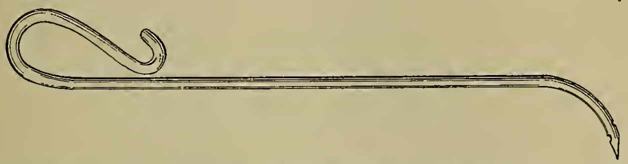

Fig. 369.—Needle specially designed to carry a thick wire. The eye is drilled obliquely, and should receive only a little loop on the end of the wire; this loop should be made previously.

them as proper routine practice, and strongly advises against their use except by those who have had experience in operating, who have formed the habit of taking precautions, and who have the aid of skilled assistants.[1] Operation should only be performed on healthy persons of suitable age, when the separation is over $\frac{1}{2}$ inch or when there is much laceration or interposition of the capsule.[2] If a patient is still able to extend the limb and the lateral expansions of the quadriceps have not been widely torn, a useful limb will be obtained by conservative treatment even if the bone-fragments separate, and operation is not demanded. A working man needs the operation more than a gentleman of leisure because he is in more vital need of a sound knee-joint. A young or middle-aged person is more active than an elderly person, hence, in him operation is more strongly indicated than in an elderly man. Barker believes strongly in wiring recent transverse fractures. He does it with antiseptic care soon after the accident, and permits passive motion or even slight active motion immediately after the operation. Massage is begun the day after the operation, and is practised daily for two weeks.

Barker[3] uses a special needle (Fig. 369) and silver wire of the thickness of a No. 1 English catheter. This wire is straightened and softened in a spirit-flame. He rubs the bone-fragments together in order to dislodge blood or fibrous

[3] See the objections of Sir William Stokes to Barker's method, in "Brit. Med. Jour.," Dec. 3, 1898.

material, and when marked grating occurs, introduces the wire. A puncture with a small knife is made through the middle of the upper attachment of

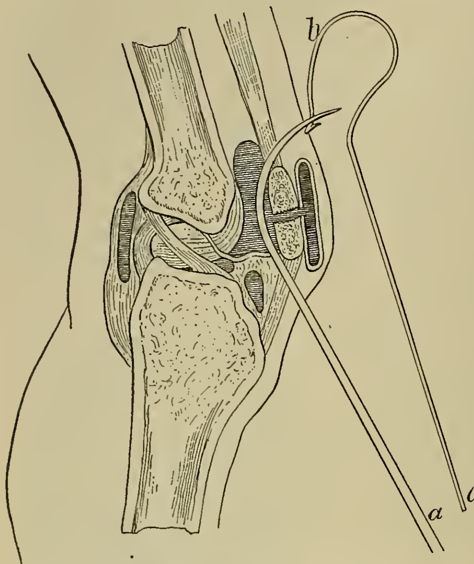

Fig. 370.—Needle (*a*) introduced behind the fragments, and receiving one end (*b*) of the silver wire (*b*, *c*) (Barker).

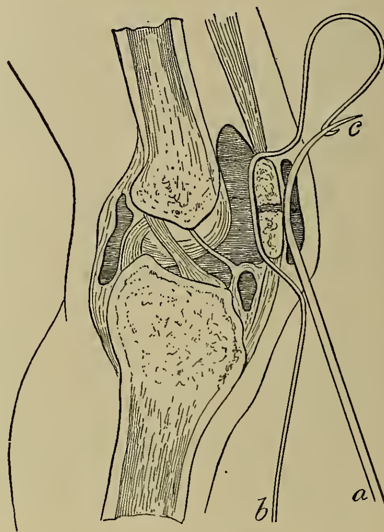

Fig. 371.—Needle (*a*) passed in front of the fragments and receiving the other end (*c*) of the silver wire (*b*, *c*) (Barker).

the patellar ligament. The needle, not carrying any wire, is made to enter through this opening into the joint, is passed back of the fragments, pierces the tendon of the quadriceps at the upper edge of the upper fragment, and its point is cut upon with a knife. The wire is inserted into the eye of the needle and the needle is withdrawn and unthreaded. The empty needle is pushed through the lower opening, is carried in front of the patella, is made to emerge at the upper opening, is threaded with the protruding wire and withdrawn (Figs. 370, 371). The wires are threaded into bars and twisted (Fig. 372), the ends are cut off, and antiseptic dressings are applied. There are objections to Barker's operation: It does not allow us to remove blood-clots from the joint; if a bit of tissue intervenes between the fragments, it cannot be removed; and a foreign body is left permanently in the joint.[1] If an operation is thought advisable, we deem it best to do an open operation, making a semilunar or a central longitudinal incision, freeing the joint from blood-

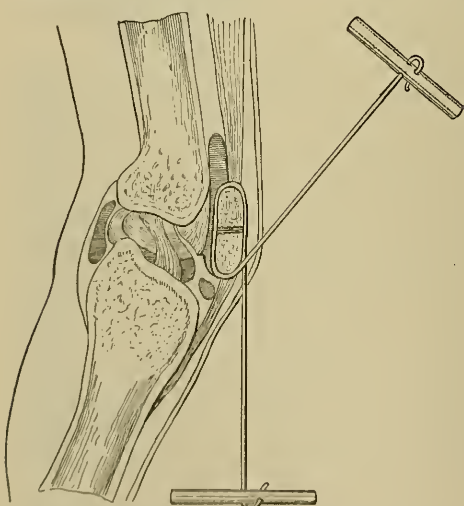

Fig. 372.—Wire in position around fragments and threaded through metal bars. The lower and posterior wire runs upward to the left of the upper, ready for twisting (Barker).

[1] "Brit. Med. Jour.," April 11, 1896.

clots by irrigation with hot salt solution, removing all tissue from between the fragments, drilling the fragments, passing silver wire, twisting the wire and drawing the fragments together, and closing the wound (Fig. 373). Instead of wire, silk may be used. In cases in which there is no very strong tendency to separation the fragments can be held together by several catgut sutures through the periosteum at the fractured edges or by a strong catgut suture passed through the ligamentum patellæ and the quadriceps tendon and carried in front of the fracture (Stimson). The limb should be placed on a posterior splint. In seven or eight days the superficial sutures are removed and a plaster-of-Paris splint is applied. In a few days the patient gets about on crutches.

Fig. 373.—Wired fracture of the patella (St. Joseph's Hospital case; operated upon and skiagraphed by Dr. Nassau).

In a month the dressing is cut down the front and worn only in the daytime, and passive motion is begun. The splint is discarded at the end of the third month.[1] Among other operative procedures we may mention the following: Encircling the fragments by a silk suture (the circumferential suture). This suture may impair bone nutrition and retard union. Ceci drills the bones subcutaneously and passes wire through the drill-holes in the form of a figure of 8. Passing subcutaneously a ligature around and over the fragments (Butcher). Incision and approximation of the fragments by fixation hooks or metal pins.

[1] Stimson, "Annals of Surgery," August, 1898.

Fractures of the patella by direct force are vertical, stellate, oblique, V-shaped, or transverse; are often incomplete and occasionally compound or comminuted (Fig. 374). Ransohoff maintains that fractures from direct force are more common than from muscular action and are usually transverse and associated with some comminution ("Jour. Amer. Med. Assoc.," Oct. 13, 1906).

Compound fracture of the patella is very rarely seen in Philadelphia hospitals. The records of the Boston City Hospital (an institution in which multitudes of fractures are treated) show only 8 compound fractures of this bone in forty-two years (Scannell, in "Boston Med. and Surg. Jour.," Nov. 15, 1906).

Symptoms of Simple Fracture.—Fractures of the patella by direct force are followed by discoloration, swelling, great difficulty in movement, and much pain. There may or may not be crepitus. The degree of separation of the fragments depends upon the direction of the line of fracture and the extent of bone involved. Bony union is apt to occur after such a fracture when there was not wide separation.

Treatment.—A fracture resulting from direct force may often be treated by a posterior splint and the application of a bandage. If there is any separa-

Fig. 374.—Comminuted fracture of patella.

tion, the fragments should be approximated by adhesive strips, bandages, and compresses. At the end of three weeks remove the posterior splint, apply a plaster-of-Paris splint, and get the patient about on crutches. The danger in these cases is ankylosis rather than non-union; hence, in the fourth week cut the plaster splint down the front and begin passive motion of the knee-joint. At the end of six weeks cease wearing the dressing in the daytime, and at the end of three months discard it entirely. In those cases in which an oblique fracture or a transverse fracture with wide separation arises from direct force, treat as advised for transverse fracture from muscular action. The question of operation is practically the same as for transverse fracture from muscular action. In every compound fracture of the patella, if amputation can be avoided, incise the soft parts freely and irrigate the joint with hot saline fluid. Remove hopelessly loosened fragments. Those not completely separated may in some cases be sutured into place. Drain for twenty-four or forty-eight hours.

Ununited and Badly United Fracture of the Patella.—There is usually a band of union, but it may be very thin and the fragments may be far asunder. It is commonly taught that the degree of functional impairment depends

directly on the amount of separation. This is not strictly true. There may be great separation and but little impairment of function, the fragments being firmly united by a dense fibrous band. There may be little separation and yet lameness, stiffness of the joint, and imperfect power of extension. The reason for this has been pointed out by Bruns, of Tübingen.[1] He says there may be complete failure of union, even when the separation is trivial, and failure of union produces impaired function. If separation is considerable, the fragments are apt to tilt and tissue is often interposed between them. Functional difficulty is more often met with when the fragments are far apart than when they are near together, because non-union is more common. Even if non-union occurs, in some cases the quadriceps is still able to act upon the tibia by means of the fascia lata, ligaments at the sides of the joint, or bands from the vasti to the lower fragment. Besides non-union, functional impairment may be due to anchoring of the upper fragment to the femur. The upper fragment may be anchored to the femur by the interposition of the fibrous investment of the knee-cap, which covers the fractured surface of the upper fragment and may grow fast to the capsule of the joint (Bruns).

The *treatment* of ununited and badly united fracture is discussed on page 534.

Fractures of the Leg.—In leg-fractures both bones or only one bone may be broken.

Fractures of the tibia are divided into: (1) fractures of the upper end; (2) separation of the upper epiphysis; (3) fractures of the shaft; (4) fractures of the lower end, and (5) separation of the lower epiphysis.

Fractures of the upper end of the tibia are uncommon. They may be transverse, oblique, or vertical, running into the joint. The *cause* is direct violence.

Symptoms.—In fracture of the upper end of the tibia there is contusion of the soft parts. In a *transverse* fracture there are mobility and crepitus, but there is little displacement. In *oblique* fracture crepitus and mobility are marked, the axis of the limb is altered, and the fragments may be displaced. In fractures entering the joint there is great swelling of the knee-joint. *Comminuted* fractures exhibit marked signs, union is readily obtained, but if the joint has been damaged, stiffness is sure to ensue.

Treatment.—Reduce displacement by extension and manipulation. The special apparatus used for treatment depends on the case. In some cases extension is required, in some a posterior splint is applied and the limb is suspended from a gallows, in some a double inclined plane is employed, and in some a plaster-of-Paris splint is used.

The double inclined plane in the form of McIntyre's splint is frequently employed, or a double inclined plane in the form of a fracture-box may be preferred. The extremity should be immobilized for four weeks, when passive motion should be begun. Passive motion is to be made daily, the dressing being reapplied after each séance. In five or six weeks the dressings are removed and the patient allowed to go about on crutches. The crutches are soon abandoned for a cane, and later all support is dispensed with. If a fracture extends into the knee-joint and the ill-adjusted fragments block the articulation, the joint should be opened and the fragments placed and fixed in proper position.

Separation of the tubercle of the tibia is due to violent contraction of the quadriceps, and occurs only in those under twenty years of age. The fragment is drawn up and can be felt, and the patient is unable to use the limb. In a case in which the tibial spine has been torn off, it may be nailed in place,

[1] "Beiträge zur klinischen Chirurgie," "Mittheilungen aus der chirurg. Klinik zu Tübingen," Bd. iii, Heft 2, 1888.

or the limb should be placed on a posterior straight splint and the fragment should be pulled down into place by adhesive strips and bandages. The splint should be worn for five weeks.

Avulsion of the Spine of the Tibia.—This is a very rare accident. There are but 4 cases on record, and in only 1 of them (Pringle's) was the diagnosis made during life, and it was made in that case by exploratory incision. The tibial spine is torn off by the anterior crucial ligament. The causative force is probably flexion, abduction, and internal rotation of the leg (J. Hogarth Pringle, "Annals of Surg.," August, 1907). After the acccident the leg at the knee is in extreme abduction. Exploratory incision may be necessary for diagnosis. The treatment is to suture or nail the bone-fragment in place.

Separation of the Upper Epiphysis of the Tibia.—This is an injury of extreme rarity. It does not seem to occur after the sixteenth year. It is caused by a twist or by violent abduction or adduction of the leg. It may lead to lessened growth of the limb. The *treatment* is as for a fracture of the upper end of the bone.

Fractures of the Shaft of the Tibia.—The *causes* of these fractures are direct force, indirect force, or torsion. A fracture in the upper part of the bone is usually transverse; in the lower part it is usually oblique (T. Pickering Pick).

Symptoms.—In transverse fracture of the shaft of the tibia there is no deformity, and the support of the fibula may even permit of walking; there is fixed pain; there may or may not be inequality of the fragments felt by the finger; and there are pain, tenderness, crepitus, mobility, and often linear ecchymosis. In oblique fractures there usually exist crepitus, a little mobility, and distinct deformity. The deformity depends on the direction of the line of fracture, and, as this line is usually from above downward, inward, and a little forward, the lower fragment usually passes behind the upper fragment and rotates inward.

Treatment.—In treating fractures of the shaft of the tibia effect reduction by making extension from the foot and counterextension from the knee, the knee-joint being in partial flexion. If there is much swelling, put the limb in a fracture-box (Figs. 375, 376, and Pl. 7, Fig. 1), swing the box from a gallows, and apply an ice-bag for twenty-four hours. A silicate of sodium or a plaster-of-Paris dressing is applied when the swelling subsides, or the dressing may be used at once instead of a fracture-box if swelling is slight. As soon as the limb is immobilized in a silicate or plaster dressing the patient gets about on crutches. The dressing is removed after five weeks, and the patient goes about for one week on crutches, lightly using the foot, and then for a time walks with the aid of a cane. At the end of eight or nine weeks the cane may often be dispensed with, the amount of use of the leg being daily augmented.

Fractures of the Lower End of the Tibia: Fracture of the Inner Malleolus.—The *cause* of fracture of the inner malleolus is direct force or traction upon the internal lateral ligament.

Symptoms and Treatment.—The *symptoms* of fracture of the inner malleolus are pain, tenderness, some downward displacement, depression above the ends of the fragments, mobility, and crepitus. The *treatment* is to push the fragments into place and use side-splints or a fracture-box for two weeks, when a plaster-of-Paris or a silicate dressing may be substituted and the patient ordered to use crutches. Remove the plaster four or five weeks after it is applied, and direct the patient to gradually bear his weight upon the leg, as outlined above.

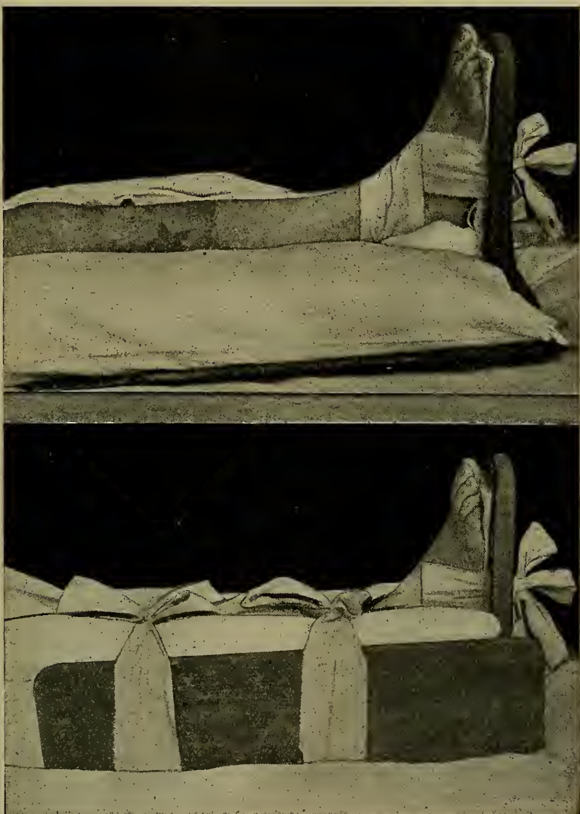
Separation of the lower epiphysis of the tibia is a rare accident, but is commoner than separation of the upper epiphysis. The *treatment* is a fixed dressing for six weeks.

Fracture of the fibula alone is commoner by far than is fracture of the tibia alone. Fractures in the upper two-thirds, which are rare, are usually

due to direct force. Fractures in the lower third are frequent, and arise from indirect force.

Fractures of the Upper Two-thirds of the Fibula.—In these fractures the *cause* is direct force.

Symptoms.—In fracture of the upper two-thirds of the fibula the patient is frequently able to walk. The bone is deeply situated, and displacement cannot often be detected. There is a fixed pain, which is intensified by movement and by pressure. Pressure upon the lower fragment does not move the upper fragment. Crepitus is sometimes obtained, and linear ecchymosis is



Figs. 375, 376.—Fracture-box in fractures of the bones of the leg.

apt to appear. The bone is normally elastic, hence slight mobility is of no value diagnostically.

Treatment.—In treating a fracture of the upper two-thirds of the fibula apply a plaster-of-Paris or a silicate bandage and direct that it be worn for five weeks. Weight is not to be put upon the foot for six weeks after the accident.

Fractures of the Lower Third of the Fibula.—In these fractures the *cause* is usually indirect force, especially twists of the foot. Forcible inversion of the foot pulls upon the external lateral ligament and the external malleolus, forces the fibula outward, and tends to break it, the lower fragment being displaced outward. Forcible eversion pulls the internal lateral ligament off from the inner malleolus (often breaks the malleolus) and fractures the fibula above the ankle, the bone being displaced inward.

Pott's Fracture.—By the term "Pott's fracture" is meant a fracture of the lower fifth of the fibula produced by eversion and abduction of the foot. Stimson points out that the production of Pott's fracture is often aided by the weight of the body. The lesions which arise depend upon whether the chief force is eversion or abduction. "If eversion is the sole, or main, movement, the force is exerted through the internal lateral ligament and breaks the internal malleolus squarely off at its base; then it presses the external malleolus outward, rupturing the tibiofibular ligament, and breaks the fibula close above the malleolus. Sometimes instead of pure rupture of the tibiofibular ligament there is avulsion of the portion of the tibia to which it is attached."[1] Stimson further points out that if abduction is the preponderating force there is an oblique fracture of the anterior portion of the internal malleolus or more frequently rupture of the anterior portion of the internal lateral ligament. There are, as in the former case, rupture of the tibiofibular ligament and an oblique fracture of the fibula several inches above the external malleolus. It is evident that the degree of injury produced by eversion and abduction depends on the point at which the force is arrested. It may be arrested after the inner malleolus has been separated or the anterior fibers of the deltoid ligament torn, and in this case the tibiofibular articulation remains intact and the fibula is not broken. It may cease after separating the tibiofibular articulation, and in this case too the fibula escapes. It may be continued until the fibula breaks. In this fracture the astragalus passes outward, somewhat backward and also upward, the later deviation being due to separation of the tibiofibular articulation. The chief trouble in reduction and treatment is this outward and backward dislocation of the foot.

Fig. 377.—Pott's fracture. Dupuytren's splint. Note length of splint; position of straps; arrangement of padding; space between foot and splint (Scudder).

Fig. 378.—Pott's fracture.

Symptoms.—The foot is displaced outward, and a little backward and upward, and the inner malleolus or the tibia from which it was torn is ex-

[1] "A Practical Treatise on Fractures and Dislocations," by Lewis A. Stimson.

tremely prominent. There is great lateral mobility and often anteroposterior mobility at the ankle-joint. Stimson points out that there are three points where pressure is certain to provoke pain: in front of the tibiofibular ligament, at the base or anterior border of the inner malleolus, and over the seat of fracture through the fibula.

Treatment.—Thorough reduction is of the greatest importance. If thorough reduction is effected, a good result will probably be obtained; but if thorough reduction is not effected, the patient will be permanently crippled to a greater or less extent. In order to effect reduction it may be necessary to anesthetize the patient. The patient's knee is flexed, the heel is pulled strongly forward and inward, and the lower end of the tibia is pushed backward. This corrects the ankle dislocation, and then the valgus must be overcorrected (Jones). Inversion of the ankle is imperative.

Some surgeons at once after reduction apply a plaster-of-Paris bandage. This treatment is objectionable because the deformity may be partially reproduced after the application of the dressing, the surgeon being unable to see it and unable to correct it.

If there seems to be no strong tendency to a recurrence of deformity, a fracture-box can be used. After reducing displacement in such a case, place the limb in a fracture-box containing a soft pillow. A bird's-nest pad of cotton or oakum is made for the heel (see Figs. 375, 376). A fillet around the ankle fastens the foot to the foot-piece of the box; a pad of oakum rests between the foot-piece and the sole. A compress is placed below the outer malleolus and another one above the inner malleolus. Close the sides of the box and tie them together with a bandage, and swing the box on a gallows. Every day let down the sides of the box and rub the leg, the ankle, and the foot with alcohol. In ten days apply a plaster-of-Paris bandage and let the patient get about on crutches. Remove plaster at the end of the fifth week after the accident, and let patient go about with crutches for one week and with a cane for a week longer.

I am accustomed to dress most cases of Pott's fracture with a *Dupuytren splint.* This is a straight splint (Fig. 377 and Pl. 7, Fig. 9) which reaches from above the head of the tibia to below the sole of the foot. This splint is padded, and a pyramidal pad with the base down is laid upon the inner surface of the leg, above the inner malleolus, the splint being put upon the inner surface of the leg, over the pad. The splint is fastened as shown in Plate 7, Fig. 9, and Fig. 377. If the short splint shown in Plate 7 is used (it only goes to the head of the tibia), the leg is semiflexed upon the thigh and is laid upon the outer surface on a pillow. After ten days of Dupuytren's splint, apply the plaster-of-Paris bandage, which is to be worn as above directed. Bryant treats Pott's fracture with a posterior splint, two lateral splints, and a swing. Stimson uses a posterior and lateral splint of plaster of Paris. This splint does not slip, as may Dupuytren's dressing, and does not hide the seat of fracture from view, as does complete encasement with plaster of Paris. It is a most useful dressing. When the patient begins to walk the callus may bend. If it does, eversion will be produced. In order to prevent this make the patient walk for a number of weeks upon a shoe heel raised on the inside in order to induce the position of varus. A very heavy man should also wear for several weeks an iron brace on the outside. I have given above the conservative treatment of Pott's fracture. I have come to the conclusion that operation should be the rule in this injury and not the exception. The fracture is so often followed by pain, swelling, and disability. Pain and disability are so largely due to malunion or fibrous union of the broken malleolus, and it is so easy to fix the fragment in place by nails or sutures, that the conclusion seems obvious that in proper subjects operation should be performed. As Heath and Selby show, in an important article ("Annals of Surg.," Jan.,

1908), operation also allows us to return the tibialis posticus to its normal position and thus flat-foot is prevented. The plan suggested by Heath and Selby ("Annals of Surgery," Jan., 1908) is excellent. The fragment may be sutured in place by silver wire or chromic gut. If the tendon of the posterior tibial is displaced, the torn annular ligament is sutured so as to hold the tendon in place, a drain of rubber tissue is carried down to the bone, and the soft parts are sutured. The parts are dressed and a fixation apparatus is applied. The drain is removed in twenty-four hours. In eight weeks the patient should be walking freely (see cases reported by Heath and Selby, Ibid.). Pott's fracture may be *compound*, a portion of the inner malleolus or of the tibia projecting through the wound. If it is necessary to introduce through-and-through drainage, the foot must be placed and kept at a right angle to the leg. If a compound fracture exists, the malleolus must be nailed in place or sutured by silver wire or chromic gut. In a reported case the wire was passed through the joint and around the fragment, and the result was good.[1] Nailing seems a better plan.

Fig. 379.—Fracture of both bones of leg. Bad position.

Fracture of both bones of the leg is a very common injury, is often compound, and is not unusually comminuted. Fractures by direct force, such as blows or kicks, are commonest in the upper half of the leg. Fractures by indirect force, as by falls, are commonest in the lower half of the leg. In fractures from indirect force the tibia breaks first, and then the fibula breaks at a higher level. The point of greatest liability to fracture from indirect force is the junction of the lower and middle thirds. Fractures of the leg are usually oblique, but they may be transverse if arising from direct force. Spiral, torsion, or V-shaped fractures and longitudinal breaks sometimes occur. In oblique fractures, as a rule, the line of fracture runs from behind, downward, inward, and a little forward.

Symptoms.—Fracture of both bones of the leg is easy of recognition. The fibular fracture is detected as before described. By running the finger along the crest of the tibia displacement will be found, except in transverse fractures, when it may not occur. The common displacement is for the lower fragment to ascend and pass behind the lower end of the upper fragment and to rotate a little outward, and for the upper fragment to project in front. The ascent of the lower fragment is due to the action of the gastrocnemius and soleus muscles. If the line of fracture is in a direction the reverse of that which is usual, the lower fragment ascends in front of the lower end of the upper fragment. In fracture of both bones of the leg there are marked mobility and crepitus, severe pain, and inability to walk. In fractures from direct force there is more or less damage to the soft parts. A fracture of the shaft of the tibia near the ankle is distinguished from a

[1] "Rev. de Chir.," vol. viii, 1888.

dislocation by the fact that the deformity is easily reduced, but tends to recur in the fracture, and, further, that in a fracture the relations of the malleoli to the tarsus are unaltered, whereas in a dislocation they are altered.

Treatment.—If the fracture is near the ankle-joint, the action of the tendo Achillis may maintain deformity, and in such cases the tendon should be divided. All fractures of the lower third are difficult to reduce and often require extension by the pulley. In very few will perfect apposition of the fragments be brought about, and the best we can usually attain is good alignment (Jones). In treating a simple fracture of the lower two-thirds of the bones reduce by extension and counterextension, and use a fracture-box (see Figs. 375, 376). The compresses used in Pott's fracture are not required. If the soft parts are bruised, use evaporating lotions for a day; if they are abraded, apply antiseptic dressings. The fracture-box should be swung upon a gallows. After three weeks apply a plaster-or-Paris or silicate of sodium dressing and let the patient sit up in a chair daily during one week; at the end of this time the patient may get about on crutches. At the end of six weeks after the accident remove the plaster, and let the sufferer go about on crutches for two weeks and with a cane for two weeks more. Brinton was accustomed to dress a fracture of both bones of the leg for two weeks in a fracture-box, for two weeks in side-splints made of metal, and for two weeks in an immovable dressing, allowing the patient to get about on crutches as soon as the plaster is put on. Instead of the fracture-box we may use a posterior splint, two lateral splints, and a swing. The Thomas bed-splint is a very useful dressing. Nathan R. Smith's anterior splint is used by some in the treatment of fractures of the leg. Some surgeons apply plaster of Paris in the form of an ambulatory dressing. In this dressing a solid apparatus reaches to the lower third of the thigh and below the sole of the foot. When the patient walks the weight is transmitted to the thigh (see Figs. 274 and 275). In fractures of the upper third of the leg the McIntyre splint or the double inclined plane is used. If the fracture is *compound*, asepticize thoroughly, make a counteropening, insert a drainage-tube, dress with bichlorid gauze, apply a plaster bandage, and cut trap-doors over the openings of the tube (see Fig. 279), or dress with the bracketed splint and plaster of Paris (see Fig. 280). Remove the tube, as a rule, in about forty-eight hours; but the patient's temperature is the guide, not time of retention.

In many fractures of the lower third operation is indicated to accomplish reduction and fixation.

Fractures of the bones of the foot are rather rare accidents, although not so unusual as we once thought, for the *x*-ray has taught us that a considerable number of supposed sprains are, in reality, fractures. Owing to the number of the bones and to the elasticity of their connections the force of blows and falls is spread and dissipated. The bones most often broken are the astragalus and the os calcis. Fractures from direct force are often compound. The *cause* of fracture of either the scaphoid, the cuboid, or one of the cuneiform bones is direct force. Simple fractures of the os calcis and astragalus may arise from crushes or twists of the foot, but result, as a rule, from indirect force, such as falls. The calcaneum may be broken by a direct blow. In rare instances the os calcis has been broken by contraction of the great calf-muscles. Forcible dorsal flexion of the foot may fracture the neck of the astragalus (Eisendrath). Compound fractures may result from gunshot-wounds, crushes, and falls.

Symptoms.—The history of the nature of the accident is of great importance. In fracture of the os calcis there are severe pain, tenderness, swelling, crepitus, mobility, often an apparent widening of the bone, and not unusually a loss of the arch of the foot (Pick). In some cases the posterior fragment is drawn up by the calf-muscles, and in other cases there is no deformity. In fracture

of the astragalus displacement may occur which resembles that of a dislocation. Crepitus may or may not be detected. It can be elicited, as a rule, by rotating the foot while the heel is firmly held. If crepitus cannot be detected we are not certain that a fracture is present, even though the patient may be unable to stand and there are swelling and pain on pressure. The malleoli may seem on a lower level than normal if the astragalus and os calcis have been crushed. Sometimes the foot is shortened and perhaps the fragments have been dislocated (Eisendrath, in "Annals of Surg.," March, 1905). The x-rays will make the diagnosis certain. Fractures of the other bones of the tarsus are difficult of detection except by the x-rays. There may or may not be crepitus, which, if it exists, is difficult to localize; there is pain on standing and on pressure, and there is bruising of the soft parts.

Treatment.—In simple fracture of the os calcis and astragalus without displacement place the foot at a right angle to the leg and apply a plaster cast. This is cut down the front so that it may be removed easily. On the third or fourth day follow Eisendrath's advice and begin massage to reduce swelling and prevent muscular atrophy (Ibid.). The cast is worn for eight weeks, when the patient may begin to put weight upon the extremity. If a flat-foot has resulted from the accident, a support must be worn (see page 742). If there is displacement in a simple fracture of the os calcis or astragalus it is wisest to operate. Perfect correction is not possible otherwise and no apparatus is satisfactory. The fragments are restored after incision and may be nailed or wired in place. A fragment may require removal or the badly splintered bone itself may have to come away. If the tendo Achillis is torn loose, it should be sutured to the os calcis. Fractures of the other bones of the tarsus are almost always compound, and the injury may require drainage and immovable dressing, excision of bones, or even amputation. If they are not compound, they may be treated by a plaster-of-Paris dressing or may require incision and fixation or removal.

Fig. 380.—Fracture of metatarsal bones.

Fractures of the metatarsal bones are almost invariably due to direct force and are almost always compound. Robert Jones has published skiagraphs of a fracture of the fifth metacarpal bone from indirect force. Crepitus may be absent because of impaction or fixation by interosseous ligaments. Jones says such a fracture may be produced by the pressure of the body weight on an inverted foot the heel of which is raised ("Annals of Surgery," June, 1902). When only one bone is broken, displacement is slight, there is severe pain on motion and pressure, and crepitus can generally be obtained. Pain is produced by flexing the toes, putting weight upon the toes, as in walking, and by inverting or everting the foot. Fracture of the third metatarsal is apt to destroy the arch of the foot. A simple fracture of a metatarsal bone is treated by an immovable dressing for four weeks. Fractures from crushes usually demand excision or amputation.

Fractures of the phalanges of the toes are due to direct force and are often compound. They may require immediate amputation.

Treatment.—In a compound fracture where amputation is unnecessary, drain with strands of catgut for forty-eight hours and dress antiseptically, at the end of this time apply over the bichlorid gauze a gutta-percha or a pasteboard splint extending from beyond the end of the toe to well up upon the sole of the foot, and fix the splint in place with a spiral bandage of the

toe and instep. The splint is to be worn for four weeks. In a simple fracture fasten the injured toe to an adjacent toe or toes by a plaster bandage and wear the dressing for three weeks.

Diseases of the Joints

Synovitis is a primary inflammation of the synovial membrane alone. If other structures besides the synovial membrane are involved the condition is known as "arthritis." Two forms of simple synovitis exist—namely, *acute* and *chronic*. Some surgeons speak also of *subacute* cases.

Acute Simple Synovitis.—The *causes* of acute simple synovitis are contusions, sprains, twists, and overuse. The causative influence of exposure to cold or damp has been much debated. It seems probable that in some cases cold produces vasomotor paresis of the vessels of the synovial membrane, a condition which may be followed by inflammation. In synovitis the synovial membrane is red and swollen, and the joint contains an excess of turbid fibrinous fluid. If the inflammation advances, arthritis arises and sometimes blood is effused.

Symptoms.—A prominent symptom of acute synovitis is pain, which is increased by motion of the joint, by pressure upon the articulation, and by a dependent position of the limb. The pain is worse at night. Pressure upon the edge of the cartilage does not cause pain, but friction of the synovial membrane at once develops it. The patient places the limb in the position which gives the greatest ease, and the part becomes more or less fixed in this position because the muscles about the joint are rigid. A fluctuating swelling is noted in a superficial joint, most marked between the ligaments, which swelling bulges out the synovial area and hides or obscures the articular heads of the bones. The swelling is due early to excessive secretion of synovia, and later to effusion of liquor sanguinis. Bulging takes place at points where the capsule is thin, and at such points fluctuation may be detected. Fluctuation in the elbow is sought for posteriorly. Fluctuation in the knee is sought for on either side in front. A large effusion in the knee floats the patella up from the condyles (*floating patella*). A small effusion in the knee can be detected by Fiske's plan, which is as follows: Tell the standing patient to bend forward at the hips, resting each hand on the front of the corresponding thigh. The anterior structures of the joint are thus relaxed, and, by tapping the patella, even a small effusion can be discovered. Bulging cannot be distinctly recognized in the hip or shoulder unless effusion is great. The skin over the joint is rarely reddened, but feels hot to the hand of the observer (over superficial joints, but not over the shoulder and hip); the joint is partly flexed; fever exists, varying in degree with the size of the joint, the acuteness of the attack, and if infection occurs fever is a striking feature. Suppuration rarely follows simple synovitis, but it may do so, the area of synovitis being a point of least resistance to organisms carried by the blood or lymph. If suppuration takes place, rigors occur, there is a septic temperature, and the joint soon gives evidences of containing pus. These evidences are violent pain, increased tenderness, dusky discoloration if the joint be superficial, greater muscular spasm, periarticular edema, and constitutional symptoms of sepsis. Traumatic synovitis without infection tends toward cure without suppuration if the patient is healthy, and after it ankylosis is rare.

Treatment.—In treating acute synovitis immobilize the joint. In severe cases place it in such a position that the limb will still be useful even if ankylosis occurs. In mild cases immobilize in the position of rest, apply leeches, and use the ice-bag or the Leiter coil. After a day or two apply gentle pressure, intermittent heat, and iodin and ichthyol. If the effusion is very great and persistent, and pressure, heat, and sorbefacients fail to remove it, aspirate with

aseptic care. If effusion recurs after aspiration, use massage and the hot-air oven, or apply plaster-of-Paris dressing or use flying blisters. If there is any evidence of infection, follow Murphy's advice, that is, aspirate the joint and inject a mixture of formalin in glycerin (2 per cent.). As a rule this treatment will rapidly bring about a cure. The mixture of formalin and glycerin should have been made at least twenty-four hours before use. A rubber bandage is often useful toward the termination of a case of acute synovitis.

Chronic synovitis follows acute synovitis or it may be chronic from the start. Many cases called chronic synovitis are, in truth, tuberculous disease. The synovial membrane looks nearly natural, but is edematous, and the joint contains an excess of fluid. If the quantity of fluid is large, the disease is called *hydrops articuli*, or *dropsy*. A large amount of fluid in the knee-joint "floats" the patella upward. Tuberculous infection may occur in very prolonged cases. In prolonged tuberculous synovitis the synovial membrane may thicken in some places, soften in others; it is often adherent, and the villous processes hypertrophy. If the membrane becomes extensively softened (*pulpy degeneration*), the softened areas bulge and caseation eventually occurs. In the knee-joint a traumatic synovitis is sometimes linked with *inflammation of the semilunar cartilages*. Roux tells us that this inflammation may be produced by a squeeze, a twist, or a direct force, but a squeeze is the common cause. Hyperextension of the knee may squeeze the cartilage, and so may attempting to rise from a stooping posture.[1] If this injury has taken place, the disability will be prolonged.

Symptoms.—In chronic synovitis pain may be absent or may be present only during exercise or from pressure, and be slight even then. There may be seizures of pain; there is some limitation of movement; passive motion may develop creaking or joint-crepitus; fluctuation is apparent and there is atrophy in the muscle about the joint. The atrophy of the muscles associated with an inflamed joint is a reflex atrophy and is named after Charcot. The aspirating needle will give exit to a viscid straw-colored or bloody fluid unless the material is gelatinous.

Treatment.—Rest and pressure are of great service. Pressure may be obtained by the application of Martin's rubber bandage. A plaster-of-Paris dressing is probably the best way to combine rest and compression. Massage, douches, frictions, passive movements, and flying blisters should be used. Painting the joint with iodin and spreading over it blue ointment, and rubbing in ointment of ichthyol (50 per cent. with lanolin) may do good. Counter-irritation by the actual cautery is a valuable expedient. The Bier treatment (see page 112) is often of benefit. Injections of dilute carbolic acid in the parts about the joint rapidly relieve the pain (see page 640). Some surgeons advise aspiration, washing out with salt solution, injecting a 5 per cent. solution of carbolic acid or formalin-glycerin (2 per cent.), and immobilizing. Incision and drainage constitute a radical but proper plan in cases unamended by simpler methods. If pulpy degeneration exists, perform an excision or an erasion. If pus forms, incise at once and drain. Internally, treat any existing diathesis and give nutritious food, tonics, and stimulants. Chronic synovitis is often greatly benefited by the use of a hot-air apparatus. The limb is wrapped in flannel and is placed in an oven. The oven is heated by Bunsen burners. The temperature is raised to 250° or even 300° F., and the limb is subjected to this for one hour. The oven should be used daily, and as the patient becomes accustomed to it even a higher degree of heat can be tolerated. This high degree of heat can be borne only when it is perfectly dry. Any moisture scalds the patient. The Lentz oven has in it ventilation openings to get rid of moisture and the sweat is taken up by the flannel. The

[1] "Gaz. des Hôp.," No. 125, 1895.

flannel must not be applied so thickly as to keep the heat notably from the joint, nor must so little of it be used as to permit of its soaking with sweat. Fig. 381 shows the Sprague hot dry-air apparatus. Dr. H. A. Wilson inserts in the oven humidin, a product obtained in the purification of salt, which material absorbs the moisture entirely. Cotton should not be used to wrap the limb, because, if the bottom of the oven becomes very hot, the cotton may ignite and burn the patient. A physician or nurse should constantly watch the apparatus during its employment.[1] Bier's box is of wood lined with asbestos. It is heated through a flue by gas or alcohol lamps. Aspiration and the subsequent use of a plaster-of-Paris bandage may be tried in lingering cases of chronic synovitis.

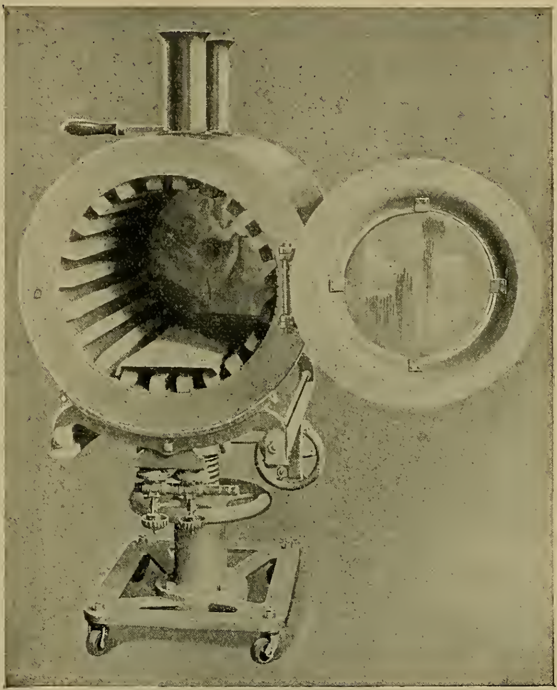


Fig. 381.—Sprague hot dry-air apparatus.

Arthritis.—By this term is meant not only inflammation of a synovial membrane, but also of other structures composing and surrounding a joint. It may follow traumatic synovitis; it may be due to pus-organisms, to tubercle bacilli, to infectious diseases (gonorrhea and typhoid fever), to rheumatism, to gout, to syphilis, and to lesions of the spinal cord. Arthritis may be either acute or chronic.

Poncet's Tuberculous Arthritis (*Tuberculous Articular Rheumatism*, see page 250).—It was pointed out by Grocco in the early 80's that tuberculous patients may develop joint disease without tubercles, cold abscesses, or destruction of the joint. Poncet, of Lyons, has written extensively on this subject. He maintains that joint inflammation is often the first evidence of extra-articular tuberculosis or of a distant latent lesion of tuberculosis. The joint inflammation is due to toxins, the joint fluid does not contain bacilli, and tubercles do not develop in the joint structures.

Such a joint may eventually develop into a true tuberculous joint with bacilli and tubercles. In many cases the joint recovers, with some stiffness or perhaps even ankylosis. The process may be acute, subacute, or chronic. One joint only may suffer. Several or most of the joints may be simultaneously involved. It is most apt to arise after an operation on tuberculous glands or bone. Fever exists in Poncet's arthritis. Matas ("Southern Med. Jour.," Oct., 1911) thus describes tuberculous rheumatism:

"It may be a flitting arthralgia, a mere soreness, a dropsical synovitis, or it may persist as a hypertrophic or atrophic arthritis. It may present itself as a progressive polyarthritis deformans or as a dry senile arthritis (morbus coxarius senilis). The acute, as well as the chronic, form of this type of rheu-

[1] H. A. Wilson, in "Annals of Surgery," Feb., 1899.

matism may end in ankylosis. Many cases of spinal rigidity, spondylosis, scoliosis, painful flat-foot, genu valgum, coxa vara, and even certain cases of dry otitis media with ankylosis of the ossicles of the ear, and, in fact, all the osteo-articular affections of childhood and adolescence associated with defective osteogenesis, may owe their origin to the disturbing influence of a latent or obscure tuberculous toxemia.

"The most benign of the tuberculous rheumatic affections is a simple arthralgia—a sore or painful joint. There is pain without any objective signs, and yet this is often the precursor of a manifest visceral tuberculosis. The acute and subacute forms of the disease are usually confused at the bedside with the manifestation of ordinary acute rheumatism. Nevertheless, the clinical picture of acute tuberculous rheumatism is distinctly graver; there are fever, rapid pulse, profuse sweats, and frequent attacks of dyspnea. This is brought about by associate general infections involving the serous cavities, the pleura, peritoneum, pericardium, and the meninges. But in the majority the evolution of the disease is slow and more benign. The joint symptoms appear in successive stages separated by intervals of rest more or less long, and are distributed over various joints, ending ultimately in ankylosis. The disease is more often chronic, and many patients either recover altogether or remain permanently crippled or deformed; others die of marasmus or complications from associate visceral disease. Therapeutically, this form of rheumatism is not relieved by any of the usual antirheumatic remedies, and is improved or cured solely by treatment which aims at the cure of the tuberculous infection."

Fig. 382.—Tuberculous arthritis of wrist.

Tuberculous Arthritis (*White Swelling*, so christened by Richard Wiseman; *Strumous Joint; Pulpy Degeneration*).—*Pathology and Symptoms.*—The predisposing causes of tuberculous arthritis may be strains, blows, twists, or cold (see page 223). The real cause is the tubercle bacillus. A single joint is attacked. Other joints may subsequently become involved so that several suffer simultaneously, but it is rare that the process is active in more than one joint at the same time. During the course of tuberculous disease of a joint (except of the shoulder-joint) phthisis is not common, although it may develop after the joint gets well. The same is true of tuberculous glands. During the existence of phthisis or tuberculous glands tuberculous arthritis does not frequently arise.

The primary infection with tubercle bacilli is usually in the bone, though it may be in the synovial membrane, the joint-capsule, or the structures about the joint. The frequency of the bony origin of tuberculous arthritis is shown by John B. Murphy's statement that in 128 cases of tuberculosis of the knee it was demonstrated in all but 2 that the condition originated in the bone ("Jour. Am. Med. Assoc.," May 20–27, June 3, 1905). If the primary infective focus is in the bone, a portion of the cartilage undergoes destruction and the joint is opened, or a sinus forms and perforates the synovial membrane. When tuberculous inflammation attacks the synovial membrane granulation tissue is formed, and the capsule and periarticular structures soon become involved in the process; the parts thicken and soften from caseation, and they may be covered with tubercles, though but little fluid is usually effused into the joint. Some few cases present large joint effusions, but in most cases fluctuation is absent. Capsular thickening may or may not be manifest. Soon after tuberculous arthritis begins the joint becomes rigid, irritation having induced muscular spasm. This reflex rigidity fixes the joint more or less completely, and atrophy of the rigid muscles soon begins. There is usually some pain in tuberculous arthritis; it is seldom marked except on motion or when the epiphysis is involved, and it may be referred to a distant part. For instance, in hip-joint disease the pain is often referred to the inner side of the knee, and in Pott's disease of the spine the pain may be referred to the abdomen. A cardinal sympton of tuberculous disease of a joint is localized tenderness. In other types of infection the tenderness is widespread. Attempts at motion demonstrate the limitation of movement due to muscular rigidity and also produce pain. A child that suffers from a tuberculous joint is apt to be restless in sleep, moaning and tossing, and to wake at times crying out in terror (*night-cries* and *night-terrors*). In the ordinary form of tuberculous arthritis there occurs what is known as *gelatiniform degeneration;* the granulation tissue is formed in large amount as fungous growths; the structures are markedly edematous and softened; the relaxed ligaments yield under pressure; the natural contour of the joint is lost and it becomes spindle shaped; all the structures, articular and periarticular, are glued into one mass; the skin about the joint is white, thick, and adherent, and in it one or more large veins are seen; fluctuation or pseudofluctuation is noted when caseation has occurred; pain is not often severe, but it can usually be elicited by certain motions or by firm pressure, but the pain will always be severe when the epiphysis is involved; the temperature of the part is seldom elevated; deformity results from destruction of bone, cartilage, and ligament, from muscular spasms, and from the habitual assumption of certain attitudes to secure relief from pain. There is soon impairment of joint motions. When the products of a tuberculous arthritis caseate the thick liquid seeks exit by forming sinuses, and from them caseous pus flows. If a sinus becomes infected with pyogenic cocci, and the joint itself becomes their prey, acute suppuration arises in the joint, and constitutional involvement is pronounced and perilous to life.

In *pannous synovitis* a large effusion is formed, there is but little granulation tissue, though the tubercles are present in large numbers, and the ligaments and structures about the joint are slightly or not at all implicated.

Diagnosis and Prognosis.—Tuberculous chronic synovitis produces great swelling and distinct thickening of the capsule with obliteration of the outlines of the joint, no severe pain, and no tendency to early subluxation. Tuberculous arthritis rarely causes distinct fluctuation, does not thicken the capsule, causes reflex muscular spasm, rigidity of the joint, muscular atrophy, severe pain on movement, and eventually subluxation (Shaffer). In syphilitic arthritis there is usually some fluctuation, distinct enlargement of the joint, limitation of motion, no reflex spasm, trivial atrophy, but distinct pain on motion (James

K. Young, "Therapeutic Gazette," June 15, 1902). Acute rheumatism attacks more than one joint, is very rare in children under five, and produces high fever. The x-rays aid in the diagnosis of tuberculous arthritis and enable us to tell the extent of bone involvement.

The diagnosis of a tuberculous joint is often difficult, and sometimes impossible, and the prognosis is always grave. In only a very few cases, even when recognized early, is a cure obtained without some impairment of joint function. The best that can usually be accomplished is a cure with more or less ankylosis, fibrous or bony; and often ankylosis is complete. Long after the disease is apparently cured, it may break forth anew. Tuberculous lesions may arise in a distant organ or general tuberculosis may occur. Caseation is apt to produce severe constitutional disorder. Infection by pus organisms gives rise to grave danger of septicemia. Death is not unusual from exhaustion, from septicemia, from disseminated tuberculosis, from tuberculosis of an important organ, or from amyloid disease.

Treatment.—Conservative treatment is especially successful in children. According to Hoffa, in 75 per cent. of cases in children non-operative treatment will produce cure ("Die Bekampfung der Knochen- u. Gelenktuberculose in Kindesalter Tuberculosis," iv, 1, 1905). The conservative treatment consists in open-air life, if possible in a sanatorium, the following of the plans outlined under Tuberculosis, immobilization and extension of the joint, and injections of iodoform emulsion or formalin-glycerin (2 per cent.). Even when tuberculous pus forms, the same treatment may be followed unless there is violent pain or elevated temperature which does not quickly abate, in which case operation must be performed. Cases treated early by conservative methods may get well with a movable joint, but in most cases there is a stiff joint when the disease is arrested. Constitutionally, the treatment is directed against the tuberculous diathesis. The patient should be placed under good hygienic conditions. A change of climate is often of the greatest importance. Many cases do well at the seaside; others require high altitudes, and all should live in the open air. The value of sunlight is set forth on page 231. The Finsen light, too, is of service. Treatment by tuberculin is considered on page 235. Locally, rest is of the first importance, and fixation is maintained for many weeks. Rest is best secured by immobilization and traction, and traction is applied or maintained by splints, by Plaster-of-Paris bandages, or by extension appliances. The hot-air apparatus may be of some benefit. If it is employed, it should be used daily, the limb being immobilized during the remainder of the twenty-four hours. Fixation must be maintained as long as pain exists or muscular spasm is present. Fixation must be abandoned gradually, and mobility is to be slowly regained. During restoration to mobility, if pain arises, the part must be immobilized temporarily. Movements should never be violent, prolonged, or repeated at too close intervals. Forcible breaking up of an ankylosis is never advisable in the knee, ankle, or hip; it is seldom advisable in the wrist, elbow, or shoulder. Such an attempt may be followed by a fresh outbreak of the disease. Osteotomy or resection will more safely correct a faulty and disabling deformity. In a tuberculous joint injection of formalin-glycerin, as advised by Murphy, is a valuable procedure. Several injections or a number may be made. The joint is aspirated and the mixture introduced. About 4 drams are used in the knee, about 2 drams in the ankle. After injection extension is applied. The mixture used must be at least twenty-four hours old. In tuberculous joints intra-articular injections of iodoform are often of the greatest value. This drug strongly stimulates the formation of fibrous tissue. If sufficient fibrous tissue is formed the tuberculous foci will be firmly encapsuled and the case will be cured. Iodoform is particularly called for when no bone disease is shown by the x-ray or discovered

by incision. The joint is incised, adhesions are gently broken up, the capsule is sutured except for a small space, the nozzle of a syringe is inserted and a mattress suture draws the capsule tightly about the nozzle (Brackett's plan). The emulsion is injected under tension and then the capsule is closed tightly. In a large joint a 4 per cent. emulsion is used; in a small joint a 10 per cent. emulsion. The part must not bear weight for six months. Bier's plan of inducing passive hyperemia is often of great service (see pages 112–115). Aspiration or incision can be used for fluid accumulations. Caseous masses are often let alone, or an aspirator is used and the joint drained, washed out with saline solution, and injected with an emulsion of iodoform and glycerin (10 per cent.). From 1 to 2 drams are injected into the joint of a child, from 2 to 5 drams into the joint of an adult. Even surface lesions are not curetted. Bier's treatment should be associated with immobilization and systemic treatment. It is more serviceable in tuberculosis of the small joints than in disease of the large articulations. There are certain contra-indications to Bier's treatment, viz.: serious pulmonary involvement, extensive amyloid degeneration, and the existence of such an unfavorable position of the parts that cure by ankylosis would mean a less useful limb than cure by resection (Bier at Internat. Surg. Congress of 1905). One advantage of this treament is that we can employ active and passive motion early, except, according to Bier, when the foot or knee is diseased. Even in very serious cases cure may be obtained without any limitation of activity, and as the patient can get about it is not necessary to restrain him long in a hospital. Personally I believe that fixation should be the basis of treatment in most cases, and that passive hyperemia, compression, counterirritation, and intra-articular injections should be additions to fixation. Injections of balsam of Peru or of iodoform emulsion about the joint once a week are efficient in some prolonged cases, but are not to be used early. It is not wise to attempt to correct faulty position until the focus is well.

Fistulæ are frequently treated by the method of Beck, of Chicago, that is, by the injection of a paste containing bismuth. In early cases a bismuth-vaselin paste is used, in late cases a bismuth-wax-paraffin paste.

Beck described his method in the "Illinois Med. Jour.," April, 1908. The vaselin paste is composed of 30 parts of subnitrate of bismuth and 60 parts of vaselin, mixed and well stirred while boiling. The paste for later cases is composed of 30 parts of subnitrate of bismuth, 5 parts of white wax, 5 parts of soft paraffin, and 60 parts of vaselin, mixed while boiling. One per cent. formalin is often added to these pastes. The paste is injected cold before an *x*-ray picture is taken, and the picture shows all the ramifications of the fistula. The paste is left in for treatment. If a sequestrum exists it should be removed before the paste is injected. It is not necessary, but is advisable, to dry the fistula before injecting.

The paste is sterilized before using. It is sucked up into the syringe while still liquid and is cooled to the requisite temperature and hardened to the proper consistency by running cold water over the syringe. It is injected very slowly and the injection is continued until a sense of pressure annoys the patient. Then the syringe is laid aside, a bit of gauze is held for a time over the outlet of the fistula to keep the paste from running out, and an ice-bag is put over the region to quickly harden the injected material. There is no pain from such an injection. Beck employs the first paste until pus disappears and then uses the second.

The value of this paste is that it distends and fills the abscess-cavity and sinus, and affords a trestle or frame for granulations to grow upon. Considerable of the paste may run out of the fistula during the first twenty-four hours. In shallow sinuses it all runs out. In deep and tortuous fistulæ much of it remains for weeks and is slowly absorbed. In empyema and bone-cavities

it is slowly absorbed. Beck holds that the paste is bactericidal, astringent, and non-toxic. Cases of pigmentation of the lips, gums and cheeks, and cases of ulceration in the mouth from absorption of bismuth have been recorded, and at least 8 deaths are on record (Reich, in "Beiträge Zur klinischen Chirurgie," Nov., 1909). Beck limits the first dose to 100 gm., but increases the amount later. Because of possible danger of poisoning Blanchard uses a paste of white wax and vaselin without bismuth. Not over 4 oz. of bismuth paste should be injected. As Bell points out, if a large quantity is injected an opening must be left. This precaution may prevent poisoning. Some think the poisoning is due to bismuth, others believe it is due to arsenic held as an impurity. David and Kauffman ("Illinois Med. Jour.," Oct., 1909) point out that there may be acute cases of poisoning which are liable to be fatal, and chronic cases which tend to recovery. In an acute case of bismuth-poisoning there is pigmentation of the gums, ulcerative stomatitis, dyspnea, delirium, and albuminuria. David and Kauffman regard pigmentation of the gums, lips, or cheeks as an indication of toxic action and a sign to discontinue the drug. The use of bismuth paste is undoubtedly a valuable method. I have seen sinuses heal under it after they had resisted various other plans of treatment. It may be used in sinuses, cold abscesses, empyemata, tuberculous joints, and other conditions.

If these means fail, if the patient gets worse, if there is persistent fever or violent pain, if sequestra exist, if there is mixed infection, or if the condition of the sufferer renders dangerous the prolonged conservative course, operate, removing the entire diseased area by erasion, by excision, or possibly by amputation. If the *x*-ray picture shows extensive sequestrum formation, operation is indicated. If amyloid degeneration exists, conservative treatment is contra-indicated and so is resection. Amputation must be done. Always remember that an incomplete operation or a partial removal, unless it consists of simple drainage, is worse than no operation, as it opens the portals to systemic infection, and may be responsible for the development of general tuberculosis, septicemia, or pyemia. Simple drainage, as previously stated, is seldom advisable. Garré is of the opinion that the hip, wrist, and shoulder do best by conservative treatment; the knee, elbow, and ankle, by operative treatment (John W. Churchman, in "Am. Medicine," April, 1906).

Tuberculosis of Special Joints; Tuberculosis of the Vertebræ (see page 844).—**Tuberculosis of the Sacro-iliac Joint** (*Sacro-iliac Disease*).—This is an uncommon affection, and is especially rare before the age of fifteen. The disease may begin in the joint, may arise in adjacent bones, or may result from a cold abscess burrowing into the joint. In some cases it is associated with extensive disease of the pelvic bones. The disease, if undetected, may lead to dissemination of tubercle, to abscess, or even to death.

Symptoms are often obscure. The disease is frequently confounded with vertebral caries, hip-joint disease, or sciatica. The patient limps on walking, but can stand on either leg; there is pain in the sacro-iliac joint, about the hip, and down the thigh; tenderness is manifest on pressure over the joint and on pushing the ilia together; there is fulness over the sacro-iliac joint, but the hip is not flexed unless iliac abscess exists.[1]

Treatment.—Rest in bed for months, using also a felt case for the pelvis. Counterirritation by blisters and the actual cautery. In some cases injection of formalin-glycerin or of iodoform; in others, incision and curetting. I have operated on 9 cases, with 1 death. In 1 case in the Jefferson Medical College Hospital the abscess was pointing in both the back and groin. Both areas were incised, the diseased bone was removed, and the boy ultimately recovered. In another case the abscess pointed in the groin. The treatment was as previously set forth, and the patient, a woman, recovered. The best way to reach

[1] See A. G. Miller, "Edinburgh Med. Jour.," May, 1805.

the joint is to chisel or bore through the ilium above the great sacrosciatic foramen.

Tuberculosis of the Hip-joint (*Hip Disease; Morbus Coxarius; Morbus Coxæ; Hip-joint Disease*).—The primary lesion may be in the synovial membrane, but it is more often in the bone. It may begin in the acetabulum; it may begin in the femur. In 95 per cent. of cases it begins in the head of the femur. If it begins in the femur, it usually arises on "the distal side of the epiphyseal cartilage" (Senn). Sometimes primary tuberculosis arises in the trochanter major, and never involves the joint. When the synovial membrane becomes involved at any point, spread throughout the joint is rapid. In many cases the articular cartilages are attacked, and in some cases the epiphyseal cartilage is destroyed. It is commonest in children, but it may arise in adults and even occasionally in those of advanced years; 62 per cent. of cases arise in children under ten years of age and 80 per cent. of cases occur before the twentieth year (Bryant). Traumatism and cold may be predisposing causes. The disease strongly tends to caseation and the formation of sequestra.

Symptoms.—It has been usual to divide the disease into three stages: (1) the stage of microbic deposition and multiplication, the products of the bacilli causing irritation and new growth; (2) the stage of progression, with formation of masses of granulation tissue and effusion into the joint, and (3) the stage of caseation, with destruction of the joint and often of the structures about it. Bradford and Lovett[1] protest against this. They say: "It has been customary to divide hip-disease into stages, and to ascribe to these stages certain definite symptoms. Neither from a clinical nor a pathological point of view is it desirable to attempt such a division." As H. Augustus Wilson says: "Tuberculous bone and joint disease should be considered as the primary invasion or incipiency, and all other symptoms should be regarded as results and not as an integral and necessary part of the trouble."

The symptoms of incipient coxalgia are slight and may be overlooked entirely. In a child there are night-terrors; on getting about in the morning the child shows no lameness, but a limp develops during the day, and the little one soon grows tired while playing and lies down to rest. There is a slight limp; some muscle spasm may be noted, and pain may be complained of at night in the hip, in the front of the thigh, or at the inside of the knee. Tapping the sole of the foot, the thigh and leg being extended, may develop pain, just as it will develop pain in any inflammatory involvement of the joint, but the employment of this method is objectionable. It may injure a joint already damaged by the tuberculous process, and it gives no information which cannot be obtained by a safer mode of investigation. After all, pain on tapping the sole of the foot means only what muscular rigidity means, and muscular rigidity is always present and is easily demonstrable by careful manipulation. The diagnosis of incipient coxalgia is more or less problematical.

As the disease progresses more positive symptoms are observed. The limp grows worse; the hip is broadened by an effusion into the joint, and fluctuation may possibly be detected; the thigh muscles atrophy; the extremity is pushed forward, abducted, and everted. The position is described as flexion, abduction, and outward rotation (Fig. 383). This position may not be obvious; in fact, the limb may be extended by the side of the companion extremity. When it is, there is a forward curve of the lumbar spine (lordosis) and a lateral curve of the lumbar spine, which raises the pelvis on the sound side and depresses it on the diseased side. These lumbar curves serve to bring the femur toward the middle line, give the extremity the appearance of being lengthened, enable the sufferer to walk (Fig. 383), and cause him to

[1] "Orthopedic Surgery."

rest his weight on the sound limb. Apparent lengthening means abduction. In some few cases adduction exists rather than abduction. The abduction, which is usual, releases tension of the fascia lata, and thus abolishes pressure upon the joint through lessening of pressure upon the great trochanter, and also relaxes the outer portion of the Y-ligament and the ligamentum teres. The flexion relaxes the anterior portion of the capsule and the psoas muscle and prevents pressure of its tendon upon the front of the joint. Outward rotation relaxes the inner portion of the Y-ligament and the posterior portion of the capsule. Pain exists, often sudden or starting, and is located in the joint, on the front of the thigh, and to the inner side of the knee in the course of the obturator nerve; the pain is aggravated at night, and full extension and complete abduction are not possible. The gluteal muscles waste, and the gluteal crease is on a lower level than is that of the sound side. The gluteal crease may be nearly or quite effaced because of hypertrophy of the subcutaneous layer (Alexandroff), or from slight flexion of the leg (McClellan). As the disease progresses adductor spasm causes adduction, and the limb is flexed, adducted, and apparently shortened. This apparent shortening is accomplished by a lateral curvature of the spine, which keeps the limb from crossing its fellow and being useless. It does so by raising the hip of the

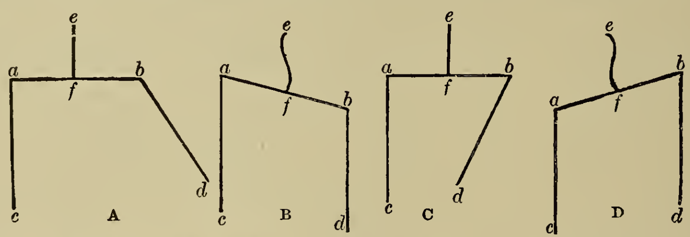

Fig. 383.—Positions in hip-joint disease. A: *e–f*, lumbar spine; *b–d*, limb fixed in flexion and abduction, useless for walking. B: *e–f*, lumbar spine. Patient corrects the condition in Figure A by curving the lumbar spine forward and rotating the pelvis on its transverse axis, thus making the femur point downward. The lumbar spine is curved laterally, the pelvis ascending on the sound side and descending on the affected side (apparent lengthening). C: *b–d*, limb fixed in flexion and adduction. D: *e–f*, curve of lumbar spine to correct condition in Figure C (apparent shortening). (After the plan of Howard Marsh and Treves.)

diseased side and drawing the femur outward (Fig. 383). This causes apparent shortening (Howard Marsh, in Treves's "Manual of Surgery"). The above symptoms arise chiefly from unconscious efforts to obtain ease, from joint-effusion, reflex irritation, and involuntary or spasmodic muscular contractions. There is an appearance of lengthening or shortening, but it is only apparent, not real. The real position is shown on Plate 8, Fig. 4. The fluid effusion may be absorbed or may find its way externally by means of sinuses. The latter condition is known as *abscess of the hip*. The absorption of the exudate or the rupture of the capsule permits the contracting muscles to bring the head of the femur into firm contact with the acetabulum or its brim; the bones are worn away and destroyed, real shortening results, there is adduction, and flexion is increased as shortening becomes more marked.

In advanced cases of coxalgia the head of the femur passes upward and outward upon the rim of the acetabulum, the thigh is flexed and fixed, and attempts at extension when the patient is recumbent cause the pelvis to tilt forward and occasion a marked lumbar curve (lordosis) (Pl. 8, Fig. 2), which is due to the pelvis moving with the femur as if ankylosed, and which disappears on flexion. In this condition adduction occurs because of the ascent and movement outward of the head of the bone. Shortening is marked. After a hip abscess finds an external outlet pyogenic infection is very apt to take place

and suppuration arises, which is followed by that state which is designated as "hectic." If a cure follows advanced coxalgia, partial or complete ankylosis takes place; if death ensues, it may be due to septicemia, tuberculosis of the viscera, exhaustion, or amyloid degeneration.

Diagnosis is very easy in well-established cases of hip-disease, but very difficult when the disease is incipient. Always make a systematic and thorough examination. Undress the patient and place him recumbent with his legs extended upon a table or a hard mattress. Note if the heels are level and if the iliac spines are on the same level (a depressed spine on the affected side means abducted extremity, the degree of which is determined by carrying the limb out until the spines are horizontal; elevation of the iliac spine on the affected side means adduction, the amount of which is determined by adducting the limb until the spines are horizontal, Fig. 383). The amount of flexion is ascertained by lifting the knee until the curved spine has become straight. Try all the movements belonging to the joint, to detect any limitations; observe if bringing down the knee produces lordosis; look for swelling and for muscular wasting; feel if the head of the bone is enlarged; determine if motion produces pain or if pressure develops tenderness; and always carefully elicit the history of the attack, of the person, and of the family.

Hip disease may be confounded with spinal caries in which a psoas or a lumbar abscess has formed, with sacro-iliac disease, with infantile paralysis, with congenital dislocation of hip, with lordosis from rickets, with gluteal abscess, and with bursitis of the gluteal bursæ. In hip disease there is always some lameness; pain may be severe, may be trivial, or may be absent entirely, and may be in the hip or be referred to the front of the thigh or the inner side of the knee. Always remember that the pain is not characteristic, and that pain in the same localities may arise from aneurysm of the femoral or iliac arteries, from abscess in Scarpa's triangle, from caries of the lumbar vertebræ, from sacro-iliac disease, and from cancer of the rectum. Altered position of the limb, limitation of movement in the hip-joint, muscular wasting, and swelling soon arise in hip-joint disease.

In disease of the sacro-iliac joint examination shows that the movements of the hip-joint are unlimited and produce no pain, and that pain is developed by pressure over the sacro-iliac articulation and by pressing the ilia together. In infantile paralysis there is no pain, but there is paralysis with great muscular atrophy, which comes on with considerable rapidity. In spinal caries with psoas abscess the evidences of disease of the vertebræ are clear and a collection of fluid is located in the groin external to the femoral vessels. The tuberculous pus of hip abscess generally gathers under the tensor vaginæ femoris muscle, but it may reach Scarpa's triangle by passing through the cotyloid notch or through the bursa under the psoas muscle; it may even appear under the glutei. Matter from a caseating acetabulum may reach the interior of the pelvis and appear above Poupart's ligament.

In gluteal bursitis the symptoms last for many months, and do not remit as the symptoms of early hip disease are apt to do. The pain is but moderate, and is aggravated by exercise, but passes away on going to bed, and is felt back of the hip and back of the knee. There is a certain amount of limitation of motion and there is a positive limp, which arises early. In marked cases fluctuation can be detected in the upper gluteal region.[1]

Prognosis.—If the case of hip disease is seen early the chances of cure are excellent in children, in whom the disease may be arrested at any stage. The longer the duration of the disease and the older the subject, the more unfavorable is the prognosis. Many months will be required to elapse before a cure

[1] See E. G. Brackett's important paper on "Gluteal Bursitis" in the "Transactions of the American Orthopedic Association," vol. x.

can be effected, and advanced cases only get well by means of ankylosis with shortening and deformity. Hip disease may recur years after apparent cure, and a person who has or has had hip disease runs a chance of developing visceral tuberculosis.

Complications.—The complications that may accompany hip disease are the following: *Abscess*, as above noted. *Tuberculous meningitis*, or the condition known as "acute hydrocephalus" or "water on the brain," may arise during the progress of the case or after apparent cure, and is apt to ensue upon incomplete operations. It is almost inevitably fatal. *Phthisis pulmonalis* is a rare complication, but a not uncommon sequence, perhaps arising, sooner or later, after the hip disease has been cured. *Amyloid, lardaceous,* or *waxy degeneration of viscera* (see page 239) follows upon profuse and long-continued suppuration and is apt to arise in the liver, spleen, kidneys, or intestinal mucous membrane. Tuberculosis is not the only cause of amyloid degeneration, syphilis being responsible for at least 30 per cent. of all cases. In amyloid disease of the liver the organ is much enlarged, smooth, painless, and of increased consistency; there is no jaundice, the spleen is apt to be enlarged, and albuminuria is the rule. In amyloid kidney large amounts of pale urine of low specific gravity are voided; albumin is usually present in large amount, but may be absent; globulin may often be found, as may also hyaline, fatty, or granular casts; the patient is anemic and dropsy usually exists. Test the hyaline casts with iodin for amyloid material. Amyloid changes are usually slow in onset, but they may be rapid; they are commoner in men than in women, and are most frequently encountered in individuals between the ages of ten and thirty. Slight amyloid change may be recovered from, but an extensive degeneration brings about a fatal result.

Fig. 384.—Thomas's posterior splint.

Treatment.—In most of these cases conservative treatment is advisable. Antituberculous treatment is used in all cases. In incipient hip disease the treatment usually advocated is rest. The patient is placed upon a solid mattress and extension is applied. In children under ten years of age a weight of from 3 to 5 pounds is used; in individuals between ten and twenty a weight of from 5 to 8 pounds is used. A long splint is often applied to the sound side to keep the patient recumbent and horizontal. A cradle is employed to hold up the bed-clothing. The extension is applied in the long axis of the limb, the extremity being placed in the line of the deformity due to disease and being properly supported. In lordosis from thigh-flexion the limb is raised until the iliac spine is straight (Pl. 8, Fig. 5). If the spine is depressed on the affected side, the limb is abducted (Pl. 8, Fig. 6); if the spine is elevated, the limb is adducted until the spines are horizontal (Pl. 8, Fig. 7). The object of extension is to overcome muscular spasm and so put the part in a condition of physiological rest. Muscular spasm is a great factor in destroying structures. Spasm presses the parts together, and as a result of pressure plus bacterial action destruction occurs. The extension and traction tire out the muscles and cause spasm to cease. Extension will remove flexion in two weeks in a recent case and in the course of some months in an older case. As flexion is relieved the pillows are removed and the leg lowered, but extension is maintained in the long axis of the thigh. Abduction and adduction cannot be removed by simple extension in the axis of the limb.

Abduction demands no special treatment. In a movable joint it will disappear, and in an ankylosed joint it is an advantage, compensating by apparent lengthening for the shortening due to bone-absorption or to stunted growth of the limb. Adduction requires an addition of several pounds to the extension weight, the use of a long splint on the sound limb, and the drawing up of the sound side by a rope and pulley toward the head of the bed. The weight used to pull the sound side toward the head of the bed is equal to that used to pull the diseased side to the foot of the bed. This expedient is used for a month or six weeks. In old cases, in which the weight will not bring about extension, the patient is anesthetized, the limb is gently straightened a very little, and the weight is reapplied.

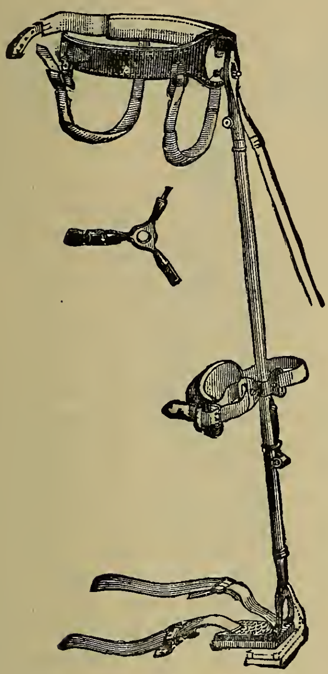

Fig. 385.—Sayre's long splint.

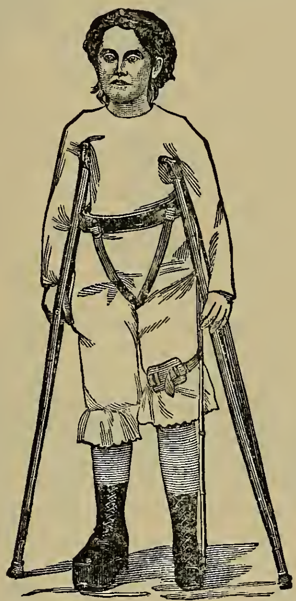

Fig. 386.—Wyeth's combination method.

Extension in a mild case must be continued for three months after the symptoms have disappeared, and in a severe case the period must be six months. The weight is gradually taken off; if symptoms recur, the weight is reapplied; if they do not recur, apply a traction splint or a plaster dressing, put a high-heeled boot on the sound limb, and send the patient out on crutches. In young children extension can be made while the child is in a wheeled carriage, thus enabling the patient to go out in the fresh air and sunlight. The general treatment is tonic and restorative. The joint is so deeply placed that external applications are useless. In the treatment of hip disease Thomas's splint (Fig. 384) is used by many, and it may be combined with weight extension; or Sayre's splint (Fig. 385) may be employed. Wyeth's apparatus (Fig. 386) is a favorite with many American surgeons.

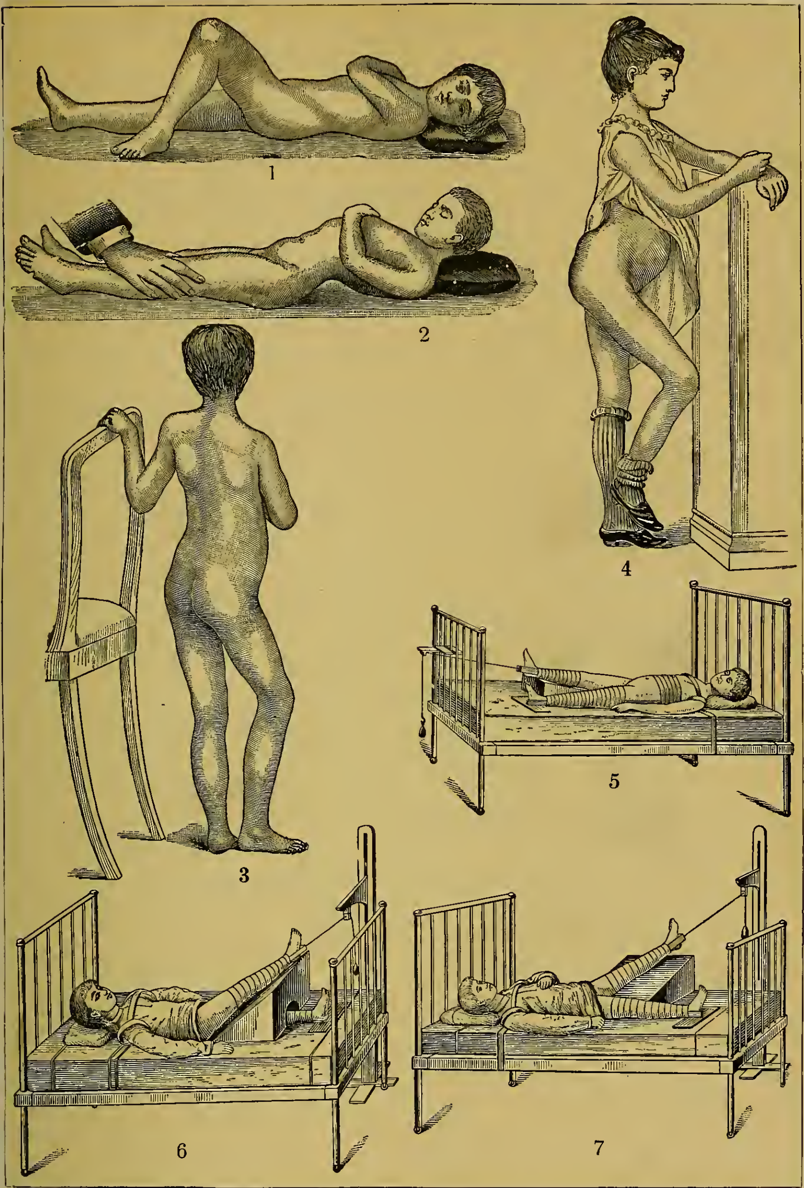
If the limb is in good position, or has been brought into good position, either by weight extension or straightening under ether, plaster-of-Paris is a useful dressing. It is applied from the toes up, and includes the entire extremity and also the pelvis. A patient wearing plaster may get about on crutches when the sole of the foot of the sound extremity is raised by the wearing of a thick-soled shoe.

Treatment by Weight-bearing and Fixation by Hip Spica of Plaster of Paris (*Lorenz's Method*).—This plan is based upon the principle that ankylosis is to be secured in every instance. To keep the patient in bed is to keep him from the open air and sunlight, which are so necessary in tuberculosis. Such confinement favors muscular atrophy, leads to anemia, and lessens vital resistance. The hip is placed in 20 degrees of flexion, 20 degrees of abduction, and 5 degrees of external rotation, and is fixed by a short plaster spica of the hip. The patient walks and so antagonizes muscular spasm. The joint surfaces bear weight, which leads to a useful increase of blood supply (curative hyperemia), but do not grind upon each other, hence, the spread of the disease is not favored. That muscles increase in size is shown by the fact that the cast gets tight and must be changed from time to time. The open-air life and exercise are of the greatest benefit to the patient and a gain in weight is the rule. Cases in a debilitated condition or those with discharging sinuses must not be treated by this plan "without the temporary use of crutches" (H. A. Wilson, in "Southern Med. Jour.," Dec., 1908). The plan is more suitable for incipient than for advanced cases. The average duration of treatment is claimed to be about ten months (H. A. Wilson, Ibid.). It is true that the method affords easier access to the open air than does the bed treatment, but why should every patient be doomed to ankylosis when we know that in many cases joint function may be retained by treatment looking to that end?

Intra-articular Injections and Operation.—If in spite of treatment the condition does not improve or if it becomes worse, use intra-articular injections of formalin-glycerin or iodoform. Always try these injections before doing a resection unless the *x*-rays show a large sequestrum. Sometimes they succeed, and if they do, resection is unnecessary. Asepticize the surface, carry a small aspirating needle into the joint, irrigate the joint with salt solution, and inject a sterile emulsion of iodoform and glycerin (see page 622). In one week, if reaction has ceased, repeat the injection. In another week repeat it again. It may be necessary to give from ten to twenty injections. The proper spot for puncture is thus determined: Draw a line from a point $\frac{1}{2}$ inch outside of the middle of Poupart's ligament to the outer edge of the great trochanter. Puncture at the middle of the outer half of this line (De Vos). I have not attempted to remove the disease surgically early in any case and greatly doubt the wisdom of doing so. Huntington and some other surgeons advocate early operation in children instead of simply fixation, extension, and rest. Huntington ("Amer. Jour. Med. Sciences," July, 1905) recalls that when the lesion is in the head of the femur it tends to perforate into the joint, and he advises trephining at the lower border and outer aspect of the great trochanter and tunnelling the neck and head of the femur with a curet. Bradford objects to this method in most cases on the ground that unless the disease is localized and the cavity is well walled off and unless injury to the localizing barrier is avoided, the operation may be responsible for dissemination of the bacteria.

If an abscess forms, incise it with the most thorough antiseptic care, let the fluid drain away, irrigate the cavity with salt solution, remove any sequestra, inject with iodoform emulsion, sew up without drainage, and dress antiseptically. In some cases the sequestrum is extra-articular. In many cases no sequestrum is found. If this method fails, drainage must be employed. The old plan of not operating until rupture was seen to be inevitable would be wrong to-day. To open early and antiseptically often means rapid healing, the prevention of burrowing, a lessened danger of visceral infection, and an earlier cure. In contrast to what happens when a very large cold abscess is opened, hectic will rarely arise when a tuberculous joint is opened and drained with aseptic care.

Excision of the hip is to be performed when there is a large sequestrum or severe fistulæ (Garré, "Deutsch. med. Woch.," 1905, Nos. 47 and 48);



1, 2. Effects on the Lumbar Spine of Flexing and Extending the Diseased Leg in Hip Disease (Albert). 3, 4. Positions in Coxalgia (Albert). 5. Extension in Hip Disease (Treves). 6. Extension of the Limb in a Flexed and Adducted Position (Treves). 7. Extension of the Limb in a Flexed and Abducted Joint (Treves).

when the head of the femur is detached and lies loose in the joint; when profuse suppuration continues for a long time, and other methods fail to arrest it; when amyloid disease is threatening; or when very faulty position is inevitable without operation. Excision is an operation of considerable danger, and the older the person, the greater the danger. Schede advocates arthrectomy in some cases as a substitute for resection. Senn tells us that opinion as to resection has greatly changed of late, and it is now taught that the operation is advisable in all cases where fixation, extension, intra-articular and parenchymatous injections have failed to arrest the disease (Senn, on "Tuberculosis of Bones and Joints"). Resection of the hip does not give a very satisfactory functional result. When there is extensive disease of the femur, when excision has been tried and has failed, when the patient has not the recuperative power to withstand the long siege of illness following excision, or when there is amyloid disease, amputate.[1] Amputation of the hip-joint for tuberculous disease is a very successful procedure.

Knee-joint Disease (*White Swelling*).—After the hip, the knee is, of all joints, the commonest site for tuberculous disease. Knee-joint disease can begin as a synovitis, but oftener begins as tuberculous inflammation of the femoral or the tibial epiphysis. Tuberculous disease rarely attacks the bone on the diaphyseal side of the epiphyseal line; a single focus only exists, as a rule, and a sequestrum is seldom formed. In very rare instances the patella or the semilunar cartilage is primarily attacked. It may begin at any age, but is most common in children and young adults. If an acute synovitis ushers in the case, there may be a large effusion into the knee-joint and partial flexion, but swelling is usually slight in knee-joint disease. Pulpy degeneration of the synovial membrane occurs; the joint enlarges; the ligaments soften; the skin becomes edematous, and muscular spasm exists. The leg becomes flexed; the tibia displaced backward and outward; the foot is everted; and lameness arises, due chiefly to deformity. Muscle atrophy is marked above and below the joint. Pain may be absent, is often slight, and is rarely severe. Local tenderness is very common. When the disease begins in the bone or an epiphysis there are pain, tenderness, lameness, swelling, inability to extend the limb completely, sudden spasmodic muscular contractions, and final involvement of the joint. When an abscess forms, it may destroy the joint very rapidly or it may break externally.

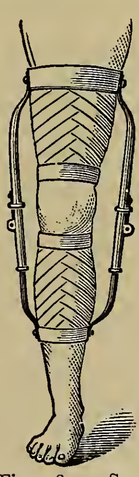


Fig. 387.—Sayre's knee splint applied.

Fig. 388.—Hutchinson's knee-joint splint.

Treatment.—In treating knee-joint disease conservative treatment is usually tried, but often fails. A plan of doubtful value is to make a mixture of guaiacol and olive oil (1 : 4). Once a day the surface of the knee is exposed by removing dressings, is painted with this mixture, and the painted surface is covered with cotton-wool. Rest is of the first importance, and may be secured by the application of splints (Figs. 387, 388), the use of extension (Fig. 389), or the employment of a plaster-of-Paris bandage. In any case the patient must be kept in bed for a few weeks; he may then be permitted to go out upon crutches, wearing a high-heeled shoe upon the foot of the sound limb. In cases in which treatment is begun early the

[1] See the admirable article by Howard Marsh in Treves's "Manual of Surgery."

disease may often be arrested in from eight to twelve months. If the symptoms do not abate after a number of weeks, or if the condition grows worse and caseation occurs, aspirate, irrigate, and inject iodoform emulsion or formalin-glycerin. Intra-articular injections are not unusually curative. Insert the needle in the angle between the outer edge of the patella and the ligament of the patella (De Vos). Repeat the injection in one week if reaction has abated, and continue as directed for the injection of the hip-joint. If this plan fails, incise the capsule, remove all fragments and tuberculous foci, irrigate with normal salt solution, inject iodoform emulsion, and sew up without drainage (Neuber's plan). A more severe case requires drainage. If these means fail, or if the case is too far advanced to permit of their use, open the joint and perform an excision or an erasion (see pages 697 and 703). Excision gives a satisfactory result in most cases, although it leaves a rigid knee and marked shortening. Garré considers any shortening over 5 cm. a bad result, and he got such a bad result in 7.5 per cent. of his 117 cases. In children shortening follows even conservative treatment, and the shortening which follows excision is due in part to removal of bone and in part to impairment of the nutritive power of the epiphyseal cartilage. Some cases demand amputation, which, if the patient's health is much impaired or if amyloid disease exists, is to be preferred to excision. Amputation is preferred to excision in very young children and aged people.

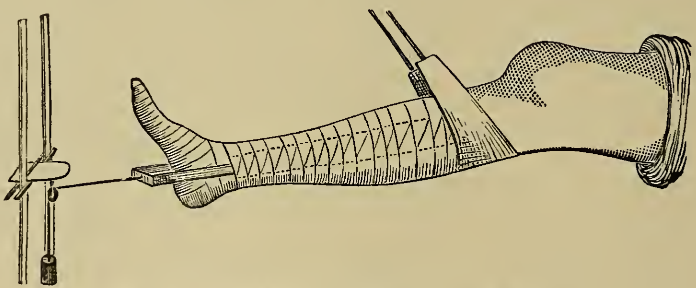

Fig. 389.—Sayre's double extension of the knee-joint.

Ankle-joint disease may begin in the synovial membrane, in the tibial epiphysis, or in the tarsus. The origin is frequently synovial.

The *symptoms* are pain, swelling, lameness, limitation of joint-movements, and atrophy of the calf muscles. Caseation often occurs and sinuses form.

Treatment.—Conservative treatment with injections of iodoform or of formalin-glycerin will cure many cases. Rest is obtained by means of splints or plaster-of-Paris bandages. Caution the patient to avoid standing upon the diseased extremity. In making an intra-articular injection insert the needle below the outer malleolus. When caseation occurs, it is advisable to open the joint, wash out with normal salt solution, inject iodoform emulsion, sew up the incision, and put up the ankle-joint in plaster. When there is considerable bone disease, when fistulæ exist, when adjacent joints or tendons are diseased, or when joint-disorganization occurs, perform an excision or an erasion. Some cases demand amputation (Syme's amputation being preferred by some, amputation above the ankle being approved by many). Osteoplastic resection is sometimes advised (Wladimiroff-Mikulicz operation). Operative treatment is more satisfactory in children than in adults (Garré).

Shoulder-joint disease is not common; it is rare in children and is commonest in adults; it may begin in the synovial membrane, but usually begins in the head of the humerus. The glenoid cavity is rarely attacked. Pain is slight, atrophy of the deltoid and other muscles is noted, the joint is stiff, and the scapula follows the motions of the humerus. Caries sicca is the usual

cause of destruction. In many cases swelling is not obvious, the joint shrinking because of destruction of the head of the bone and contraction of the capsule (Senn). Abscess-formation is unusual. If an abscess forms, it may open in the axilla, through the deltoid muscle, or at some far distant point. Shoulder-joint disease is frequently complicated by pulmonary tuberculosis.

Treatment.—A majority of cases recover by the use of conservative treatment, a stiff joint resulting. Put on a shoulder-cap, apply the second roller of Desault, and hang the hand in a sling. Maintain rest for at least four months. Arthur Gillette's plan is very efficient. It consists in placing in the axilla a wedge-shaped pad with the base up. The arm is allowed to hang. Aspiration and injection of iodoform emulsion or of formalin-glycerin are of great service in synovial tuberculosis. In making an intra-articular injection the needle is entered below the acromion, while the arm is held against the side and the forearm is at right angles to the arm and across the front of the chest (De Vos). If caseation occurs, open the joint, remove tuberculous foci, wash with hot saline fluid, inject iodoform emulsion, and close without drainage. In a decidedly severe case, drain. Caries sicca may occur. In rare instances dead bone will have to be gouged away. Excision is sometimes required, but the results are seldom satisfactory.

Elbow-joint disease may begin in the humerus or the ulna. The head of the radius is rarely the primary focus. In some cases the synovial membrane is first attacked. The disease is most frequent in young adults. The joint is swollen, its movements are somewhat limited, muscular wasting is pronounced, and pain is generally slight. Tuberculous pus may form.

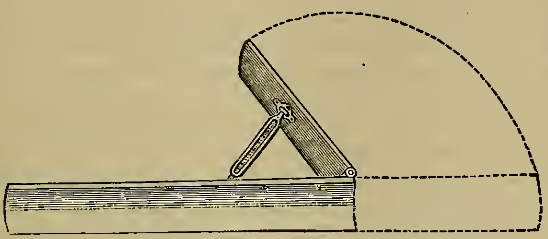

Fig. 390.—Stromeyer's anterior angular splint.

Treatment.—In treating early elbow-joint disease, especially in young children, conservative treatment is very successful. Rest is secured by means of an anterior angular splint (Fig. 390) and a triangular sling or a plaster-of-Paris dressing. Splints are to be worn for from four months to a year. Injections of iodoform emulsion or formalin-glycerin are usually employed. Insert the needle for injection by the outer side of the olecranon. In a cure by conservative methods a stiff joint will usually result. It may be necessary to perform resection because of extensive bone disease. Resection gives an excellent functional result.

Wrist-joint disease may arise at any age, and is sometimes met with in late middle life or even in old age. The joint presents a puffy swelling, loses its normal contour, and becomes spindle shaped. Hand-movements are impaired, pronation and supination cannot be performed completely or satisfactorily, the joint is stiff and partly flexed, the grasp is enfeebled, pain may be severe or slight, the skin is sometimes, but seldom, hot, and muscular atrophy is marked. This form of tuberculosis may begin in the synovial membrane, in the bones, or in the tendon-sheaths. The prognosis is better than in tuberculosis of any other joint. There is usually preservation of considerable function on recovery.

Treatment is usually conservative and very successful, giving, as a rule, a functionally useful joint and movable fingers. Garré recommends a trial of the method even when there are fistulæ and when there is necrosis of the carpus. Apply a Bond splint and sling or put on a plaster-of-Paris bandage and maintain strict rest for from four to six months. Aspiration and injection of iodoform emulsion or formalin-glycerin may be practised. Enter the needle at the dorsal edge of the radial styloid process, and again at the upper edge of the pisiform bone (DeVos). In some cases it is well to incise, wash with salt solution, inject iodoform emulsion, and close without drainage. Severe cases demand incision and drainage with the maintenance of rest. Resection is to be avoided if possible. It gives a bad functional result, the amount of bone removed leaving the tendons too long and contractures of muscles being common (Garré). It may be demanded because of extensive caries or sequestra formation. Amputation is occasionally necessary.

Non-tuberculous Arthritis.—Most of these cases, acute and chronic, are of infectious origin. Some of them are non-infectious. Among the non-infective forms are the joint lesions of locomotor ataxia and syringomyelia—constitutional conditions, as gout, purpura, hemophilia, and scurvy—functional derangements expressed by articular neuralgia or intermitting hydrops and traumatic states (Hoffa, in "Zentralbl. f. Chir.," xxxiv, 1907; and Bloodgood, in "Progressive Medicine," Dec. 1, 1907).

Traumatic Arthritis.—This may be due to a single injury (a sprain or a bruise) or to some continuing cause (genu valgum may cause arthritis of the knee; flat-foot may be responsible for arthritis of the knee or hip).

If a contusion or sprain causes relaxation of the capsule or fixing tendons, the joint becomes loose and injures itself again and again during movement. It does the same thing when there are loose bodies or enlarged synovial fringes. Traumatic arthritis usually involves but one joint. Recent traumatic arthritis is treated by protecting the joint, massage, hot air, and passive motions.

If a continuing cause is present it is to be removed. Distant causes may be removed by orthopedic apparatus or by operation. Causes within the joint may be sought for by arthrotomy, and when found they should be removed. For instance, in the knee, *inflamed synovial fringes* may be responsible for chronic inflammation. They get caught between the joint surfaces, are squeezed, and trip the victim. They should be removed. Lockwood ("Brit. Med. Jour.," July 3, 1909) points out that an overgrowth of fat may get between the tibia and femur and be squeezed. This surgeon calls attention to the fact that there are "adipose pads immediately above the articular surface of the femur, and on either side of the upper end of the patella" (Ibid.). He calls them the *pads of Malgaigne*, after the French surgeon who described them in 1859. If they are subject to repeated traumatism they should be removed.

Infective Arthritis.—In this condition the inflammation is due to bacteria. In some cases pus forms and pyogenic bacteria are demonstrable in fluid removed by aspiration. In other cases, perhaps exhibiting as acute symptoms, no pus forms and no bacteria are demonstrable in the fluid removed by aspiration. The latter cases are due to toxins or to bacteria of attenuated virulence. Secondary infection may occur. In most cases the disease is polyarticular, but if a wound is causal the arthritis will be monarticular. The bacteria may reach a joint by way of a wound from an adjacent focus of osteomyelitis, from a near or distant area of infection, from the genito-urinary tract, or by way of the tonsils. Bacteria not directly introduced into the joint reach it by way of the blood or lymph.

The disease may arise during the course of gonorrhea or any infectious process. It may arise when no area of infection can be discovered. It may

arise in the course of an acute infectious disease (such as erysipelas, typhoid fever, pneumonia, influenza, mumps, dysentery, diphtheria, measles, scarlatina, variola), and may be due to pyogenic cocci, to the specific micro-organism of the acute infectious disease, or purely to microbic products. Joint inflammation arising in the course of or as a sequel to an acute infectious disease may or may not suppurate.

Symptoms.—If no suppuration takes place, the *symptoms* of the attack resemble those of rheumatism; if suppuration occurs, the symptoms are the same as those of acute suppurative arthritis, with which disease this form of infective arthritis is identical. Suppuration rarely occurs. Ashby has well described the arthritis which sometimes follows *scarlatina.* It involves the wrists, finger-joints, tendons of the forearms, the knees, ankles, or spine. The joints are painful, but are rarely much swollen or discolored (Howard Marsh). We can distinguish infective arthritis from rheumatism by the fact that it does not migrate and is uninfluenced by antirheumatic remedies. Dislocation may follow the acute manifestations of infective arthritis. In the hip it may simulate congenital misplacement.

Treatment.—In every case in which we suspect the condition, diagnostic aspiration is performed. If the fluid obtained contains bacteria Murphy's formalin and glycerin should be injected (2 per cent.). The mixture must be at least twenty-four hours old. In many cases this treatment is of the greatest value. If aspiration and injection fail, arthrotomy and irrigation are indicated. In all clinically severe cases and in all prolonged cases, open and irrigate, first with corrosive sublimate solution (1 : 1000), then with normal salt solution. Recent cases which are not very acute and are free from pus may be closed without drainage.

Pyogenic or Acute Suppurative Arthritis.—This condition is a form of infective arthritis and is usually due to the Staphylococcus pyogenes aureus or to the Streptococcus pyogenes, which find entrance by means of a wound, by the spontaneous evacuation into a joint of the products of an osteomyelitis, by extension of suppurative inflammation through contiguous structures, or by the blood-stream. It is necessary to remember that causative bacteria may have entered the blood or lymph at a point near to or distant from the joint (tonsils, ethmoid cells, urethra, a focus of osteomyelitis, puerperal sepsis, etc.). Of course, a wound into a joint may be the open gateway for infection. A traumatism may create a point of least resistance and bacteria may be derived from the blood or lymph. It is not very unusual for traumatic arthritis to eventuate in pyogenic arthritis. Particularly in youths and young children the symptoms of arthritis may overlie and hide a causative osteomyelitis. Sometimes gonorrhea is the cause and in rare cases septicemia is causal. In pyogenic arthritis all the joint-structures are involved and suppuration rapidly appears. Synovial membrane is converted into granulation tissue and cartilage is destroyed by pus. The greater the intensity of the inflammation, the larger the amount of granulation tissue, hence, ultimately, the greater the amount of scar tissue and the greater impairment of joint function.

The *symptoms* of acute suppurative arthritis are usually a chill followed by fever and a rapid pulse. There are severe pain, which is aggravated by motion and is worse at night; discoloration, heat, and edema of the skin; partial flexion of the joint; fluctuation, and marked constitutional symptoms of sepsis. The joint tends to rapid disorganization, and fatal septicemia is very apt to occur. In pyemic arthritis several joints become infected.

Treatment.—In every suspicious case immediately aspirate. If bacteria are found in the aspirated fluid, at once open the joint (*arthrotomy*) and irrigate it with corrosive sublimate solution (1 : 1000) and then with salt solution. In early cases which are not very violent formalin-glycerin may be injected,

the wound closed, and the limb immobilized after the operation. In a late case or a violent case, drain by rubber tissue. Always be sure whether or not arthritis is the result of osteomyelitis. If osteomyelitis exists the area of bone disease must also be operated upon. Arthritis due to staphylococci and streptococci is often secondary to bone suppuration. If a periosteal abscess exists the joint condition is almost certainly secondary. If osteomyelitis exists it requires prompt and radical treatment (see page 507). In advanced cases involving the knee Allen and Alden ("Surg., Gynecol., and Obstet.," July, 1909) open the joint by a transverse incision below the patella, disinfect with pure carbolic acid followed by alcohol, and pack with iodoform gauze. I would only regard this as justifiable in advanced and very severe cases, as it is sure to be followed by ankylosis. Although in late cases which recover after arthrotomy and irrigation there is always more or less ankylosis, many cases treated early recover without serious impairment of joint function. Early arthrotomy is of the utmost importance, and if the aspirated fluid contains bacteria we should never postpone operation or hold it in reserve while we employ Bier's hyperemic or any other conservative method. Radicalism is here the course which promises the greatest safety, and the surest retention of joint function.

Typhoid Arthritis.—This disease is a form of infective arthritis. That the bacteria of typhoid may inflame the joints is proved, and it seems certain that they can cause suppuration, although their pyogenic power has been disputed. Some claim that mixed infection is the real cause of pus formation in a typhoid joint. The typhoid bacilli enter the bones in many typhoid cases and sometimes cause osteomyelitis. Joint-disease is more common than bone-disease. Typhoid disease of a joint begins when the fever is abating, and more than one joint may be involved. Typhoid joints may recover permanently, may become ankylosed, may dislocate, or the joint-disease may lead to fatal sepsis. In most cases the joints recover. In slight cases the synovial membrane only is involved; in more severe cases capsule, cartilages, ligaments, and even bones are involved. Some cases suppurate. Septic typhoid arthritis may result from a mixed infection with typhoid bacilli and pyogenic bacteria, and is identical in symptoms and progress with ordinary septic arthritis. Typhoid arthritis proper may be monarticular or polyarticular, the monarticular form being the most common, and the hip-joint being the articulation most liable to be attacked. In most cases typhoid arthritis causes little pain. The swelling is marked, although in the hip it is concealed. Pus rarely forms. Keen calls attention to the fact that in the 84 cases of typhoid arthritis which he collected spontaneous dislocation occurred in 43, nearly all in the hip.[1] Fluid from a typhoid joint may be sterile (bacteria having died), may show mixed infection, or may give a pure culture of typhoid bacilli (A. G. Ellis, in "Jour. of Infectious Diseases," April 1, 1909).

Treatment.—A mild case is treated as a simple synovitis. If diagnostic puncture obtains fluid free from bacteria, no more radical method than aspiration and irrigation is required. If the fluid contains bacteria, inject formalin-glycerin. If this fails, incision and drainage are demanded. In some cases an autogenous vaccine appears to be of service, in others it fails utterly.

Gonorrheal Arthritis or Gonorrheal Rheumatism.—During the progress of gonorrhea the development of a painful joint does not of necessity prove the existence of gonorrheal rheumatism, for ordinary rheumatism is just as likely to arise when a man has clap as when he has not this malady. Furthermore, the term is inaccurate, as gonorrheal rheumatism is not rheumatism at all, but is an infective disorder of the joints or of the synovial membranes, the infective material being contained primarily in the urethral

[1] Keen on "The Surgical Complications and Sequels of Typhoid Fever."

discharge. Gonorrheal arthritis is one of the forms of infective arthritis. Occasionally this form of arthritis arises from gonorrheal ophthalmia (Heiman's case); it sometimes, though rarely, arises during the height of a gonorrhea, but it is more frequently met with in chronic cases or when the intensity of the inflammation is abating in acute cases. Men suffer from gonorrheal arthritis far more frequently than do women, and the seizure is very apt to recur again and again. In some cases many joints are involved, but in most cases only a few joints suffer. Osler states that the knees and ankles are most apt to be involved in gonorrheal rheumatism, and that this form of arthritis is peculiar in often attacking joints that are usually exempt in acute rheumatism ("the sternoclavicular, the intervertebral, the temporomaxillary, and the sacro-iliac"). There are two forms of gonorrheal rheumatism—an acute and a chronic form. The poison reaches the joint by way of the blood. In some cases gonococci are found in the joint fluid; in other cases they are not found. I am inclined to believe that in the milder cases, which recover without genuine pus formation, only toxins are present in the joint. In the severe cases the organisms themselves exist in the articular fluid. Osler suggests that the non-suppurative cases are due to the action of toxins taken up from the area of primary infection, and that the suppurative cases are due to infection with pyogenic bacteria. Endocarditis may occur, and it is due to micro-organisms and not to toxins.

Changes In and About the Joint.—The inflammation of gonorrheal arthritis may be located around rather than in the joint, and especially in the tendon-sheaths. Suppuration is unusual, but it may occur in joints and in tendon-sheaths. Cultures of the exudate may or may not show the gonococci. Cover-glass preparations carefully stained may or may not show gonococci.

Symptoms.—The acute form attacks, as a rule, but a single joint, but may attack several joints. The joint trouble begins with great suddenness, and is often ushered in by chilly sensations or by a distinct chill. Moderate fever arises. The pain in the joint, severe from the first, becomes excruciating. If superficial joints suffer, the skin over them becomes red and hot, and periarticular edema soon presents itself. The fluid in the joint is in most cases serous, but may become purulent. If pus forms, the fever becomes very high and chills may occur.

A chronic condition may follow the acute, but the condition may be chronic from the start. The symptoms resemble those of the acute form, but are far milder, although acute exacerbations may occur. The joint fluid is usually serous.[1] In gonorrheal arthritis there may be transitory, intermittent, and wandering pain in and about the joint, without any other symptom; one or more joints may become swollen and painful, and moderate fever may develop. One joint, especially the knee, may swell to an enormous extent, pain, periarticular edema, redness, and fever being absent (hydrarthrosis, or dropsy of the joint). Suppuration in this form of the disease seldom occurs. The tendons, the tendon-sheaths, the bursæ, and the periosteum may inflame. Whether the joints are inflamed or not inflamed, the tendon-sheaths about the wrist and ankle and the retrocalcaneal bursæ may suffer. In some cases numerous bursæ are involved. It is often difficult and is perhaps impossible to check gonorrheal arthritis. It may last for a long period, and tends to recur again and again. Iritis, periostitis, pleuritis, endocarditis, and pericarditis have been observed as complications.

The *diagnosis* between gonorrheal arthritis and acute rheumatism rests chiefly on the great chronicity, the lesser degree of fever, the excessive tendency to recurrence, and the absence of profuse acid sweats in gonorrheal

[1] See Schuller, in "Aertztl. Pract.," No. 17, 1896.

arthritis; and on the shorter course, the higher fever, the profuse acid sweats, the lesser tendency to rapid recurrence, the greater proneness to symmetrical involvement, and the great liability to cardiac and visceral complications in rheumatic fever. Furthermore, in gonorrheal arthritis a gonorrheal infection (urethral or ocular) certainly exists or recently existed; in ordinary rheumatism a urethral discharge may, of course, happen to be present. Gonorrheal arthritis is apt to affect certain joints which acute rheumatism seldom attacks.

Treatment.—Because of the lingering character and dangerous nature of gonorrheal arthritis and because if unchecked it is liable to produce grave impairment of function, treatment should be prompt and radical, as advocated by Halsted many years ago. The joint should be aspirated and if the fluid obtained contains gonococci or any pyogenic bacteria, formalin-glycerin should be injected. If this fails, the joint should be opened and irrigated. If pus is absent and the case not very violent, the joint may be injected with formalin-glycerin and the wound can be closed without drainage. If pus is found by incision, irrigate, drain, and immobilize. In cases free from pus Bier's treatment is of value (see page 112). Drug treatment is of little value in gonococcal arthritis. The salicylates, the alkalis, and salol are useless; iron, arsenic, and strychnin are possibly of some benefit. Quinin is thought to be helpful in some cases. Large doses (1 dram) of syrup of iodid of iron are given by some clinicians, associated with tonic doses of corrosive sublimate. Iodid of potassium seems to be of a certain amount of value. The inflamed joints are usually wrapped in cotton and bandaged, and every day a little blue ointment is rubbed into the skin about them. If the inflammation lingers, it is customary to use the hot-air oven, massage, and gentle passive motion, to apply blisters, or to counterirritate with the hot iron. The object in this stage is to absorb infiltrations and adhesions and thus lessen stiffness. Early passive motion allays reflex muscular contractures, combats atrophy, and prevents adhesion (see Bier and Baetzner, in "Practitioner," June, 1912). It is thought by some competent clinicians that antigonococcic serum possesses distinct value, greatly alleviating pain and favoring the restoration of joint mobility. My experience with it is as yet too insignificant to justify me in expressing an opinion.

The value of vaccine treatment is estimated highly by some, but many have obtained no beneficial results.

Pneumococcus Arthritis.—This is a rare condition, although Herrick collected 52 cases ("Amer. Jour. of Med. Sciences," July, 1902). Examination of the blood may or may not discover pneumococci, and pneumococci may be found in the blood during pneumonia, when the joints are free from disease. The inflammation may attack any joint, but is most apt to arise in a joint weakened by previous injury or damaged by rheumatism or gout. Alcoholics are more prone to suffer than others. In a great majority of cases the disease is associated with lobar pneumonia, but Cole's case proves that the lung may be free ("American Medicine," May 31, 1902). As a rule, a single large joint is attacked, and the knee is most liable to suffer. The synovial membrane alone may be involved or cartilages may suffer and bone be attacked. The fluid may be serous, but is usually purulent (Herrick). I have seen 2 cases: in 1 case the knee only was involved; in the other, both knees, one elbow, and one shoulder were attacked. In Cole's series of 41 cases, 13 exhibited involvement of more than one joint. The inflamed joint is frequently completely destroyed. Pneumococcus arthritis develops, as a rule, soon after the crisis of pneumonia, but Herrick says it may arise as late as three weeks after the crisis.

The diagnosis is made by the history of pneumonia, the development of septic symptoms, and the signs of joint inflammation. It is confirmed

by aspiration and examination of the fluid. The disease is very fatal. In Herrick's series of cases over 65 per cent. were fatal. In Cole's series of cases there were 28 deaths and 13 recoveries. Even if the patient recovers, the convalescence is prolonged and more or less ankylosis is to be expected.

Treatment.—A non-purulent effusion may be treated by aspiration if bacteria are not found in the fluid. If the aspirated fluid contains bacteria, formalin-glycerin is injected. If this fails, or if pus is present, the joint should be opened and drained.

Syphilitic Arthritis.—(See pages 326 and 331.)

Acute Rheumatic Arthritis; Rheumatic Fever or Acute Rheumatism.—Acute rheumatism is a self-limited febrile malady whose characteristic features are polyarthritis, profuse acid sweats, and a tendency to heart involvement. There is some evidence to indicate that acute rheumatism is a form of infective arthritis, the bacteria being deposited in the synovial tissues and later perhaps entering into the joint cavity. Arthritis of many joints has followed intravenous injection into animals of diplococci obtained from the throat of a man suffering from rheumatic angina (Poynton and Paine at Manchester meeting of the Brit. Med. Assoc., 1902). John O'Conor[1] believes that acute rheumatism is a condition "something similar to gonorrheal arthritis and pyemia, the germ or toxin gaining admission to the body through the tonsil or other microbic trap-door, and that the joint invasion is promptly followed by a form of infective arthritis accompanied with general toxemia; and, furthermore, the infected joints serve as incubators, where the poison is elaborated and passed into the circulation and thus conveyed to other articulations and to the heart."

Symptoms of Acute Rheumatism.—In acute rheumatism the case begins with malaise and fever, and one or more joints become affected. The inflammation spreads from joint to joint, is apt to be symmetrical, and when it arises in fresh joints, usually disappears quickly in those previously affected. The temperature is high, the skin sweats profusely, the joints are red, swollen, hot, and excruciatingly painful, and the structures about the joints are edematous. After a short time the inflammation subsides in one joint and passes into another, the joint first attacked regaining its functions. Suppuration does not take place. Anemia is pronounced, exhaustion is profound, the sweat is sour, the saliva is acid; the urine is acid, scanty, high colored, often contains albumin, and is deficient in chlorids. Cardiac disease is apt to be produced (endocarditis, pericarditis, or myocarditis). Nodules may form upon fibrous structures, hyperpyrexia is not unusual, and cerebral or pulmonary complications may occur.

The *treatment* of acute rheumatism comprises the use of alkalis, salicylates, etc. (See a book upon practice of medicine.) O'Conor is a believer in incising and draining the inflamed joints; and if the theory of an infective origin is correct, this treatment is rational. I have never ventured to do it, but would consider the advisability of doing so if the ordinary treatment proved futile. O'Conor operates early and believes that this is the real way to arrest the disease and prevent complications, but his views have not met with general acceptance.[2]

Chronic rheumatism sometimes follows repeated attacks of acute rheumatism, but oftener arises insidiously in people who have been exposed to cold and damp, who have suffered from poverty, hardship, and privation, or have had much worry. The capsule and tendon-sheaths thicken, and there is usually but little effusion into the joint, but the articulation becomes stiff and painful. The joint-cartilages are occasionally eroded. Muscular atrophy occurs.

[1] "Lancet," Jan. 24, 1903. [2] Ibid.

Symptoms of Chronic Rheumatism.—In chronic rheumatism the affected joints are stiff and painful and are a little swollen, but not red. Dampness and cold aggravate the symptoms. One joint or many may be affected, but usually several are involved. Passive movements cause the joint to creak and develop crepitus in the tendon-sheaths. The muscles are wasted. Anemia is usually pronounced. The smaller blood-vessels become surrounded by fibrous tissue which progressively contracts and lessens the blood-supply of the synovial structures. The joints may ankylose. There is no fever and no tendency to suppuration, and the disease is incurable.

Treatment.—In chronic rheumatism maintain the general health of the patient, give courses of iron, arsenic, and strychnin, and an occasional course of iodid of potassium or a salt of lithium, and, if possible, send him every winter to a warm climate. Turkish baths give considerable temporary relief. The waters and regimen of Carlsbad and Vichy are of positive though temporary benefit, and the sufferer may obtain relief at the hot springs of Virginia. The patient must avoid damp and must wear woolens. Frictions, the douche, massage, flying blisters, counterirritation with the hot iron, ichthyol ointment, and mercurial ointment are of benefit. Subjecting the diseased joint to a very high temperature by placing it daily in a hot-air apparatus often does great good. The pains of chronic rheumatism may be greatly benefited by the plan communicated to me by Dr. J. T. Rugh. He makes a mixture of 14 min. of glycerin, 14 min. of sterile water, and 1 gr. of crystallized carbolic acid. This is injected at two points, about the articulation and in the extracapsular structures. As soon as an injection has been made the area must be vigorously rubbed to diffuse the fluid and prevent sloughing. The joint must be kept at rest for three days. Injections can be repeated at intervals of five days. In partial ankylosis it is proper in some cases to give ether and break up the adhesions.

Gouty arthritis, which appears especially in the smaller joints (as the fingers and the metatarsophalangeal joints of the great toes), is due to a deposition of urate of sodium in the joint and in the periarticular structures. The irritant urate of sodium causes inflammation, inflammation leads to the formation of granulation tissue, granulation tissue is converted into fibrous tissue, and the fibrous tissue contracts and thus deforms the joint and limits its mobility. A great mass of urates clinging to a joint constitutes a *chalk-stone.*

Symptoms.—The premonitory symptoms may be observed for a day or so, but the acute seizure usually occurs early in the morning, the patient, as a rule, being aroused by excruciating pain in the metatarsophalangeal articulation of one of the great toes. The joint swells, and the skin over it feels hot to the touch and becomes red and shiny. There is often considerable fever. After a few hours the intensity of the seizure abates, only to recur again with renewed violence early the next morning, these remissions and recurrences taking place during six or eight days, until the attack subsides. In patients with *chronic gout* many joints are stiffened and deformed as a result of repeated attacks. Chalk-stones form, and the skin above them may ulcerate. Such patients are chronic dyspeptics, have high-tension pulses, their hearts are hypertrophied, and their urine contains albumin and casts.

The *treatment* of gouty arthritis belongs to the physician, and not to the surgeon, although to the latter the symptoms of the disease should be known, so that it may be diagnosticated from other maladies.

Osteo-arthritis (*Rheumatoid Arthritis; Arthritis Deformans; Rheumatic Gout*).—In this disease, which is not a combination of gout and rheumatism, the synovial membrane and cartilages are affected, the periarticular structures are involved, and masses of new bone are formed.

Osteo-arthritis possibly has in certain cases, as John K. Mitchell long ago

pointed out, a nervous origin. It arises especially in persons who have been worried, driven, and harassed. There is apt to be muscular atrophy, trophic lesions of the hair and nails are likely to appear, and the symptoms are disposed to be symmetrical. The causative lesion has not been determined. The condition is now generally regarded as of toxic origin. The foci of infection may lie in any part of the body, but are most frequent in the tonsil, accessory sinuses of the nose and nasopharynx, the middle ear, the bronchial glands, the mesenteric glands, and the intestines, especially the large intestine. The disease is commoner in women than in men. The greatest liability exists between the ages of twenty and forty, but children may acquire the disease, and it may also be developed in people far beyond middle life. Apes in captivity may develop it. Arthritis deformans may attack the rich or the poor; it does not result from gout, nor does it often follow rheumatism; it is not caused by damp and cold, and only in rare cases does it arise after traumatism of a joint.

Osteo-arthritis differs from gout in the entire absence of urate deposit, and it differs from chronic rheumatism in the extensive alterations in the joint structures. The changes begin in the cartilage; the cartilage-cells multiply, the intercellular substance degenerates, the pressure of the bone causes thinning, and at length the cartilage is entirely destroyed and the bone exposed. The exposed bone is altered in shape, is hardened, and is worn away in the center, the periphery increasing in thickness by ossific deposit, the center deepening by absorption. The margins are not only thickened, but are bulged and lengthened by deposit. The fringes of the synovial membrane hypertrophy and multiply, and some of them are apt to break off (*loose cartilages*). The capsule and the ligaments of the joints, as a rule, become fibrous and contract; but they may soften, relax, and permit of dislocation. The joint usually contains no effusion, but in some cases there is great effusion (*hydrarthrosis*). The tendons about the joint may become fibrous and contracted, they may ossify, they may be separated from the bone, or they may be destroyed entirely. Deformity is marked and motion is limited. The fingers, when involved, show nodules on the sides of the joints (Heberden's nodules). The vertebræ may be involved. Almost all the joints may suffer. Suppuration does not occur.

Symptoms.—Charcot divides osteo-arthritis into three forms, and gives their symptoms, as follows:

1. *Heberden's nodosities*, which condition is commoner in women than in men, usually begins between the ages of thirty and forty, and is especially common in neurotic subjects. The interphalangeal joints become the victims of attacks of moderate swelling and of some tenderness, which attacks are not severe, but recur again and again. After a time small hard swellings (nodosities) appear upon the sides of the dorsal surface of the second and third phalanges, remain permanently, and slowly increase in size. The joints become stiff and creak on movement, the cartilages are destroyed, and contractions and rigidity develop, but there is no fever and the larger joints are not involved. The malady is incurable.

2. *Progressive rheumatic gout*, which may be acute or chronic. The *acute* form begins as does rheumatic fever. There are moderate fever and swelling, without redness, of a number of joints, of bursæ, and of tendon-sheaths; the joints are stiff and crepitate, and are apt to be symmetrically involved; muscular atrophy begins early and rapidly becomes decided; pain is slight. This acute form is apt to arise in young women after pregnancy, but is not unusual at the climacteric and in children. Anemia always exists. The case is apt to advance progressively until a number of joints are firmly locked, when it may become stationary. Another pregnancy will develop anew the acute symptoma. In the *chronic* form swelling and pain on movement are noted in certain joints. The involvement is apt to be symmetrical. Attacks of swelling

and pain alternate with periods of apparent quiescence, but the disease does not cease its advance. Articulation after articulation is attacked by the malady until almost all the joints are involved; deformity and stiffness become pronounced, and pain may or may not be severe. There is no fever. Muscular atrophy is marked.

3. *Partial rheumatic gout* or *monarticular rheumatism* attacks one articulation, and it is most often met with in old men. It may fix itself on the vertebral column, on the knee, on the shoulder, on the elbow, or on the hip. The joint grates and becomes stiff, swollen, and deformed; the muscles atrophy; there is usually pain, but fever is absent.

Osteo-arthritis or **partial rheumatic gout of the hip-joint** seldom occurs before the age of forty-five, but is occasionally, though very rarely, met with in persons under twenty-five. If the disease arises in an elderly person, it is often called *morbus coxæ senilis*. In some cases only the hip-joint is attacked; in many cases other joints are also diseased. Osteo-arthritis of the hip may follow an injury. Usually the disease is unconnected with traumatism, begins very gradually, and advances slowly. There is pain, often mistaken for sciatica, in and about the joint, and there is increasing stiffness. The pain and stiffness are worse when the patient first moves after resting. Lameness becomes noticeable, and grating can be detected in and about the joint. The symptoms become gradually worse, although at times they may seem to improve for brief periods. The lameness and the stiffness are greatly aggravated, and the pain becomes very severe, even when at rest. Shortening takes place, the great trochanter ascends above Nélaton's line, the limb is usually abducted, but in very rare cases is adducted, and finally ankylosis occurs.

Partial rheumatic gout of the vertebral articulations causing fixation is called *spondylitis deformans* (see p. 848).

Treatment.—Osteo-arthritis cannot be cured, but in some cases it remains stationary for many years. I have seen one case apparently arrested by removal of a diseased appendix. It is claimed by some that Lane's operation of extirpation of the large intestine may arrest it. As yet I would not feel justified in recommending a theoretical operation with the idea of directly benefiting osteo-arthritis. I would, however, remove, if possible, any *obvious* area of infection. The usual plan of medical procedure is to treat the anemia by iron, arsenic, nourishing food, and have the patient out in the fresh air as much as possible. Debility is met by the administration of strychnin. Hot baths of mineral water do good. It is claimed that the hot-air apparatus is of service. Douches improve these cases, but electricity is useless. Counterirritants do no good. Massage retards the progress of the case, relieves the pain, aids in the absorption of effusion, and delays fixation. During an acute exacerbation the joint should be put at rest for a time and evaporating lotions applied for a few hours. In an exacerbation in disease of the hip the patient should be put to bed and have extension applied. The patient is, unfortunately, liable to develop the opium-habit. If dropsy of a joint arises, try compresson by Martin's bandage, and, if this fails, aspirate and wash out the joint with a 2 per cent. solution of carbolic acid. Patients with rheumatic gout do best in a warm, dry climate. Cod-liver oil does good, as it improves nutrition and hence retards the progress of the disease. Do not be tempted to immobilize the joints beyond a day or two: fixation only hastens ankylosis. Howard Marsh[1] maintains that, as a rule, but little good comes from manipulation. He makes the following exceptions: when one joint only is affected; when the joint is very stiff but not very painful; when the patient is in good general health and is not beyond middle age. If only one joint is involved it may be proper to produce ankylosis by operation. When ankylosis occurs all symp-

[1] "Diseases of the Joints and Spine."

toms subside. Albee describes an operation for osteo-arthritis of the hip-joint. He removes a thin layer from the top of the head of the femur and a similar amount of bone from the roof of the acetebulum. The two surfaces are held in contact until union occurs. In the knee-joint Hibbs bridges the front part of the joint with the denuded patella. Later in such a case, after all symptoms have subsided, it may be justifiable to re-establish function by interposing a connective-tissue flap or chromicized pig's bladder (R. T. Taylor).

Trophic Joint Affections (*Arthropathies*).—It is well known that certain diseases and injuries of brain, cord, and nerves may be responsible for arthritic changes (hemiplegia, injury of the cord, locomotor ataxia, neuritis).

From three to six weeks after an apoplexy the joints of the palsied side are apt to suffer from inflammation. The condition following apoplexy is one of synovitis. Any joint may suffer, but the hip eldom does. A well-known arthropathy is Charcot's joint (Figs. 391, 392).

Fig. 391.—Charcot's joint.

Charcot's Disease (*Tabetic Arthropathy; Charcot's Joint; Neuropathic Arthritis*).—This condition is an osteo-arthritis due to trophic disturbance, arising in a sufferer from locomotor ataxia, and is anatomically identical with osteo-arthritis, which was described above. The knee is most apt to be attacked, and the hip suffers more often than any joint but the knee. The condition may develop in the shoulder or elbow. The smaller joints sometimes, though seldom, are involved. More than one joint may suffer. The disease in most cases begins acutely, often as a sudden effusion, which after a time may disappear. In most cases, however, the joint becomes rapidly disorganized. The swelling is usually very marked and is sometimes enormous. In the earliest stages it is due to periarticular edema and to articular effusion. Pain is slight or is absent, there is no constitutional involvement, and the condition is unconnected with injury. Some cases begin without this preliminay acute swelling, disorganization being manifest from the beginning. When disorganization has once begun, it continues inexorably. Bony masses form around the articular cavity, in the ligaments, and in the cartilages. The bones and cartilages are rapidly destroyed and absorbed; fracture is apt to occur; the joint creaks and grates; the softening and relaxation of the ligaments permit an extensive range of movement; great deformity ensues; dislocation is apt to occur; muscular atrophy is decided, and pus occasionally, though very rarely, forms. There is sometimes, but seldom, repair. Charcot's joint differs from rheumatoid arthritis in the usual acute onset and the painless course. The complete or nearly complete freedom from pain is one of the most striking features of the condition. In saying there is freedom from pain we mean freedom from pain in the joint, from the pain and tenderness in the regions in which we expect to find them in an inflamed joint. Usually these patients, though free from pain in the joint, suffer much from the lightning pains of locomotor ataxia. Gastric crises are not uncom-

mon (Bramwell). Charcot's joint is more common in female than in male tabetics. In saying that Charcot's joint is often of sudden origin, we mean that in a single night, as Charcot pointed out, swelling of a joint may arise. In a day or two the joint swelling becomes great, and if aspiration is performed, yellow serum is obtained. In a week or two the joint begins to creak on movement.

The *treatment* of Charcot's disease consists in the wearing of an apparatus to sustain the joint. Resection is recommended by some, but most surgeons do not advise its performance. Southam advocates amputation for certain cases of Charcot's joint. He has performed the operation on 4 patients. He amputated twice for ankle-joint disease and twice for disease of the tarsus. In every case the stumps healed quickly and without suppuration. Southam was led to perform amputation on his first case by the report of Jonathan Hutchinson's case of amputation of the leg for perforating ulcer and disease of the bones of the foot in a tabetic.

Fig. 392.—Charcot's joint.

Osteo-arthropathie Hypertrophiante Pneumique (*Marie's Disease*).—A condition associated with, and possibly springing from, pulmonary disease, and characterized by enlargement of joints, thickening of the finger-ends, and the formation of a dorsolumbar kyphosis. The joints are painful, the skin undergoes pigmentation, and profuse perspiration is often present. The head entirely escapes in this disease, which immunity marks a distinction from acromegaly.

Hysterical joint (*Brodie's joint*) is a condition mostly encountered in young women. The disease occurs most commonly in the knee and the hip, and often follows a slight injury which acts as an autosuggestion, a latent hysteria being awakened into action and localized, though severity of the injury does not determine the severity of the symptoms. The disease may ensue upon synovitis or arthritis, or may arise without apparent cause. The patient complains of pain in and stiffness of the joint, resists passive motion strenuously, and claims that it causes much pain. There is occasionally some muscular atrophy from want of use, and the joint is a little swollen. The skin is hyperesthetic, and a light touch causes more pain than does deep

pressure. The muscles may be rigid. The joint may be maintained either in flexion or in extension, but it is rarely in the exact degree of flexion assumed for ease in a true joint inflammation, and the position is apt to be changed from day to day or from hour to hour. The skin is usually pale and cool, but may be red and hot, because of hyperemia. A periodically developed heat may be observed, especially at night, accompanied apparently by much pain. The alleged pain in some cases is neuralgia, but in most cases is a pain hallucination. There is no effusion into the joint, and swelling does not exist, although occasionally there is slight periarticular edema. In some rare cases organic disease arises in a hysterical joint.

Hysterical phenomena are seldom isolated, but are associated with certain stigmata which may be latent. These stigmata are concentric contraction of the visual fields, pharyngeal anesthesia, convulsions, hysterogenic zones, globus hystericus, clavicus hystericus, zones of anesthesia, especially hemianesthesia, and hyperesthetic areas. Such patients are predisposed by inheritance, and have previously, as a rule, had nervous troubles. Hysterical phenomena, be it remembered, lack regularity of evolution, and are produced, altered, or abolished by mental influences and physical sensations which are without effect in causing, modifying, or curing organic disease. The general health, as a rule, is good, but neurasthenia may coexist. In examining these patients the observer will note that the symptoms disappear when the attention is diverted; that they are out of all proportion to the local evidences of disease; that there is no sign of joint destruction, and that a light touch may cause more pain than does firm pressure. If the patient is anesthetized, perfect joint mobility will be found without any evidences during function of joint changes.

The *treatment* for a hysterical joint comprises attention to the general health, the employment of nourishing and easily digested food, the prevention of constipation, and the administration of tonics if they are needed. The surgeon must dominate his patient's mind and make her realize that he is master of the case. He is to be an inexorable but just ruler—never a brutal or a cruel one. If possible, send the patient away from the harmful sympathies of her home and let her have the rest treatment of S. Weir Mitchell. Local remedies applied to the joint do harm, as a rule, by concentrating afresh the patient's attention upon the articulation, although the hot iron sometimes does good. Suggestion in the hypnotic state may be tried. The use of morphin should be avoided as being the worst of enemies. Never immobilize the joint, and always use massage, passive motions, and frictions.

Neuralgia of the joints as an independent, isolated affection is extremely rare, though as a complication of other diseases it is by no means uncommon. Neuralgia is more common outside of the joints than in them, and periarticular neuralgia is especially frequent about the knee and the ankle. Joint-neuralgia may arise in any person, but it is more commonly present in young neurotic females. The pain may be persistent, or it may occur in periodic storms, and it is often associated with neuralgia in other parts. The pain may be dull and aching, but it is more often sharp and shooting. Joint-neuralgia is associated with tenderness on pressure, soreness on motion, often with transitory swelling without redness, and sometimes with numbness of the extremities. The *diagnosis* depends on the temperament of the patient, the sudden onset of the pain, the absence of constitutional symptoms, and the free mobility of the joint, especially under ether. Articular neuralgia may depend upon disease or injury of the central nervous system, upon malaria, syphilis, neurasthenia, rheumatism, gout, hysteria, and neuritis, and may be due to reflected irritation, especially from the ovaries, the uterus, or the rectum.

The **treatment** to be observed in joint-neuralgia is to maintain the general health. Examine for a possible exciting cause, and, if found, remove it. Give a long course of iron, quinin, and strychnin or arsenic. In rheumatic or gouty subjects administer suitable drugs and insist upon the use of a proper diet. During the attack use phenacetin. Morphin must occasionally be given in severe cases, but be sparing of it, and never tell the patients they are taking it, as there is a possibility of their forming the opium-habit. Locally, employ frictions, ointment of aconite, heat, and keep upon the part a piece of flannel soaked in a mixture of soap liniment, laudanum, and chloroform (Gross). Never allow the joint to stiffen; any tendency to stiffness should be met by daily massage, frictions, passive motion, and hot and cold douches. In some rare cases nerve-stretching or neurectomy becomes necessary.

Articular Wounds and Injuries.—A *penetrating* wound is very serious, and it may be due to a compound fracture, to a compound dislocation, to a gunshot-wound, or to a stab. If a bursa near a joint be opened, secondary penetration may occur as a result of suppuration. In a penetrating wound, besides pain, hemorrhage, and swelling there is a flow of synovial fluid. A small amount of synovia flows from an injured bursa, a large amount from an open joint.

Treatment.—If a joint is opened aseptically (as when incised by the surgeon) the wound heals nicely under rest and asepsis. If a joint is opened by a septic body, suppurative arthritis is apt to arise, and the surgeon endeavors to prevent it by asepticizing the surface, irrigating the joint, draining, applying antiseptic dressing, and securing rest. Normal salt solution is the best agent for irrigation, as it does not injure joint endothelium. Active antiseptics may lessen tissue resistance, and thus may actually favor infection. In gunshot-wounds inflicted by pistol bullets or sporting rifle bullets, if antisepsis is not employed, suppuration is inevitable; hence military surgeons in the past, as a rule, have advocated amputation or excision in gunshot-splinterings of large joints. Recent experience shows that the wound of a large joint produced by a hard-jacketed and small-caliber bullet may heal with little trouble. In articular wounds the surface is sterilized, and usually the wound is enlarged, the finger is introduced to discover and remove foreign bodies, through-and-through drainage is secured, a tube is inserted, the joint is irrigated, antiseptic dressings are applied, and the extremity is placed upon a splint. Very severe joint injuries demand resection or even amputation. Ankylosis, more or less complete, often follows a gunshot-wound of a joint. If the joint suppurates, the drainage must be made more free, sinuses must be slit up and packed, sloughs must be cut away, dead bone must be gouged out, and the patient must be placed upon a stimulant and tonic plan of treatment. The above remarks do not apply to wounds inflicted by the modern military projectile. Such wounds are not of necessity infected, and recovery may be prompt and uneventful if the surface is sterilized and antiseptic dressings and splints are applied.

Sprains.—A sprain is a joint-wrench due to a sudden twist or traction, the ligaments being pulled upon or lacerated and the surrounding parts being more or less damaged. A sprain is often a self-reduced dislocation (Douglas Graham). The joints most liable to sprains are the knee, the elbow, and the ankle. The smaller joints are also often sprained, but the ball-and-socket joints are infrequently sprained, their normal range of free movement saving them; they do occasionally suffer severely, however, as a result of abduction. In a severe sprain the ligaments are torn; the synovial membrane is contused or crushed; cartilages are loosened or separated; hemorrhage takes place into and about the joint; muscles and tendons are stretched, displaced, or lacerated; vessels and nerves are damaged; the skin is often contused; and portions of

bone or cartilage may be detached from their proper habitat, though still adhering to a ligament or tendon (sprain fractures). Sprains are commonest in young persons and in adults with weak muscles. They happen from sudden twists and movements when the muscles are relaxed. A large part of the support of joints comes from muscles, and when muscles are suddenly caught unawares they do not properly support the joint, and a sprain results. A joint once sprained is very liable to a repetition of the damage from slight force. Sprains are common in a limb with weak muscles, in a deformed extremity in which the muscles act in unnatural lines, and in a joint with relaxed ligaments.

Symptoms.—There is severe pain in the joint, accompanied by general weakness. Nausea, vomiting, and even syncope may occur. There is impairment or loss of ability to move the joint. The above-described condition is succeeded by a season of relief from pain while at rest, numbness being complained of, and pain on motion being severe. Swelling arises very early if much blood is effused. In any case swelling begins in a few hours. Extensive effusion, by separating joint surfaces, produces slight lengthening of the limb. Movements of the joint become difficult or impossible; the tear in the ligament may sometimes be distinctly detected by the examining fingers; pain and tenderness become intense; joint-crepitus will be manifested, and in a day or two discoloration becomes marked. Moullin and others have pointed out that when a muscle is strained the skin above it becomes sensitive, especially at tendinous insertions over joints. As muscles are invariably strained when a joint is sprained, there is always some cutaneous tenderness. There is also tenderness over a sprained joint due to capsular injury, bands of adhesions, etc. Tenderness is apt to arise at certain reasonably fixed points: in a hip-joint injury it is found behind the great trochanter, in a knee-joint injury by the side of the patella, in an ankle-joint injury to the inner side of the external malleolus (Culp). When the vertebral articulations are sprained the muscles of the back are rigid, the skin is often sensitive, pain may be awakened by pressure or by certain movements, but there is no sign of cord injury in an uncomplicated case.

Diagnosis and Prognosis.—Sprain-fractures can be diagnosticated with certainty only by the *x*-rays. In the *diagnosis* of a sprain, fracture and dislocation must be considered. In fracture, crepitus and mobility exist; in dislocation, rigidity. The diagnosis of sprain should be made by a consideration of the joint involved, of the age, of the nature of the force, of the length of the limb, of the fact that the patient could use the joint for at least a short time after the accident, and of the local feel and movements of the part. In some cases examine under ether, in some apply the *x*-rays. Many injuries about the ankle which we would have formerly regarded as sprains, are shown by the *x*-rays to be fractures. The *prognosis* depends on the size of the joint, on the extent of laceration, on the amount of intra-articular hemorrhage, and on the age of the patient. The danger is ankylosis. A sprained joint is a point of least resistance to tubercle bacilli. In rare cases after a sprain of the hip-joint osteo-arthritis arises. In some few cases after a sprain of the hip the head of the bone undergoes absorption.

Treatment.—In a mild sprain apply at once a silicate, rubber plaster, or plaster-of-Paris dressing. The first indication after the infliction of a severe sprain is to arrest hemorrhage and limit inflammation. For the first few hours apply pressure and an ice-bag. Wrap the joint in absorbent cotton wet with iced water, apply a wet gauze bandage, and put on an ice-bag. After some hours place the extremity upon a splint and to the joint apply flannel kept wet with lead-water and laudanum, iced water, tincture of arnica, alcohol and water, or a solution of chlorid of ammonium. These evaporating lotions produce cold. Instead of them an ice-bag may be used for a day. Leeches

around the joint do good. Constitutionally, employ the remedies for inflammation. Morphin or Dover's powder is given for the pain. Judicious bandaging limits the swelling.

After twenty-four hours, if the symptoms continue or if they grow worse, use hot fomentations, the hot-water bag, plunge the extremity frequently in very hot water, or apply heat by Leiter's tubes. When the acute symptoms begin to subside rub stimulating liniments upon the joint once or twice a day and employ firm compression by means of a bandage of flannel or rubber. Frictions should be made from the periphery toward the body. Many cases do well at this stage under the local use of ichthyol and lanolin (50 per cent.), tincture of iodin, or blue ointment. Later in the case use hot and cold douches, massage, frictions, passive motion, and the bandage. Passive motion and massage are begun a day or so after swelling ceases. If they cause the swelling to return, abandon them for several days and then try them again. Blisters are used when tender spots persist and stiffness is manifest. If stiffness becomes marked, move the joint forcibly. Give iodid of potassium and tonics internally, and insist on open-air exercise. If the person is gouty or

Fig. 393. Fig. 394.

Figs. 393, 394.—Gibney's method of strapping in sprains of the ankle.

rheumatic, use appropriate remedies. Van Arsdale treats sprains by massage almost from the start. Gibney treats them by strapping with adhesive plaster. Gibney's dressing is of great service in a sprain of the ankle (Figs. 393, 394). Many sprains may be put up in an immovable dressing the first day or two after the accident. If the joint contains much blood, aspiration should be practised before the dressing is applied.

The hot-air oven is a very valuable method for treating recent sprains, and the swelling, pain, and stiffness which follow sprains of the extremities. The sprained extremity is placed in an oven, and the part is subjected to heat for an hour. The next day the treatment is repeated, and on as many subsequent days as may be necessary. In an acute sprain the pain often disappears during the first application of heat. In the intervals between the use of the oven the extremity should be at rest, perhaps upon a splint.

Sprain of the Sacro-iliac Articulation.—This condition was first described by Goldthwait. A fall, lifting a heavy weight, a blow, or a twist may injure the articulation. Normally there is slight motion, rupture or stretching of ligaments may lead to increased motion, and any considerable

range of motion at the synchondrosis means lack of solidity and want of support. A sprain may arise from long-continued standing, bending, lying, or sitting. A sprain of this articulation may be caused by parturition, and also, as shown by Dunlop, it may develop during anesthesia because of obliteration of the normal lumbar curve by lying on a flat table without a support under the lumbar region ("New York Med. Jour.," July 10, 1909). Dunlop thus explains, and I think truly, the severe backache which is so common after anesthesia.

A sprain causes severe pain, greatly aggravated by standing, by rising up from recumbency, by movements of the ilia which jar the joint, and frequently by direct pressure upon the synchondrosis. There is often lateral spinal curvature due to spasm, and the concavity is toward the injured side.

There is pain in the injured articulation, but there may be a general backache, and, just as in sacro-iliac tuberculosis (see page 624), there may be pain in the sciatic nerve, in the groin, and in the hip-joint.

When some of the sacro-iliac ligaments are ruptured or relaxed we get the chronic condition described by John Dunlop (Ibid.) and which he calls *sacro-iliac relaxation.* When this exists the individual may injure the articulation again and again because of its unsteadiness, he may now and then have trouble, he may be in a constant condition of helplessness, with backache, groinache, pain in the hip and over the ischial tuberosity, lumbar rigidity producing lateral curvature, etc. I believe in the reality of the condition.

Treatment.—A recent sprain is treated by rest in bed and adhesive-plaster strapping, reinforced by a canvas roller around the pelvis. In a chronic case (sacro-iliac relaxation), after securing by manipulation normal relations in the articulation, insist on rest and apply a spica bandage of plaster of Paris. If there is marked tendency to displacement, ankylosis may be secured by operation. Fixation by a bone-graft from the tibia should give the most rapid and permanent result (Rugh).

Rupture of the Crucial Ligaments of the Knee.—This is a rare injury. Rupture of both ligaments is unusual except in very grave injury, such as complete dislocation, and then other ligaments are also torn or destroyed.

The anterior crucial ligament instead of rupturing from force may cause avulsion of the tibial spine (see page 610). When this portion of bone is not torn off, the ligament itself tears off from the femur rather than from the tibia. The posterior ligament, too, tends to tear off from femur rather than tibia. Pagenstecher ("Deutsch. Med. Wochenschrift," Bd. xxix) believes that the anterior ligament may be ruptured by forced flexion of the knee and by blows applied to the posterior part of the head of the tibia when the knee is flexed. The same surgeon maintains that the posterior ligament may be ruptured by blows applied to the front of the head of the tibia when the knee is flexed. Pringle ("Annals of Surgery," August, 1907) maintains that the anterior ligament may be ruptured by "flexion, abduction, and internal rotation of the leg at the knee." If the ligaments are ruptured there will probably be abnormal freedom of anteroposterior movement between the femur and tibia.

Pringle (Ibid.) states that if, after an injury, the knee-joint becomes distended with blood, the inference should be that one or other crucial ligament has been injured or that the tibial spine has been torn off, unless some other lesion is obviously present; that if internal rotation of the extended leg is possible at the knee, or if the head of the tibia can be brought forward on the femur, or if there is unnatural abduction, the indications are that the anterior crucial ligament has been injured or the tibial spine torn off; that injury of the posterior crucial is suggested by the possibility of pushing the head of the tibia backward during flexion of the knee-joint.

In most cases exploratory incision is required to make the diagnosis.

The **treatment** is to open the joint and suture the torn ligament.

Ankylosis.—When a joint-inflammation eventuates in the formation of new tissue in and about the joint, contraction of this tissue limits or destroys joint mobility, producing the condition known as "ankylosis." Ankylosis may be *complete* (bony) or *incomplete* (fibrous); it may arise from contractures in the joint (*true* or *intra-articular ankylosis*) or from contractures in the structures external to the joint (*false* or *extra-articular ankylosis*).

There are qualifying terms to indicate the extent of stiffness—viz., false, spurious, true, bony, ligamentous, partial, complete, or incomplete ankylosis. The significance of the above terms will be better appreciated if ankylosis is considered as meaning a stiff joint. It may be stiff without being rigid. Fibrous adhesions produce stiff joints and they become rigid only when bony union takes place between the bones forming a joint.

Spondylitis deformans is bony ankylosis of vertebræ due to osteo-arthritis.

Arthritis ossificans is a progressive bony ankylosis in which numerous joints are involved and are finally completely obliterated. It is an ossifying arthritis.

Etiology.—There are various causes—viz., traumatism, eruptive fevers resulting in acute or suppurative synovitis or arthritis, gonorrheal arthritis, tuberculous arthritis, syphilitic affections of joints, bony fixation when a fracture is near or extends into a joint, and osteitis deformans. Simple fixation of an uninflamed joint cannot cause true ankylosis.

Pathology.—In complete—*i. e.*, bony—ankylosis the bones forming a joint become united by callus in much the same manner as bone-fragments are united after a fracture, or osseous bridging takes place at one or more places around the joint. Osseous ankylosis is preceded by a more or less prolonged stage of fibrous or partial ankylosis. In fibrous ankylosis, bands of fibrous connective tissue unite the bones forming a joint, thereby limiting the motion. In cases of joint stiffness produced by extra-articular fibrous, tendinous, or cicatricial contracture the joint proper remains free from adhesions for years, provided it is not and has not been involved in inflammatory action.

Diagnosis of bony ankylosis is usually made without difficulty except where there are several joints near together, as the carpus, tarsus, and the spine. When there are several joints near together the limitation of motion in one joint is generally compensated for by the excess in mobility of another, thereby rendering the associated parts capable of closely approaching normal function. Fibrous ankylosis is more difficult to recognize, especially if pain accompanies manipulative measures. It is most apt to be confused with fibrous, ligamentous, or cicatricial contractures of soft parts outside of a joint, but having more or less direct functional relations therewith.

Extra-articular thickening may usually be detected by the existence of resistance to free joint motion in one direction only, *i. e.*, that produced by the fibrous contracture while the joint moves freely in other directions. Muscular contracture, whether voluntary or involuntary, is but temporary, and is easily detected by the preternatual rigidity of surrounding parts. In bony ankylosis no voluntary muscular action can be detected, inasmuch as in the process of the formation of the callus uniting the bones the muscles have become atrophied from disuse. Conversely, voluntary muscle action about a joint always indicates that joint mobility is not entirely destroyed.

As muscular rigidity is one of the most important and reliable symptoms of joint inflammation and tuberculous invasion, it is a serious error to anesthetize a patient for examination of a joint until the full significance of the muscular action has been carefully studied.

Anesthesia removes the pain and abolishes muscle fixation and thus leaves

the unguarded joint free for manipulative movements, which are generally prejudicial and rarely beneficial. Where no muscle fixation is present, much may be learned by the careful study of a joint while the patient is anesthetized. We thus determine the character of the adhesions, whether they are extra-articular or intra-articular, whether they are fibrous, cicatricial, or osseous, and if bony union exists, whether it involves the entire joint or only a portion of it.

Skiagraphs are invaluable helps in making an accurate diagnosis, especially when stereoscopic plates are made. Definite information can thus be obtained as to the character of the uniting material, its extent, and definite location. Positive information will be given as to the relationship of the bones composing the joint, whether there is luxation, subluxation, flexion, or other abnormal position that may influence decision as to the therapeutic measures to be adopted. It is important to remember that a joint very rarely becomes ankylosed in the position of extension (the elbow may if treated in extension for intra-articular fracture). The almost invariable rule is that flexion is the posture of such joints, and the tendency is toward increase of the flexion until bony ankylosis occurs. In the steady progress of the flexion subluxation is apt to be induced.

Treatment of Intra-articular Ankylosis.—It is most important to prevent the occurrence of ankylosis, or in the event of its becoming inevitable, to avoid postures that will render the parts unfit for future usefulness when ankylosed.

The most useful position for a stiff joint is a matter of individual opinion; no definite rules have been accepted. In ankylosis of the elbow the flexed position is more useful in certain occupations than the fully extended arm. In other occupations the extended arm is most useful. In walking when the knee is ankylosed and does not tend toward flexion the extended leg is more useful than the flexed leg, but it is more difficult to manage when sitting.

The hip, when ankylosed at various angles, is made useful by the increased latitude of motion of the other hip and by the compensatory motion of the lumbar spine. To such an extent is the lower spine reciprocal when one or both hips are abnormal that it has been termed the third hip-joint. For general usefulness the best position for an ankylosed hip is 10 to 15 degrees of flexion, 10 to 15 degrees of abduction, and 5 degrees of external rotation. In this position, when supplemented by reciprocal action of the other hip and by the lower spine, a gait very closely approaching normal carriage may be obtained in walking, and the sitting posture may be possible.

Each individual joint has its own peculiar requirement and must become a subject for careful study in determining the most useful posture if ankylosis is to be permanent. The trend of modern surgery is to greatly reduce the time of fixation of a fractured bone in order to avoid joint stiffness and prevent muscular wasting. Early passive motion when judiciously employed does not interfere with the efficient treatment of a fracture, but does lessen the joint stiffness that is often a serious and painful sequel.

Stereo-arthrolysis "is that branch of arthroplasty whose object is to loosen stiff joints and produce new joints with mobility, following ankylosis" (R. Tunstall Taylor, "Surgery, Gynecology, and Obstetrics," April, 1912).

Brisément forcé or *redressement* are terms applied to the use of such manipulative force as the surgeon can judiciously employ in freeing a joint from fibrous adhesions. It is important to keep constantly in mind the danger of breaking the shaft of a bone or of separating the epiphysis when unguarded leverage of the entire shaft of the bone is used. It is of paramount importance to avoid brisément forcé in all cases where the ankylosis has resulted from tuberculosis. The plan is said to have been suggested by Louvrier, of Paris. It was advocated by Langenbeck. Brisément forcé is only curative when the adhesions

are limited to the synovial membrane. When portions of that membrane have been destroyed or when there are dense fibrous adhesions the ankylosis invariably recurs after manipulative force and often becomes worse than before. In bony ankylosis the method is out of the question.

In applying manipulative force it is not always advantageous to have the patient profoundly anesthetized. If he is profoundly anesthetized we may be tempted to apply too violent force. Severe lacerations of fibrous adhesions produce painful joints which necessitate fixation or rest for several days to permit the reunion of the torn structures. A little gain, care being taken to maintain the motion gained, mobility being gradually increased by short progressive steps, is always better than attempts to do a great deal at once. Of course the patient's co-operation is necessary.

When pain is great, much can be accomplished during primary ether anesthesia or while the patient is under influence of nitrous oxid. Bromid of ethyl and chlorid of ethyl are used by many because of their rapid action and brief effect. As stated elsewhere (see page 1209), I seldom use either of these drugs.

Fixation appliances of any kind are contra-indicated during corrective manipulations, as increased freedom of motion is essential rather than fixation. Voluntary efforts are needed to maintain the joint motion already secured as well as to increase the muscle function controlling the affected joint.

Among the operative procedures applicable to intra-articular ankylosis are excision to obtain a false joint (pseudo-arthrosis), excision to obtain a better position for the usefulness of the limb, breaking the bone after partially cutting it with an osteotome (osteotomy), and breaking the bone without any incision (osteoclasis). These several procedures have special advantages in different joints.

Lexer ("Zeit. f. Chir. Med. Orth.," Oct., 1908, p. 476), after resecting a knee-joint ankylosed at a right angle, transplanted the entire knee-joint apparatus from a freshly amputated limb. Complete union resulted. Muscle training was subsequently practised to improve the weak muscular control. Three and a half years later the result was excellent.

Weglowski ("Zent. f. Chir.," April, 27 1907) resorted to cartilage transplantation in a case of ankylosis of the elbow. After freeing and re-forming the ends of the three bones, two plates of cartilage (one-half thickness of rib cartilage) with perichondrium were taken from the sixth and seventh ribs and placed between the newly formed joint surfaces, the perichondrial surface being turned toward the humeral epiphysis. No special fixation was used. No drainage was employed. Active and passive motion was begun on the tenth day. In a month the patient had 60 degrees of free flexion and extension and full pronation and supination. Death from pleuropneumonia of three days' duration occurred in five weeks. Postmortem showed that the perichondrial surface of the cartilage was united to the humerus, while the opposite side was smooth, even shining; the cartilage was enlarging and passed without definite margin into the surface of the humerus.

Microscopic examination showed newly formed blood-vessels between the cartilage and bone; the cartilage was well preserved in its entire extent, the cells and nuclei staining well.

Huguier and Murphy revive a suggestion fifty years old. They interpose soft tissue between the bone ends after freeing the ends from ankylosing material ("Traitement des Ankyloses par la Résection Orthopedique et L'interposition Musculaire," par Le Dr. Alphonse Huguier). The plan was first suggested by Verneuil in 1860 ("Archives de Medicine," 1860). He cured temporomaxillary ankylosis by the interposition of temporal muscle and fascia. In 1899 Helferich suggested inserting a portion of the vastus internus muscle between the patella and femur, and two years later Cramer reported some

successful cases. Hoffa followed this method. Helfereich, in 1893, mobilized the temporomaxillary joint by the insertion of a flap from the temporal muscle. This was repeated by Lentz, Henle, and others. Mikulicz, in 1895, used a flap from the masseter muscle. Similar procedures were employed by Bilezguski, Hoffa, and Kusnetzow. Rochet and Schnudt with Glück, in 1902, used a skin-flap and had previously employed ivory joints to take the place of the excised structures. In 1901 Murphy operated by Verneuil's plan.

J. B. Murphy ("Jour. Amer. Med. Assoc.," May 20–27, June 3, 1905) reviews the literature of the attempt to produce new joints and says: "In our work we have been able, by the interposition of fascia and muscle, covered with a layer of adipose tissue, to produce normal movable joints with capsules and collagen intra-articular fluid." In cases of synovitis with adhesions he resects the capsule and replaces it by aponeurosis or muscle, and it is desirable, when possible, that the replacing piece contains fat, which, under pressure, will form a hygroma or artificial synovial cavity. In bony ankylosis he operates, separates the bones, removes adjacent bony prominences or processes, frees the soft parts, prevents the bones coming again in contact, and interposes between them tissue which will remain fibrous or will form a hygroma or artificial synovial surface. After wound healing has taken place, passive motion, active motion, and forcible extension are required.

W. S. Baer ("Amer. Jour. Orthop. Surg.," 1907, p. 234) advocates the use of sterilized oil injected into joints to prevent the formation of adhesions and thus increase the arc of motion. It may also be poured into a joint after arthrotomy. After using oil in the manner described, Baer summarizes as follows: "That injection of oil into joints under proper precautions is a harmless procedure; that the joint will apparently tolerate as much as it will hold.

"It is most useful in cases where adhesions have followed some acute infectious process, or in those stiff joints which are classified as arthritis deformans of the infectious type.

"Passive motions are made with less pain where the joint contains oil.

"It plays some part in preventing adhesions, so that the mobility of the joint is increased more rapidly."

W. S. Baer (Ibid., August, 1909) reviews the literature of the operative treatment for mobilizing joints, and advocates the use of chromicized pig's bladder as the most satisfactory material to place between the surfaces of the recently separated bones.

Chlumsky, disappointed with the results of muscle flaps, used non-absorbable materials, zinc, rubber, celluloid, silver, and layers of colloidin, but no permanent mobility was obtained. He then employed absorbable plates of decalcified bone, ivory, and magnesium, with somewhat better results. Baer's method of inserting chromicized pig's bladder followed the unsuccessful employment by him of Cargile membrane. The pig's bladder is tightly stitched by catgut sutures around the recently denuded bone and the wound is closed. A hip-joint two months after this procedure showed a voluntary flexion of 35 degrees; abduction of 15 degrees; adduction of 10 degrees; rotation of 25 degrees. Seven months after operation the mobility was better than that recorded at two months. Similar results are recorded of the knee and elbow.

Baer emphasizes the necessity of having the pig's bladder absorbable in thirty to forty days. It should be pliable enough to be adapted to the contour of the joint. Every raw surface should be absolutely separated by it from that with which it would tend to come in contact.

Thorn, after moblizing the joint, transplants a free flap of fascia to between the bone ends ("Zeitschr. f. Chirurgie." Bd. cviii). Hauer, of Baltimore, has also done this successfully. R. Tunstall Taylor has experimented elaborately in the endeavor to find a liquid and absorbable animal substance which, when

injected by a syringe between the denuded ends of the bones, would immediately solidify and prevent contact of bone ends for six or eight weeks. He finally selected yellow wax 1 part and lanolin from 2 to 6 parts (this melts at from 120° to 135° F.). Taylor has had some excellent results from this method ("Penna. Med. Jour.," Jan., 1913). He cautions us not to operate by any method for ankylosis due to infective arthritis until joint inflammation has been quiescent for a year or more.

Treatment of Extra-articular Ankylosis.—The treatment of false ankylosis depends upon the case. Recently contracted muscles or tendons require motion, massage, frictions with stimulating liniments, hot and cold douches, and the use of the hot-air apparatus. Violent breaking up is not satisfactory, neither is tenotomy nor myotomy. Old contractions of tendons require tendon lengthening by tendoplasty or myoplasty. Chronic inflammation of tendon-sheaths with adhesion of tendons requires excision of the sheaths. Whenever possible, excise a cicatrix that causes false ankylosis, and fill the gap with sound cutaneous tissue and fat. When the fixation is due to adhesive synovitis of the capsule, excise the capsule and attached ligaments; "the head and neck of the bone should then be surrounded by an aponeurosis or muscle to prevent the re-forming of adhesions" (John B. Murphy, in "Jour. Amer. Med. Assoc.," May 20–27 and June 3, 1905). Bony deposits are gouged away and tumors are removed. Contractures in cases of paralysis require electricity, passive motions, frictions with stimulating liniments, the hot-air bath, and general treatment. Constant and graduated pressure by means of splints and braces (with ratchet or screws) will, in many instances, restore function. The patient can be taught to alter the pressure frequently, making it as powerful as he is able to bear it.

Loose Bodies in Joints (Floating Cartilages).—The knee is the joint affected in 90 per cent. of cases, but the elbow, shoulder, hip, wrist, lower jaw, and ankle may suffer. There may be but one loose body in a joint, there may be two or more, there may be many, or even hundreds. More than one joint may be involved. The condition is commonest in adult men. These bodies may be free or each may have a stalk or pedicle; they may move about and occasionally block the joint, or may lie quietly in a joint-recess or diverticulum. They may be flat or ovoid, smooth or irregular, as small as peas or as large as plums, and may be composed of fibrous tissue, of cartilage, or of bone. There are numerous different modes of origin of these bodies, many being "detached ecchondroses or pieces of hyaline cartilage hanging by narrow pedicles" (Sir J. Bland-Sutton), and they result from enlargement and chondrification of the villi of the synovial membrane.

Symptoms.—Some bodies give rise to no symptoms for a long time and others merely cause synovitis. A loose body may produce pain and interfere with joint-function. The joint is weak and a little swollen, and the patient can perhaps feel the body and can even push it into a superficial area of the joint, where it may be felt by the surgeon. From time to time the body may get caught, thus suddenly locking the joint and producing intense and sickening pain, extension and flexion being impossible until the body slips out. It may slip out in a moment, but may not for hours or even for many days. A rather small body seems more apt to cause locking than a very large one, but if a large one does cause locking, it is more difficult to dislodge than is a small one. Locking of a joint by a loose body is followed by inflammation and effusion. If the loose body is dense and large, the *x*-ray may disclose it. Sesamoid bones in the gastrocnemius muscle must not be confused with loose bodies in the knee-joint. In some cases of loose body in the knee the diagnosis is impossible from dislocation of a semilunar cartilage, inflamed semilunar cartilage, and synovitis with proliferation of villi.

Treatment.—To relieve locking, employ forced flexion and sudden extension. Cure can be obtained only by operation. Let the patient bring the foreign body to a point where it can be felt by the surgeon, so that he can determine where it lodges. Asepticize the knee with the utmost care. Operate if possible under cocain; if not, give ether. If the body is felt before operating, fix it with a pin. The joint is now opened, explored with the finger, the foreign body extracted, and an exploration made to see that no other bodies are present. If a body has an attachment the pedicle is snipped through by scissors. The wound is sutured in two layers and the leg is placed upon a splint. Asepsis must be most rigid. The operation does not cure the causative process, and these bodies are apt to form again. When the knee is involved, some surgeons saw the patella transversely, open the joint widely, remove all foreign bodies, and seek to cure any causative process.

Luxations or Dislocations

A dislocation is the persistent separation from each other, partially or completely, of two articular surfaces. A self-reduced dislocation is called a sprain (Douglas Graham). There are three forms of dislocations: (1) traumatic; (2) spontaneous or pathological; (3) congenital.

1. Traumatic dislocations are due to injury. They are divided into—*complete* dislocation, in which the two articular surfaces are entirely separated and the ligaments are torn; *incomplete* or *partial* dislocation or *subluxation*, in which the two articular surfaces are not completely separated and the ligaments are rarely lacerated; *simple* dislocation, in which there is no wound leading from the surface to the articulation; *compound* dislocation, in which a wound leads from the surface to the joint; *complicated* dislocation, in which, besides the dislocation, there is a fracture, extensive damage of the soft parts, an opening which makes the case compound, or damage of a nerve or blood-vessel; *primitive* or *primary* dislocation, in which the bones remain as originally displaced; *secondary* dislocation, in which the dislocated bone assumes a new position, for instance, a subglenoid luxation of the humerus is primary, and it may become secondarily a subcoracoid luxation because of muscular contraction or attempts at reduction; *recent* dislocation, in which the displaced bone is not firmly fastened by tissue changes in its new situation, and its old socket is not obliterated; *old* dislocation, in which the displaced bone is firmly fastened by tissue changes in its new habitat, and the old socket is to a great extent obliterated (whether a dislocation is old or new depends on the state of the parts rather than on the time which has elapsed since the accident); *double* dislocation, in which corresponding bones on each side are dislocated; *single* dislocation, in which only one joint is dislocated; *unilateral* dislocation, in which one articulation of one bone is out of place; *bilateral* dislocation, in which symmetrical articulations are dislocated; and *relapsing* or *habitual* dislocation, which recurs frequently from slight force because of relaxed ligaments or lack of complete repair after the ligamentous rupture of a first dislocation.

2. Spontaneous, Pathological, or Consecutive Dislocations.—Spontaneous dislocation arises from such very slight force that the cause may not be identified, and it acts on a joint rendered lax by disease. It may arise in the course of chronic synovitis, tuberculous joint-disease, or rheumatoid arthritis. In Charcot's joint a spontaneous dislocation will occur sooner or later. In typhoid fever spontaneous dislocation is not uncommon. The hip-joint is most often the one attacked. *Dislocation of the hip in typhoid fever* follows a severe joint inflammation, is usually upon the dorsum of the ilium, and is frequently not noticed until convalescence has set in. If a typhoid dis-

location is seen early, reduction is easily effected, but if seen late, is impossible. The treatment for irreducible typhoid dislocation is the same as for any other irreducible dislocation. Dislocation may occur in the acute infectious arthritis of scarlatina, pneumonia, etc., from distention of the joint cavity with septic products or exudates. In infantile palsy muscular atrophy may be so great that a shoulder or hip may be easily dislocated.

3. Congenital Dislocations.—A congenital dislocation is due to a congenital joint malformation which renders it impossible for the bone to maintain a normal position, or is due to external violence during the period of uterine gestation. Congenital dislocations should not be confounded with dislocations produced during delivery. The hip is the joint most often involved. The shoulder suffers occasionally. Lannelongue maintains that congenital dislocation of the hip is due to atrophy of the muscles and of the acetabulum following spinal-cord disease. Verneuil thinks the dislocation is paralytic. Broca says that in view of the fact that the head of the bone is larger than the cavity in which it belongs, it is useless to attempt reduction by manipulation or extension, but many successful cases by the Lorenz bloodless method prove Broca's condemnation to have been too sweeping. Lorenz and Hoffa have each devised an operation for this condition (see page 711). Congenital dislocation of the shoulder requires incision, possibly excision, or the paring down of the head to fit the glenoid cavity (Phelps).

Traumatic Dislocations.—In the succeeding pages the traumatic form of dislocation will be particularly considered.

The **causes** of traumatic dislocations are divided into *predisposing* and *exciting.*

Predisposing causes are: (1) *age;* dislocations are commonest in middle life, the usual lesion of the young being green-stick fracture, and that of the old being fracture; dislocations of the radius are not uncommon in youth; (2) *muscular development*, dislocations being commonest in those with powerful muscle; (3) *sex*, males being more predisposed than females, because of their occupations and muscular strength; (4) *occuption* predisposes as a cause according as it demands the employment of muscular force, as in the carrying of burdens; (5) *nature of the joint*, ball-and-socket joints being more liable to luxation than are ginglymoid joints, because of their wide range of motion; (6) *joint-disease* predisposes by relaxing the ligaments; (7) *situation of the joint*, some joints being more exposed to injury than others.

Exciting causes are divided into—(1) external violence and (2) muscular action. *External violence* may be *direct*, as when a blow upon one of the bones forces it directly away from the other; or it may be *indirect*, as when force applied to a distant part of a bone is transmitted to its end and drives the bone out of its socket. *Muscular action* is a cause when sudden and violent muscular contraction occurs during the maintenance of a position of the joint which gives the muscles full sway, and throws the head of the bone against the weakest part of its retaining ligaments.

Pathological Conditions.—In a recent complete traumatic dislocation the ligaments are damaged, and may perhaps exhibit extensive laceration, or may show only a buttonhole laceration through which a bone projects. External force produces much laceration and little stretching of the ligaments; muscular action produces little laceration and much stretching of the ligaments. In some cases of dislocation due to external violence the structures about the joint are bruised or otherwise damaged; the old socket is filled with blood, and the bone in its new situation lies in a bloody area. Large vessels and nerves are rarely torn, though they are not unusually compressed.

If a dislocation is not soon reduced, inflammation arises in the old joint cavity and about the displaced bone, and the whole area becomes glued together, first,

by coagulated exudate, and finally by fibrous tissue. After a time, in ball-and-socket joints, the old socket fills with fibrous tissue, contracts, becomes irregular, and may even be obliterated; the head of the dislocated bone is altered in shape, its cartilage is destroyed or converted into fibrous tissue, and the pressure of the head of the bone forms a hollow in its new situation, which hollow becomes surrounded by fibrous tissue or even by bone. A new joint may form, the surrounding tissue becoming a compact capsule, and a bursa forming between the head of the bone and its new socket. In a dislocated hinge-joint the ends of the bone alter greatly in shape and their cartilage is converted into fibrous tissue. In an unreduced dislocation the muscles shorten or lengthen or undergo atrophy or fatty degeneration, as the case may be. An unreduced dislocation of a ball-and-socket joint may give a fairly movable new joint, but an unreduced dislocation of a hinge-joint rarely allows of much motion.

General Symptoms of Traumatic Dislocation.—In general, traumatic dislocations are indicated—(1) by *pain* of a sickening, nauseating character; (2) by *rigidity*, voluntary motion being impossible except to a slight extent in the direction of the deformity. (For instance, in dislocation of the inferior maxillary the jaw can be opened a little more, but it cannot be closed.) This rigidity brings about loss of function. When the surgeon attempts to move the joint he finds it very rigid; (3) by *change in the shape of the joint* (as flattening of the shoulder after dislocation of the humerus); (4) by *alteration in the mutual relations of bony prominences about a joint* (as the alteration of the relation between the olecranon and humeral condyles in dislocation of the elbow backward); (5) by feeling the displaced bone in its new situation; (6) by missing the head of the bone from its proper situation; (7) by alteration in the length of the limb (in dislocation of the femur into the thyroid foramen the limb is lengthened, but in dislocation on to the dorsum of the ilium it is shortened); and (8) by alteration in the axis of the bone (in dislocation upon the dorsum of the ilium the axis of the injured thigh would, if prolonged, pass through the lower third of the sound thigh); (9) by seeing the dislocation with a fluoroscope or looking at a skiagraph of it.

Diagnosis of Traumatic Dislocation.—A dislocation may be mistaken for a fracture. In dislocation there is rigidity, in fracture there is preternatural mobility; in dislocation there is no true crepitus (there may be tendon- or joint-crepitus), in fracture there usually is crepitus; in dislocation the deformity does not tend to recur after reduction, in fracture it does recur after extension is relaxed. In a sprain the movements of the joint are only limited, not abolished, by the almost complete rigidity encountered in dislocation. The change which a sprain may cause in the shape of a joint is due to effusion or to bleeding; there is no alteration in the relation of the bony prominences to one another; there is no notable alteration in the length of the limb (a slight increase in length may arise from joint-effusion, or the head of the bone may subsequently be absorbed and thus produce shortening after some weeks); there is no alteration in the axis of the bone; the bony head is not felt in a new position, and it is found in its normal place. Always remember that a fracture may exist with a dislocation. In any doubtful case—in fact, in most cases—give ether, for a dislocation should be reduced while the patient is anesthetized (except in dislocation of the jaw, of a finger, of the carpus, etc.). In some cases swelling renders the diagnosis difficult or impossible. Always compare the injured joint with the corresponding joint of the sound side. The *x*-rays constitute an invaluable method of diagnosis.

Treatment of Traumatic Dislocation.—*Recent Simple Dislocation.*—Reduce a simple dislocation under ether, as a rule. Try *manipulation*, a procedure which seeks to make the bone retrace its own pathway. If this pro-

cedure fails, employ extension and counterextension. If considerable force is needed, an assistant makes counterextension, and the surgeon fastens to the extremity a clove-hitch, which he ties about his waist, and thus secures powerful extension. Counterextension may be obtained by bands, or, in some instances, by the foot of the surgeon. The *clove-hitch* is used because it will not tighten by traction; a tightening band would lacerate the soft parts (Fig. 395). If great power is needed, compound pulleys may be employed, such as the Jarvis adjuster or some similar appliance, but at the present day pulleys are rarely used (see page 668). If these means fail, cut down upon the bone and restore it to position; operation is much safer than the application of great force. After reducing a dislocation, immobilize the joint for a time, which varies for different joints, and for the first few days combat swelling and inflammation by rest of the part and the use of evaporating lotions or an ice-bag. If there exists a fracture of the dislocated bone, apply splints and then try to reduce by manipulations, grasping the limb and the splints with one hand below and, if possible, the head of the bone with the other hand above the seat of the fracture. Allis believes that a dislocation can be reduced even when a fracture exists. It is possible to pull the dislocated head down to the joint, because a portion of periosteum and possibly tendinous material and muscle still hold the two fragments as a strap might unite two sticks. The head may be forced into place by the fingers while traction is being made. If the fracture is near the joint and the fragments cannot be fixed, try to reduce the dislocation, first striving to press the bone into place. This attempt can be greatly aided by traction upon the lower fragment. In some cases with fracture reduction can be much aided by making a small incision, screwing a gimlet into the head of the bone, and using this tool as a handle. McBurney incises, drills a hole in each bone, inserts hooks into them, and pulls the dislocated bone into position (see Figs. 277, 278). When the dislocation has been reduced, the bone-fragments should be wired or plated together.

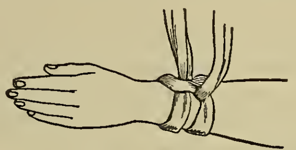

Fig. 395.—Clove-hitch knot applied above the wrist. In dislocation of the shoulder this knot is put above the elbow (after Erichsen).

Compound Traumatic Dislocation.—The opening in the soft parts may be due to external violence or to projection of a bone. Compound dislocations are very serious. Hinge-joints are more liable to these injuries than are ball-and-socket joints. Many cases require excision; some, amputation; one that does not demand excision or amputation should be treated by sterilizing the parts, restoring the dislocated bone, making a counteropening, draining, dressing antiseptically, and immobilizing. Considerable ankylosis generally ensues, except sometimes in the small joints. It is scarcely ever necessary to cut away any portion of the protruding bone to effect reduction. If a joint is badly splintered, or if the soft parts are extensively damaged, it may be necessary to excise or amputate; if the main vessels of a limb are seriously injured, amputation must be considered. If the patient is so old or so feeble that it is perilous to force him to combat a long illness, amputation should be performed.

Old Traumatic Dislocation.—The problem always presented in an old dislocation is, Shall reduction be tried or shall the bones be let alone? Sir Astley Cooper laid down this rule: "Do not attempt to reduce a shoulder-dislocation after three months, nor a hip-dislocation after two months"; but this rule was put forth before the days of ether. Do not select any fixed period of time to determine what action is advisable. In dislocation of a ball-and-socket joint considerable motion may become possible and a new joint may

form. If movement does not produce pain, a useful new joint may be obtained by the persistent employment of active and passive movements; if movement of the limb does produce pain, enough motion will not be attempted by the patient to produce a useful joint. In the former case it may be best to try to obtain a useful new joint, and in the latter case the surgeon should endeavor to reduce the old dislocation. Always remember that dislocation of a hinge-joint, if left unreduced, will never eventuate in a useful new joint.

In trying to reduce an old dislocation give ether, make movements to break up adhesions, and persist in making these motions until the head of the bone is felt to move; then try at once to reduce by manipulation or extension and counterextension, not waiting for two days, as some suggest. If the head of the bone cannot be made to move, the Dieffenbach plan has been advised, which is to cut the tense restraining bands with a tenotome. Lord Lister, being much impressed with the danger inevitably linked with forcibly dragging old dislocations into place, preferred to cut down and restore the bone, employing, of course, the strictest asepsis, and surgeons in general have adopted this view. In some old dislocations excision of the head of the bone is the proper operation.

Special Traumatic Dislocations.—Mandible.—A dislocation of the lower jaw, when there is no fracture, is almost invariably forward. Backward dislocation without fracture is extremely rare, and some have maintained that it cannot occur. Croker King reported a case in 1858. Theim has observed it seven times in five women. The condyle passes under the lower surface of the auditory canal.[1] The common dislocation is forward, and this is the form meant when we simply speak of dislocation of the jaw. There are two forms of forward dislocation—the *unilateral*, which is rare, and the *bilateral*, which is common. Dislocations of the jaw are commonest in women and during middle life. When the mouth is open, contraction of the external pterygoid muscle may pull the condyle over the articular eminence; this contraction may be brought about by yawning, vomiting, scolding, etc. When the mouth is open, dislocation of the lower jaw may be caused by a blow upon the chin; it may also be caused by forcing the mouth more widely open by pushing a bulky body between the teeth.

Symptoms of Lower-jaw Dislocation.—In the *bilateral* form the mouth is open and fixed, and it cannot be closed, though it can be opened a little more. The condyles are in front of the articular eminences, and are fixed by the action of the masseters and internal pterygoids, the coronoid processes being wedged against the malar bones. The lower jaw is advanced in front of the upper jaw and the face looks longer than natural. The lips cannot close, the saliva dribbles, swallowing and speech are difficult, there is a depression in front of each ear, the condyles are recognizable in their new abodes, the coronoid processes are detected by a finger in the mouth, and the masseters and temporals stand out in a state of rigidity. Pain may be severe, may be moderate, or may be absent. In the *unilateral* form the chin goes toward the sound side, and the mouth is not so widely open as in the bilateral form, neither is the jaw so fixed. The symptoms are similar to those of a bilateral luxation, but are not so pronounced. The hollow in front of the ear and the abnormal situation of the condyle are detected upon one side only. In an unreduced dislocation the patient may after a time establish some movements of the jaw, but the power of mastication will always be seriously impaired.

Treatment of Lower-jaw Dislocation.—In reducing a dislocation of the lower jaw the patient is usually placed with his head against the back of a chair or against the body of an assistant. The surgeon, after wrapping up his thumbs to protect them from being bitten, stands in front of the patient, puts his

[1] Theim, in "Rev. de Chir.," vol. viii, 1888.

thumbs upon the last molar teeth, and grasps the chin with his free fingers. He now presses downward and backward on the jaw, and as soon as the condyle is loosened, closes the jaw over the thumbs by pushing up the chin, using his thumbs as levers. For the last year I have followed the excellent suggestion of W. J. Young ("Brit. Med. Jour.," March 23, 1913), which is to stand behind the patient, with the patient's head against the surgeon's chest, place the right thumb far back in the right side of the patient's mouth and grasp the chin with the left hand. The right hand easily depresses the jaw and the left guides the condyle into place. Then the procedure is reversed and the left side reduced. If reduction by the hands fails, wedges should be put between the molar teeth and the chin should be pushed up either by the hands or by a tourniquet, the band of which surrounds the head and chin. In a unilateral dislocation the wedge should be used only on the injured side. In difficult cases Sir Astley Cooper pushed a round wooden ruler between the molar teeth, used the upper teeth as a fulcrum, and raised the end of the ruler as the handle of a lever. The forceps used by an anesthetist may depress the condyle from its point of fixation, whereupon the chin may be pushed up and back. Nélaton advises that the surgeon place his thumbs in the mouth of the patient and push the coronoid processes backward. After reduction a Barton bandage should be applied and worn for over two weeks. The dressing should be renewed once a day, and passive motion be begun in the second week. The bandage may be discarded at the end of the third week. Liquid diet is advisable for three weeks after the accident. In an old dislocation reduction is always attempted, at least up to a period of six or seven months after the accident. An irreducible dislocation requires osteotomy of the neck of the bone if the part cannot be restored after incision.

Dislocation of the Clavicle.—Sternal End.—There are three forms of dislocation of the sternal end of the clavicle, namely: (1) forward; (2) backward, and (3) upward.

Forward Dislocation of the Sternal End of the Clavicle (Presternal Dislocation).—The *causes* of forward dislocation of the clavicle are blows, falls, or pulls which drive or draw the shoulder backward.

Symptoms and Treatment of Forward Dislocation of the Sternal End of the Clavicle.—The symptoms manifest in dislocation of the clavicle are: prominence in front of the sternum; the acromion is nearer to the sternum on the injured than on the sound side; the clavicular origin of the sternocleidomastoid muscle is rigid; movement is difficult and painful. To reduce a dislocation of the clavicle, pull the shoulders back against the knee of the surgeon, which is placed between the scapulæ. Dress with a posterior figure-of-8 bandage (Fig. 833) or a Velpeau bandage (Fig. 835), the dressing to be worn for three weeks. After removal of the dressing apply a truss, the pad of which is put over the head of the clavicle, and which instrument is to be worn for a month. Dislocation of the clavicle is difficult to keep reduced, but even if it becomes fixed in deformity, the motions of the arm will not be impaired permanently. It can be reduced and fixed by incision and wiring.

Backward dislocation of the sternal end of the clavicle is very rare. The *causes* are direct violence and indirect force, such as falls or blows which drive the shoulder forward and inward.

Symptoms and Treatment of Backward Dislocation of the Sternal End of the Clavicle.—The symptoms are: pain, loss of function in the arm; inclination of the head toward the injured side; stiffness of the neck; the shoulder passes forward and inward, and often falls downward; a depression exists over the sternoclavicular joint; the head of the clavicle cannot be felt, or is found back of the sternum. The displaced clavicle may press upon the trachea, the esophagus, or the great vessels, inducing dyspnea, dysphagia, obliteration of

pulse in the arm of the injured side, or great venous congestion of the head (see Pick). The usual method of treatment is to pull the shoulders backward and apply a posterior figure-of-8 bandage (Fig. 833), which must be worn for three weeks. If pressure-symptoms are urgent, it is the rule to incise, restore the bone to place and wire it, or resect the displaced head.

Upward dislocation of the sternal end of the clavicle is very rare. The *cause* is indirect force, which carries the shoulder downward, inward, and backward (Smith).

Symptoms and Treatment of Upward Dislocation of the Sternal End of the Clavicle.—The chief symptom is impaired function of the arm; the shoulder passes downward and inward, the clavicular axis is altered, and the displaced head is felt. Dyspnea may or may not exist. To treat this dislocation, put a pad in the axilla and press the elbow to the side (in order to throw the bone outward), and try to push the head into place. Apply a Desault bandage (Fig. 836) and place a firm pad over the sternoclavicular joint. The deformity is apt to recur, but a useful limb will nevertheless be obtained. The best method of treatment is to wire the bones in place.

Dislocation of the acromial end of the clavicle is almost always upward, but it may be below the acromion. The *cause* is violent force, which, if so

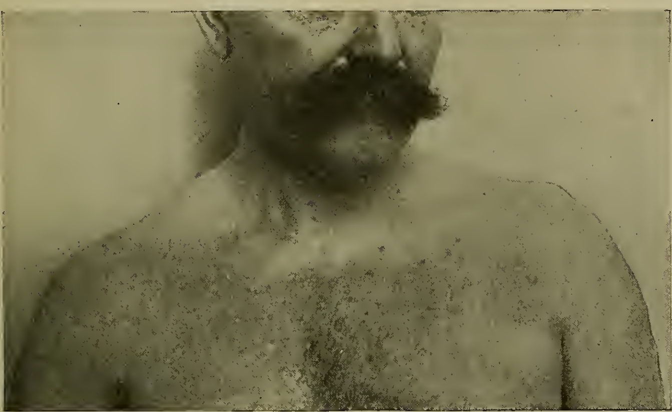

Fig. 396.—Dislocation upward of acromial end of clavicle.

applied to the scapula as to drive the shoulder forward, may produce a dislocation upward. A dislocation downward is due to blows upon the upper surface of the outer end of the clavicle.

Symptoms and Treatment.—In dislocation of the acromial end of the clavicle upward there are noted: prominence of the clavicle upon the top of the acromion; impaired function of the arm (it cannot be lifted over the head); the shoulder falls downward and passes inward; there is apparent lengthening of the arm; the head is bent toward the injured side, and the clavicular origin of the trapezius is strongly outlined (Pick). In *dislocation downward* both the acromion and the coracoid are very prominent, the clavicular axis is altered, and there is depression over the sternoclavicular joint. The surgeon usually endeavors to reduce a dislocation upward by placing the patient supine on a hard table, pulling the shoulder back, and pushing the bone into place. After reduction the old method of treatment was to apply a Desault bandage, which was kept on for three weeks, and decided deformity, enduring pain, and disability were looked for as inevitable. Stimson used to apply dressings of adhesive plaster. The author has seen several cases treated by the apparatus of Thomas Leidy Rhoads. The apparatus completely corrected the deformity, and the patients made a most satisfactory recovery.

The essential element of Rhoads's apparatus is a trunk-strap applied after reduction of the dislocation, as shown in Figs. 397, 398. If the deformity can be completely corrected, Rhoads's apparatus will serve a good purpose, but in many cases it is impossible really to reduce the deformity or after apparent

Fig. 397.

Fig. 398.

Figs. 397, 398.—Rhoads's apparatus for treating dislocation upward of the acromial end of the clavicle.

reduction the deformity at once returns. This is due, as Moore[1] points out, to the fact that the superior acromioclavicular ligament is torn from the clavicle, but remains attached to the scapula, and when reduction is attempted, is pushed under the clavicle and nothing remains to hold the clavicle "in place but the skin and superficial fascia." I agree with Moore that the best treatment is incision, replacement, and suturing the acromion to the outer end of the clavicle. The bones are sutured with silver wire or kangaroo tendon, the acromioclavicular ligament is sutured with catgut, the wound is closed with sutures of silkworm-gut, and the patient is kept supine in bed for three weeks. I have operated successfully on 5 of these cases.

Fig. 399.—Subcoracoid dislocation of shoulder.

Dislocation downward is reduced and treated in the same manner as dislocation upward.

Simultaneous dislocation of both ends of the clavicle is a very rare injury. It is treated as is single dislocation.

The so-called **dislocation of the lower angle of the scapula** is not, as was long taught, a dislocation at all. The lower angle and vertebral border deviate from

[1] "Annals of Surgery," May, 1902.

the chest. This condition was thought to be due to the bone slipping from under the latissimus dorsi muscle, but it is now known to be due to *paralysis* of the *serratus magnus muscle*, the bone being acted upon by the trapezius, pectoralis minor, levator anguli scapulæ, the rhomboid muscles. Examination shows that the scapula will not rotate normally forward. This is demonstrated by extending the arms in front to a right angle, the gliding forward of the scapula upon the sound side being marked, but upon the diseased side being slight or absent.

Treatment of paralysis of the serratus magnus muscle comprises massage, electricity, passive motion, and deep injections of strychnin.

Katzenstein advocates operation for serratus palsy. He makes an incision near to the midline of the back, exposes portions of origin of the trapezius and rhomboideus major, divides them, carries the cut muscles downward and outward, and sutures them to the periosteum of the seventh, eighth, and ninth ribs and to the latissimus dorsi. He then makes an "incision along the inner surface

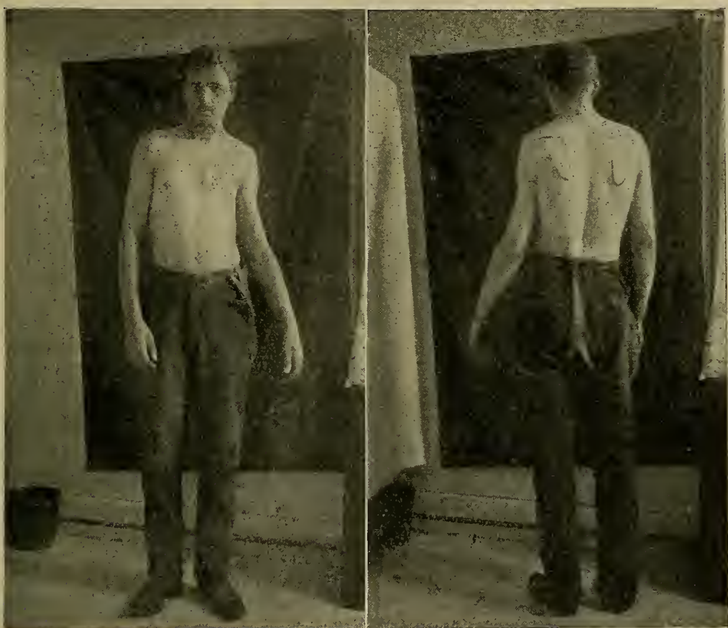

Fig. 400.—Subcoracoid dislocation of the left humerus (St. Joseph's Hospital case; photographed by Dr. Nassau).

of the arm from the middle up through the axilla to end on the thoracic wall." He divides the humeral insertion of the great pectoral and sutures its tendon to the axillary border and the anterior scapular muscles (Binnie's "Operative Surgery").

Dislocation of the Humerus (Shoulder-joint).—This injury is quite frequent because of the free mobility of the shoulder-joint, its anatomical insecurity, and its exposed situation; it rarely occurs in the very young and in the aged, and is oftenest encountered in muscular young adults. Shoulder dislocation is produced by throwing the arm into abduction. In this position the head of the humerus presses against the lower and front part, that is, against the thinnest and most poorly supported portion of the capsule. In almost all cases the tear in the capsule occurs between the tendon of the subscapularis and the triceps. Hence, most dislocations are *primarily* subglenoid, although the bone usually moves to some other position, being dragged or

driven there by the injuring force or being pulled there by muscular action. Dislocation forward is much more common than dislocation backward because the long head of the triceps keeps the head of the bone from going posterior and because the anterior are stronger than the posterior muscles. Four chief forms of shoulder-joint dislocation exist, namely: (1) forward, inward, and downward, under the coracoid process—subcoracoid; (2) downward, forward, and inward, beneath the glenoid cavity—subglenoid; (3) backward, inward, and downward, under the spine of the scapula—subspinous; and (4) forward, inward, and upward, under the clavicle—subclavicular.

A very rare form of shoulder-joint dislocation has been described, which is known as the *supracoracoid*. Another rare form is the *luxatio erecta*.

Subcoracoid Luxation (Figs. 399, 400).—The subcoracoid variety of dislocation embraces three-fourths of all shoulder-joint luxations. It may be caused by direct force driving the head of the humerus forward and inward, or by indirect force, such as falls upon the hand or the elbow. In this dislocation the head of the bone lies against the anterior surface of the scapular neck below the coracoid process. A part of the anatomical neck of the humerus lies upon the anterior margin of the glenoid cavity, and the head of the bone is above the tendon of the subscapularis muscle.

Fig. 401.—Axillary dislocation of the right humerus.

Subclavicular luxation is very rare. It is caused by the same sort of violence which produces subcoracoid luxation. The head of the bone rests upon the thorax, below the clavicle, and underneath the pectoralis major muscle.

Subglenoid or Axillary Luxation (Fig. 401).—It may be produced by contraction of the great pectoral and latissimus dorsi muscles when the arm is at a right angle to the body, but it is usually due to falls upon the hand or the elbow when the arm is raised and the head of the bone is against the lower portion of the capsule. In this dislocation the head of the bone rests upon the border of the scapula, below the tendon of the subscapularis, in front of the long head of the triceps, and above the teres muscles. Most dislocations of the shoulder are primarily subglenoid, the position perhaps being subsequently altered by muscular action.

Subspinous luxation is a rare injury. Pick met with this accident in a man who, while having his hands in his pockets, fell upon the front of the point of the shoulder. The head of the bone reposes beneath the scapular spine, between the infraspinatus and teres minor muscles.

Supracoracoid luxation is seldom encountered. The head of the humerus rests upon the coraco-acromial ligament or upon the acromion process, and the acromion or the coracoid is always fractured.

Luxatio Erecta.—In this injury the arm is markedly abducted and in some cases the elbow is actually raised above the patient's head. As a rule, the forearm rests behind the occiput, sometimes on the top of the head. The patient holds the forearm to the occiput or vertex to avoid pain. It is, in reality, a form of subglenoid luxation. In such an injury the head of the bone has passed under the subscapularis muscle and also under the teres major or the lower border of the great pectoral. Judd, Hulke, Cleland, and others have reported cases.

Symptoms of Dislocation of the Shoulder-joint.—Dislocation is diagnosticated by—(1) pain of a sickening character; (2) flattening of the shoulder, the head of the bone having ceased to bulge out the deltoid muscle; (3) apparent projection of the acromion through sinking in of the deltoid; (4) hollow beneath the acromion, over the empty glenoid cavity, and the bone missing from its normal habitat. This hollow may be easily appreciated by the finger, especially when the extremity is somewhat abducted; (5) rigidity (some movement is possible in the direction especially of an existing deformity, but mobility is strictly limited and attempts at motion produce great pain); (6) Dugas's sign: the elbow cannot touch the side when the hand is placed upon the sound shoulder, and the hand cannot be placed upon the sound shoulder if the elbow is to the side (this is due to the rotundity of the chest. In a dislocation the head of the bone is already touching the chest, and the bone, being approximately straight, cannot touch it in two places at the same time. If the elbow can be placed against the chest with the hand on the sound shoulder there cannot be dislocation; if it cannot be so placed, there must be dislocation); (7) finding the head of the bone in a new situation; (8) examining by means of the *x*-rays. Symptoms 1 to 5 inclusive may be grouped as Erichsen's list of signs. The form of dislocation is made out by a study of the direction of the axis of the limb, the existence and extent of lengthening or of shortening, and the situation of the head of the bone.

In a shoulder-joint dislocation the head of the bone may press upon the brachial plexus and produce pain and numbness, and occasionally traumatic neuritis or paralysis; sometimes pressure upon the axillary vein causes intense edema, and pressure upon the axillary artery diminishes or obliterates the pulse. The axillary vessels may be torn and the muscles may be lacerated badly. The capsule is torn and considerable blood is usually effused. Swelling is due first to hemorrhage, and secondly to inflammation. Partial dislocation sometimes, though rarely, occurs. What is usually spoken of as "partial dislocation" or "subluxation" is a condition in which the head of the humerus passes forward under the coracoid because of rupture of the long head of the biceps or because this tendon slips out of its groove, the ligaments of the shoulder-joint being intact.

The following table from T. Pickering Pick's work on "Fractures and Dislocations" makes the above points clear:

	Direction of the Axis of the Limb.	Alteration in the Length of the Limb.	Presence of the Head of the Bone in New Situation.
Subcoracoid.	The elbow is carried backward and slightly away from the side.	Very slight lengthening.	The head of the bone cannot easily be felt; it is found at the upper and inner part of the axilla.
Subglenoid.	The elbow is carried away from the trunk and slightly backward.	Very considerable lengthening.	The head of the bone can easily be felt in the axilla.
Subspinous.	The elbow is raised from the side and carried forward.	Lengthening intermediate in degree between the subglenoid and the subcoracoid.	The head of the bone can be felt and be grasped beneath the spine of the scapula.
Subclavicular.	The elbow is carried outward and backward.	Shortening.	The head of the bone can readily be seen and be felt beneath the clavicle.

Diagnosis of Shoulder-joint Dislocation.—In *fracture of the neck of the scapula* the acromion is prominent, a hollow is detected below it, and a hard

body is felt in the axilla; but the coracoid process descends with the head of the humerus, which it does not do in dislocation. Furthermore, in fracture there is mobility; in dislocation, rigidity. In fracture crepitus is present; in dislocation it is absent. In fracture the deformity is easily reduced, but it at once recurs; in dislocation the deformity is with difficulty reduced, but does not recur. In fracture the elbow can be made to touch the side when the hand is upon the sound shoulder; in dislocation it cannot be so manipulated. In *fracture* of the *anatomical neck of the humerus* deformity is slight; the head of the humerus is found in place, does not move when the shaft is rotated, and is not in line with the axis of the bone. Crepitus exists in the fracture if impaction is absent. In *paralysis of the deltoid muscle* there is distinct flattening, but the bone is felt in place and there is no rigidity. The x-rays are invaluable in diagnosis.

Treatment of Shoulder-joint Dislocation.—Reduction by manipulation is usually readily accomplished in a recent case of shoulder-joint dislocation. If a simple trial without ether fails, an anesthetic should be administered. Ether is given, but not chloroform, for chloroform seems to be particularly dangerous to life when given to enable the surgeon to reduce a dislocation of the shoulder. *Forward dislocations* (subcoracoid, subclavicular, and axillary) are reduced by *Kocher's method* (Fig. 402). This method was introduced by Kocher in 1870 ("Sammlung klin. Vorträge," No. 83). Reduction by this

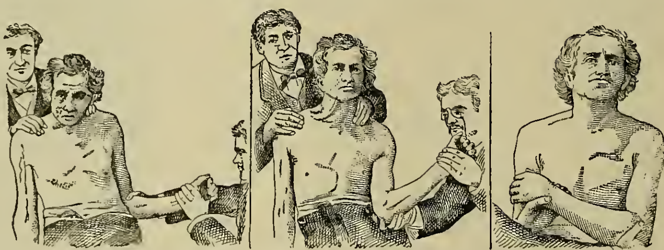

Fig. 402.—Kocher's method of reduction by manipulation: *a*, First movement, outward rotation; *b*, second movement, elevation of elbow; *c*, third movement, inward rotation and lowering of the elbow (Ceppi).

method can frequently be effected without the aid of ether. The patient should be recumbent. Slowly but forcible adduct the abducted elbow and get it finally against the side. At the same time draw it slightly backward. The forearm is flexed. If there is much muscular resistance, follow Keetley's advice, and not only bring the elbow to the side, but push it backward and inward toward the spine. Grasp the elbow with one hand, and the wrist with the other, and slowly make external rotation until the forearm points outward from the body. We thus carry the head of the humerus to the margin of the glenoid cavity. External rotation must be done slowly and gently. When we first try it there is much muscular resistance. If enough force is used to overcome the resistance the surgical neck of the bone may be broken. By gently and gradually persisting in external rotation the muscles are finally tired out and relax. Next lift the elbow anteriorly as far forward as it will go, so as to bring the head of the humerus to the glenoid margin just opposite the capsular tear (Keetley). Then throw the bone into place by gradually swinging the forearm inward across to the other side of the chest, that is, by internal rotation. The formula is, flexion of the forearm, external rotation, lifting the elbow forward, internal rotation of the arm, and lowering the elbow. The motions to unlock the bone and start it to retrace the steps it took when emerging should be gentle, not forcible, slow, not sudden, and rigid muscles should be tired out and made to relax by steady traction upon them. Sudden

and violent motions increase rigidity. Adduction stretches the upper portion of the capsule and presses the head against the glenoid. External rotation opens the tear in the capsule. Elevation relaxes the untorn part of the capsule and coracohumeral ligament and stretches the torn portion. On this fulcrum the head, which is the end of a lever, is forced into place. If in trying Kocher's plan external rotation of the humerus does not take place, abandon the method, as persistence will fracture the humerus. Another method of manipulation is as follows: if the *right* shoulder is dislocated, the surgeon stands behind the patient (who is sitting erect); if the *left* shoulder is dislocated, he stands in front of the patient. The surgeon holds the forearm flexed upon the arm with his right hand and makes external traction and rotation, and with the fingers of his left hand he tries to force the bone into place.

In *Henry H. Smith's method* for forward dislocation the surgeon stands in front of the patient. If the *left* shoulder is dislocated, the surgeon grasps it with his left hand; if the *right* shoulder is dislocated, he grasps it with his right hand, the thumb resting on the head of the bone. With his disengaged hand the surgeon grasps the elbow, abducts it, makes traction and external rotation, and suddenly sweeps the elbow inward, aiming it at the sternum, and tries with his thumb to push the bone into place. In *subspinous luxations* reduction may be effected if the surgeon stands behind the patient, makes abduction, traction, and internal rotation, sweeps the elbow inward toward the spine, and with the thumb aids the bone in its return into position. Raising the elbow far above the head and sweeping it inward will reduce some dislocations. As the head of the bone slips back a distinct jar is felt and a snap is heard, the motions of the joint are again obtainable, and with the hand on the opposite shoulder the elbow may be made to touch the side.

Reduction by Extension.—Before attempting the reduction of a dislocation of the shoulder-joint by extension the patient should be anesthetized and placed upon a low bed or upon the floor. The surgeon then places his foot, covered only by a stocking, in the axilla. Place the sole of the foot, not the heel, against the chest high up, the instep being made to touch the humerus and the heel the border of the shoulder-blade, a towel being first put into the axilla to rest the foot against (Fig. 403). If the left arm is dislocated, use the left foot, and vice versâ. The elder Gross approved of making extension while sitting between the patient's limbs. Make steady extension, which will in many cases bring about the reduction. If it fails to cause reduction, bring the patient's arm across the chest and use the foot as the fulcrum of a lever. If the humerus is pretty firmly fixed in its abnormal position, make counterextension with a foot in the axilla and make extension by fixing a clove-hitch (see Fig. 395) *above the elbow* and fastening to it bands which go over one shoulder and under the other shoulder of the surgeon. The back may thus be used for extension, the hands being left free for manipulation (Allis's and Pick's plan). Lateral extension is used by some surgeons. The patient lies down, a large piece of canvas is split, the arm is passed through the split, and the body is thus fixed. The arm is pulled to a right angle with the body and traction is applied.

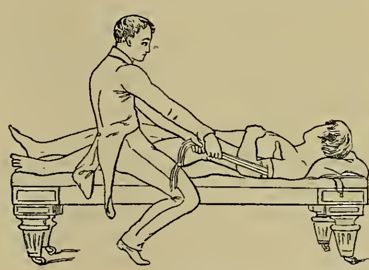

Fig. 403.—Reduction of shoulder-joint dislocation by the foot in the axilla (Cooper).

The late Prof. Joseph Pancoast favored *Sir Astley Cooper's method* of placing the unanesthetized patient in a chair and using the knee as a fulcrum,

pushing the elbow to the side (Fig. 404). Brunus, in the thirteenth century, devised the method of *upward extension.* In applying this method the surgeon takes his place behind the patient, steadies the scapula with his hand, and carries the patient's arm upward and backward above his head, making extension and external rotation (Fig. 405). *La Mothe's method* is applied with the patient supine upon the floor. The surgeon places his foot upon the shoulder to make counterextension, and makes extension as in Brunus's method. It is a useful expedient, when either of these plans is applied, to have an assistant make the traction while the surgeon manipulates the head of the bone. Cock advises, when reduction fails, that an air-pad be placed in the axilla and the arm be bound to the side—a method by which reduction will sometimes take place after two or three days.

Fig. 404.—Reduction of shoulder-joint dislocation by the knee in the axilla (Cooper).

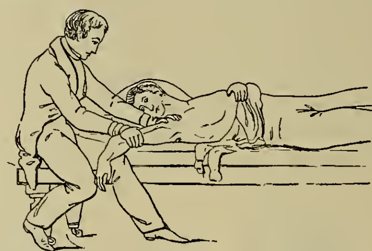

Fig. 405.—Reduction of shoulder-joint dislocation by upward extension (Cooper).

Pulleys should not be used to pull the bone into place, as they develop a dangerous force. In a dislocation irreducible by ordinary force, antiseptic incision is safer and better than the pulleys. After incision try to restore the bone to place.

In reducing a dislocation the axillary artery or vein may be ruptured, fracture of the neck of the humerus may take place, injury to the brachial plexus may occur, or the soft parts may be badly damaged. After reducing a dislocation apply a Velpeau bandage, keep the shoulder immobile for one week, then make passive motion daily, reapplying the dressing after each séance. The patient may wear a sling alone during the third week, after which period he may use the arm. (For Compound Dislocations, see page 658.)

Unreduced and Irreducible Dislocations of the Shoulder.—In some cases where we find there is considerable movement without pain we can, by manipulation and active motion, increase the range of movement and the usefulness of the new joint.

As a rule, in a youth or a middle-aged person we attempt bloodless reduction if the head of the bone is movable and there is no prospect of a useful new joint. Give ether, break up adhesions by forced flexion and extension, and try Kocher's method, and, if this fails, the other methods, but never use violent force. In reducing an old dislocation we may fracture the surgical neck of the humerus. I have seen this happen twice. The proper treatment is incision and pulling the head into place by McBurney's hooks. In attempting reduction of an old dislocation by force the brachial plexus may be lacerated or one or both of the axillary vessels may be torn. If an axillary vessel is torn, it must be at once exposed by incision. A large tear in either vessel requires a ligature about the vessel on each side of the tear. A small tear may be sutured (Keetley, in "Lancet," Jan. 23, 1904). Rather than use sufficient force to endanger the vessels in attempting to reduce an old dislocation, practice

incision. In some cases after incision the head of the bone can be pulled and pushed into place. In other cases the head must be resected. After reduction of an old dislocation immobilize for three weeks, and begin passive motion after seven days.

If a *dislocation* is *complicated* by a *fracture of the humerus*, try to pull the head of the bone opposite the joint. This may be possible if the two fragments are held partly together by a fair amount of periosteum and muscle. Traction is exerted upon the arm, and an attempt is made to manipulate the head into the socket (Allis's plan in the hip). McBurney incises, fixes a hook in the scapula and a hook in the head of the humerus, pulls the head into place, and wires the fragments (see Figs. 277, 278). In an emergency gimlets may be used instead of the hooks. In some cases it is necessary to excise the head of the bone.

Habitual or Recurrent Dislocation.—Habitual or recurrent dislocation of the shoulder, following an original traumatic dislocation, results usually from a slight or trivial force. It is apt to take place when the arm is in abduction, slight rotation frequently being necessary. In some cases rotation will produce a dislocation while the arm is near the side of the body. Little is known of the frequency with which these cases occur, but they are probably much more frequent than is generally supposed. The frequency of the recurrences in the individual cases varies widely. In some they occur more or less regularly every two or three years, while in others they have been known to take place daily and even several times a day. In most cases in the intervals between the recurrences the joint functionates normally without difficulty, although the patient fears abduction because of its influence in favoring a recurrence. In rare cases pain persists a long time after each dislocation, so that if the recurrences are frequent, the patient may be compelled to give up work.

Cause.—The essential cause is a relaxation of the capsule at the site of the original tear, produced by the addition to the old or original portion of capsule of a new or cicatricial portion bridging over the gap between the margins of the tear produced by the first dislocation. The failure of these margins to unite closely is due to the repeated emergence of the humeral head forcing them apart before union is complete. The defects in the head of the humerus which have been found at autopsy and operation have, probably, only a slight and secondary causal importance, while the fractures of the greater tuberosity of the humerus sometimes occurring in dislocations of the shoulder are probably not followed by recurrent dislocations.

Treatment.—Excision of the head of the humerus has been abandoned in these cases. Capsulorrhaphy for the shortening of the relaxed anterior portion of the capsule has given excellent functional results. Dawbarn, of New York, did this operation in my clinic, upon a city fireman, and the result was a perfect success. The capsule may be exposed through the usual resection incision along the anterior margin of the deltoid. This may be modified by an additional incision outward at right angles to the first, and the insertion of the pectorlais major may be partially divided. T. Turner Thomas makes an axillary incision along the inner border of the coracobrachialis, passing between this muscle and the axillary vessels and nerves, and avoiding particularly the circumflex and musculocutaneous nerves. The subscapularis muscle is partially divided to give a freer exposure of the capsule. This route exposes, by a small incision, the site of the original tear in the capsule. It avoids division of the deltoid and gives dependent drainage if drainage is necessary.

The relaxed portion of the capsule may be shortened by taking up a reef with catgut or silk sutures, without opening and exploring the joint for loose pieces of bone; the capsule may be incised transversely to its longitudinal

fibers and the margins of the incision overlapped; an oval piece may be excised and the edges united by sutures; or the margins of the original tear may be found and sutured together.

Dislocation of the elbow-joint is not infrequent, and is commonest in children. Both bones or only one bone of the forearm may be dislocated, and the dislocation may be partial or complete.

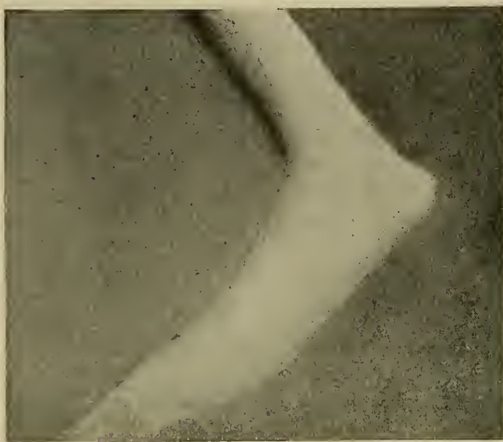

Fig. 406.—Dislocation of both bones of the forearm backward.

Dislocation of Both Bones Backward (Fig. 406).—The *causes* of backward dislocation of both bones of the forearm are falls upon the extended hand or twists inward of the ulna (Malgaigne). The coronoid process lodges in the olecranon fossa of the humerus.

Symptoms of Backward Dislocation. — In complete dislocation of both bones of the forearm the olecranon is very prominent. The distance between the point of the olecranon and the apex of the inner condyle is notably greater than on the sound side; the forearm is flexed, supinated, and shortened; the lower end of the humerus projects in front of the joint, below the skin-crease; the head of the radius is found back of the outer condyle; and there are the general symptoms of dislocation. Fracture of the coronoid rarely occurs with backward dislocation, but if it does occur, there will be crepitus and mobility. Fracture at the base of the condyles is distinguished from dislocation of both bones of the forearm backward by the following points: in fracture there are found the ordinary symptoms; measurement from the condyles to the styloid processes does not show shortening; there is no alteration of the normal relation between the olecranon process and the condyles; and the projection in front of the joint is above the crease of the bend of the elbow.

Fig. 407.—Reduction of elbow-joint dislocation.

Treatment of Backward Dislocation.—Reduction must be effected early in dislocation of both bones of the forearm, because it will soon become impossible, and an unreduced dislocation means a limb without the powers of flexion, pronation, and supination. The surgeon may place his knee in front of the elbow-joint, grasp the patient's wrist, press upon the radius and ulna with his knee, and bend the forearm with considerable force, the muscle pulling the bones into place (Sir Astley Cooper's plan). Forced flexion, traction, and extension may be tried (Fig. 407). Put the arm in Jones's position for two weeks, and make passive motion daily after the first few days.

Dislocation of Both Bones Forward.—The *cause* of forward dislocation of both bones of the forearm is a blow on the olecranon when the arm is flexed. It is an unusual accident.

Symptoms and Treatment.—The *symptoms* of forward dislocation of both bones of the forearm are: the forearm is flexed and lengthened; some slight motion is possible; the olecranon is on a level with the condyles if unfractured, hence its prominence is gone; the humeral condyles are felt posteriorly, and the radius and ulna are felt anteriorly. The *treatment* of this injury consists in early reduction, which is accomplished by means of forced flexion, extension, and pressure, placing the part in Jones's position for two weeks, and making passive motion daily after the first few days.

Lateral dislocation of both bones of the forearm is usually incomplete.

Symptoms and Treatment of Outward Dislocation.—The *symptoms* of outward dislocation of both bones of the forearm are: the forearm is flexed, fixed, and pronated; the joint is widened; the head of the radius projects externally and has a depression above it; the inner condyle projects internally and has a depression below it; the olecranon is nearer than normal to the external condyle and further than normal from the internal condyle. Reduction is effected by extension of the forearm and pressure inward upon the head of the radius. Apply an ascending spiral reversed bandage of the forearm, a figure-of-8 bandage of the elbow-joint, and a sling. Make passive motion after a few days. The bandages must be worn for two weeks.

Fig. 408.—Forward dislocation of the radius.

Symptoms and Treatment of Inward Dislocation.—In dislocation inward of both bones of the forearm the position of the forearm is the same as that in dislocation outward; the sigmoid cavity of the ulna projects internally, and the external condyle projects externally. Reduction is effected by extension of the forearm and pressure outward on the ulna, subsequent treatment being the same as that employed in the preceding form.

Dislocation of the ulna alone is very rare, and can take place only backward.

Symptoms and Treatment.—Dislocation of the ulna alone is indicated by the forearm being flexed and pronated. The head of the radius is found in place, and the olecranon projects posteriorly. The *treatment* of this injury is the same as that for dislocation of both bones.

Dislocation of the radius forward (Fig. 408) is the commonest form of dislocation of the elbow. This injury is caused by a fall upon the hand with the forearm in pronation and extension, or is produced by blows on the back of the joint; forced pronation alone will not cause it.

Symptoms and Treatment.—The *symptoms* in dislocation of the radius forward are: the forearm is midway between pronation and supination, and is semiflexed; attempts to increase flexion cause the radius to strike against the humerus with a distinct blow; the head of the radius is felt in front of the outer condyle and is missed from its proper abode. Reduction is effected by flexion over the knee, extension, and manipulation. The subsequent treat-

ment is Jones's position and passive motion. Deformity is apt to recur after reduction because of rupture of the orbicular ligament. If permanent dislocation exists, resection of the head of the radius is necessary. Passive motion should be begun in two weeks after the resection. The results as to function and strength are usually excellent.

Dislocation of the radius backward (Fig. 409) is caused by falls on the hand or by blows on the front of the joint.

Symptoms and Treatment.—Backward dislocation of the radius is indicated by the forearm being slightly flexed and fixed in pronation, by some impairment of flexion and extension, and by the head of the radius being felt behind the outer condyle. Reduction is effected by flexion over the knee, extension, and manipulation, and the subsequent treatment is the same as that given for the preceding dislocation.

Fig. 409.—Dislocation of the radius backward.

Dislocation of the radius outward is very rare. In this injury the head of the radius is distinctly felt. Reduction is effected by extension and pressure; the subsequent treatment is the same as that for the above-mentioned dislocations.

Subluxation of the Head of the Radius.—This name is given to an injury which is very frequent in children between two and four years of age. It results from traction upon the hand or the forearm, and often arises when the nurse or the mother pulls upon a child's arm to save it from a fall or to lift it over a gutter. Some writers hold that pronation as well as extension is required to produce the injury; many surgeons claim that extension and adduction are the causative forces. Hutchinson asserts that supination may cause subluxation. Bardenheuer assigned falls as causes.

The *symptoms* are very characteristic. The history points to the injury. Pain and perhaps a click may be felt about the elbow, and pain and a click may also be felt in the wrist at the time of the accident. The arm hangs by the side, with the elbow-joint slightly flexed and the forearm midway between pronation and supination. Flexion to an angle of less than 60 degrees and complete extension are resisted and are very painful, but movements between 60 and 130 degrees are free and painless.[1] The movements of the wrist-joint are free and painless. The elbow-joint presents no deformity. Pressure over the head of the radius causes pain. Strong pronation is painful; strong

[1] See the instructive article by W. W. Van Arsdale, in "Annals of Surgery," vol. ix, 1889.

supination is very painful, and there seems to be a mechanical obstacle to its performance. Forced supination develops a distinct click at the head of the radius, and causes pronation and supination to become natural and free from pain. The condition will be reproduced if the parts are not immobilized for a time. The nature of the lesion is not understood, and various conditions have been thought to exist by different observers. Among them may be mentioned the following: a slight anterior displacement of a head of the radius; a slight posterior displacement; locking of the tuberosity of the radius behind the inner edge of the ulna; dislocation of the triangular cartilage of the wrist; intracapsular fracture of the radial head; painful paralysis from nerve-injury; displacement by elongation, the return of the bone being prevented by collapse of the capsule; and the slipping up of the margin of the orbicular ligament over the rim of the head of the radius.

Treatment.—In order to reduce, place the forearm at a right angle to the arm and make forcible supination. Apply an anterior angular splint, and have it worn for four or five days, or put the part in Jones's position for an equal period.

Dislocation of the wrist is very uncommon and is caused by a fall upon the hand.

Backward Dislocation of the Wrist.—*Symptoms.*—The deformity in backward dislocation of the wrist (Fig. 410, A) resembles that of Colles's fracture (Fig. 410, B). The fingers are flexed, the wrist is bent backward, the radius projects on the front of the wrist, the carpus projects on the dorsal

Fig. 410.—Deformity in dislocation of the wrist backward (A) and in Colles's fracture (B) (Stimson).

surface of the forearm, the relation of the styloid process of the radius to the styloid process of the ulna is unaltered (it is altered in Colles's fracture), there is rigidity, and crepitus is absent.

Forward dislocation of the wrist is very unusual and is caused by a fall upon the back of the hand.

Symptoms and Treatment.—In forward dislocation of the wrist the radius and ulna project posteriorly and the carpus projects in front. The *treatment* in both of these dislocations is reduction by extension and manipulation, the use of a Bond splint for ten days, and the employment of passive motion after five or six days.

Dislocation at the inferior radio-ulnar articulation is rare and is caused by twisting.

Symptoms and Treatment.—In *forward* dislocation at the inferior radio-ulnar articulation the forearm is pronated, the space between the styloid processes is diminished, and the ulna forms a projection posteriorly. In *backward* dislocation the forearm is supinated, the space between the styloid processes is diminished, and the ulna projects in front. Reduction is accomplished by extension and manipulation. Two straight splints (as in fracture of both bones) are to be applied for four weeks, and passive motion is to be made in the third week.

Dislocation of Individual Carpal Bones.—Pick says there is one weak spot, which is "between the head of the os magnum and the scaphoid and semilunar bones," and the os magnum may be forced up. The lesion is called

by some dislocation of the os magnum backward. Codman and Chase ("Annals of Surgery," March and June, 1905) regard the injury as really *dislocation of the semilunar forward*, a dislocation which may be associated with fracture of the carpal scaphoid. The injury is caused by forcible overextension or by twisting of the wrist. According to Codman and Chase, the injury is most frequently met with in men between the ages of thirty and forty, results from violent force, immediately produces severe pain, soon followed by tenderness and ecchymosis. On examination a silver-fork deformity is observed, the posterior projection being the os magnum, this projection being separated from the radius by a groove which marks the former situation of the dislocated semilunar. The dislocated bone is felt under the flexor tendons of the wrist, the palm seems shorter than its fellow, the fingers are partly flexed, active or passive motion causes pain, and the x-rays exhibit the dislocated bone (Ibid.).

Treatment.—According to Codman and Chase, recent dislocations (even after the fifth week) may be reduced by hyperextension followed by hyperflexion over "the thumbs of an assistant held firmly in the flexure of the wrist or the semilunar" (Ibid.).

If bloodless reduction fails, the author advises palmar incision and reduction, and if this fails, excision of the bone. If in excising the semilunar the scaphoid is found to be fractured, the proximal part or the entire scaphoid must also be removed.

Dislocation of a metacarpal bone is seldom encountered. The first metacarpal bone is most liable to dislocation.

Symptoms and Treatment.—Dislocation of a metacarpal bone is obvious because of projection. It is reduced by extension and manipulation, a straight splint and large pad for the palm are applied (as in fracture of the metacarpus), and the splint is worn for three weeks.

Dislocation at a metacarpophalangeal articulation is uncommon. Backward dislocation is the most common. The *cause* is a fall upon the hand.

Symptoms and Treatment.—A dislocation at a metacarpophalangeal articulation is obvious. Reduction is easily effected by extension and manipulation, except in the case of the thumb. A splint must be worn for three weeks.

Dislocation of the Metacarpophalangeal Joint of the Thumb.—In this dislocation the phalanx usually passes backward. In some cases the long flexor of the thumb gets to the ulnar side of the head of the metacarpal bone and hinders reduction (J. Hutchinson, Jr., in "Brit. Med. Jour.," Jan. 15, 1898). The chief impediments to reduction, as demonstrated by Farabeuf, are the sesamoid bones and glenoid ligament, which accompany the base of the phalanx in the dislocation. It is not probable that the catching of the metacarpal bone between the two heads of the flexor brevis, which often happens, is an important impediment.

The *symptoms* of *backward* dislocation are as follows: The base of the first phalanx rests upon the metacarpal bone; the head of the metacarpal bone projects forward and buttonholes the muscles of the thumb; the first phalanx of the thumb is strongly extended, and the terminal phalanx is semiflexed. The *symptoms* of *forward* dislocation are as follows: The base of the first phalanx is felt in the palm, and the head of the metacarpal bone is felt posteriorly.

Treatment.—In treating *backward* dislocation of the metacarpophalangeal joint of the thumb reduction is difficult. Always give ether. Keetley's directions are to adduct the metacarpal bone into the palm (this relaxes the flexor muscles) and to have an assistant hold it; bend the thumb strongly back, extend, pull the thumb toward the fingers, and suddenly flex. To get a firm enough grasp for these manipulations use the apparatus of Char-

rière or of Levis (Figs. 411, 412). If the above maneuvers fail, incise freely on the dorsum and reduce. Tenotomy is seldom of service. After reduction of this dislocation a splint must be worn for three weeks. In *forward* dislocation reduction is easily effected by strong extension and forced flexion. A splint is to be worn for three weeks.

A **dislocation of a phalanx** may be complete or may be partial. It is most common between the first and second phalanges.

Symptoms and Treatment.—Dislocations of the phalanges are obvious. In reducing such dislocations employ extension and manipulation. Use a splint for one week.

Dislocations of the Ribs and Costal Cartilages.—The ribs may be dislocated from the vertebræ. This accident is seldom uncomplicated, and cannot be

Fig. 411.—Levis's splint for reducing dislocation of phalanges.

differentiated from fracture without a skiagraph. The diagnosis is rarely made, and the injury is treated as a fracture. The ribs may be dislocated from their cartilages, one or more ribs being displaced. The end of the rib forms an anterior projection, there is a depression over the cartilage, and crepitus is absent. *Treatment* is the same as that employed for fractured ribs. The costal cartilages may be displaced from the sternum, forming an anterior projection upon this bone. Reduction is brought about by placing the patient upon a table, with a sand-pillow between the scapulæ, pushing back the shoulders and chest, and forcing the cartilage into place. The dressings are the same as those used for fractured sternum. The cartilages of the lower ribs (sixth, seventh, eighth, ninth, and tenth) may be separated. The inferior cartilage goes forward and can be felt. Pick states that reduction is brought about by causing

Fig. 412.—Levis's splint applied.

the patient to hold the chest full of air while efforts are made to push the cartilage into place. The injury is dressed as are fractured ribs (see page 544).

Dislocation of the Sternum.—In dislocation of the body of the sternum the manubrium is separated from the gladiolus. The injury is a rare one, is usually associated with fracture, and is most common in the young. It is due in most cases to violent direct force inflicted by a fall or heavy blow; it may be due to indirect force and arose in a reported case of acute tetanus. The *symptoms* and *treatment* are the same as those of fracture (see page 546). Dislocation of the ensiform process is one of the rarest of injuries. It is usually due to direct force, but Polaillon reports a case caused by tight lacing.

Pelvic dislocations are almost always complicated by fracture. A pubic bone can be dislocated by falls from a height or by the application of violent force

to the acetabula. The condition may happen from accident while riding a horse. The dislocation may be up or down, front or back, and it may damage the urethra or the bladder. The patient cannot stand; there are great pain and recognizable deformity. Treat by molding the bones into place, by applying a pelvic girdle, and by rest in bed for four weeks. Pure separation or relaxation of the symphysis is seldom the result of injury and is usually due to childbirth. In this condition there is mobility, pain on pressure and movement, and pain on abduction of the thighs. The treatment is rest in bed and the application of a pelvic girdle. Occasionally in traumatic and also in postobstetric separation it is necessary to wire the bones. Dislocation of the sacro-iliac joint is produced by falls. Movement on the part of the patient is diffi-

Fig. 413.—Thyroid dislocation of the femur eight weeks after the accident. Reduced by open section (Rugh).

cult or impossible; there is violent pain, and often paralysis (from pressure upon nerves). In dislocation backward there is apparent shortening of the leg, eversion of the foot exists, and the ilium moves posteriorly and upward. In dislocation forward the anterior superior iliac spine projects and the pelvis is broadened. Sacro-iliac dislocation is reduced by holding the pelvis firm and making extension by means of a pulley. The patient stays in bed for four weeks and wears a pelvic belt as in fracture.

Dislocation of the coccyx is considered on page 549.

Dislocation of the Femur (Hip-joint).—Dislocation of this joint is not often encountered, as the hip-joint is very strong. It is most apt to occur in a young adult. In forcible extension the head of the femur presses against the capsule of the joint, but the capsule here is very thick, and certain muscles, the rectus,

psoas, and iliacus, are pulled tight and serve to strengthen it. The head of the bone cannot go directly upward because of the acetabulum (Edmund Owen). The weak point of the acetabular rim is below; the weak part of the capsule is also below; hence forced abduction is apt to push the head of the bone through the lower part of the capsule, a dislocation occurring primarily into the thyroid foramen. The signs of the dislocation depend upon the untorn portion of the capsule. The anterior portion of the capsule, including the Y-ligament, usually escapes laceration. Vessels are rarely injured. Muscles are often torn. In some cases the sciatic nerve is lacerated, bruised, or caught up on the neck of the femur during the circumduction of attempted reduction. Four forms of hip-joint dislocation are usually described: (1) upward and backward, on the dorsum of the ilium; (2) backward, to the border of the sciatic notch; (3) downward, into the obturator foramen, and (4) inward, on the pubes.

Fig. 414.—Dislocation of femur upon the dorsum of the ilium (Dr. Ohnesorg's case).

All dislocations are primarily inward or outward. From these initial positions the head may be shifted to any region about the socket within reach of the remnant of untorn capsule (Oscar H. Allis). Allis rejects the old classification and suggests the following:

$$\left.\begin{array}{l}\text{Low thyroid,}\\ \text{Mid- "}\\ \text{High "}\end{array}\right\}\text{All present abduction and outward rotation.}$$

Reversed thyroid:

$$\left.\begin{array}{l}\text{Low dorsal,}\\ \text{Mid- "}\\ \text{High "}\end{array}\right\}\text{All present adduction and inward rotation.}$$

Dislocation upon the dorsum of the ilium (Fig. 414) is the commonest form. One-half of all hip dislocations are of this variety. It is *caused* by a fall or a blow when the limb is flexed and abducted (as in carrying a weight upon the shoulder), by a fall upon the knees or feet, by a weight striking the back while bending, etc. Allis says rotation inward is the chief element in its production. In this dislocation the head of the femur goes upward and backward, rests upon the ilium, and is always above the tendon of the obturator internus muscle. This dislocation is secondary to thyroid dislocation, muscular action shifting the bone from its initial seat of displacement.

Signs.—Dislocation upon the dorsum of the ilium is indicated by the following symptoms: the buttock appears flat and broad; the great trochanter is above Nélaton's line and is deeply placed; the head of the bone can be detected in its new situation; deep pressure in front of the joint finds a hollow; the leg is shortened by about 2 or 3 inches; the fascia lata is relaxed; in some thin people the socket can be outlined; when the patient is recumbent the injured extremity can be brought to the perpendicular without flexing the leg (Allis); the knee is somewhat flexed; the thigh is slightly flexed,

inwardly rotated, and adducted (Fig. 415) (this is shown by the fact that the axis of the thigh of the injured side, if prolonged, would pass through the lower third of the sound thigh); when the capsule is extensively lacerated there may be no adduction and may be eversion (Allis); the heel is raised, and the great toe of the foot of the injured side rests upon the front of the instep or the ankle of the sound side (Fig. 415); rigidity exists; voluntary movement is impossible, though some passive motion is possible in the direction of the deformity (the deformity can be made more marked). If a patient is recumbent and the knees vertical, the foot of the sound extremity is free of the bed, but the foot of the injured extremity touches the bed (*Allis's sign*).

Diagnosis.—Examine first without anesthesia. The x-rays are invaluable in diagnosis. If the x-rays are not obtainable, examine again while the patient is anesthetized. Dislocation is distinguished from intracapsular fracture by noting the inversion, the great shortening, the absence of crepitus, the age of the subject, and the nature of the force. The nature of the force, the inversion, and the absence of crepitus mark the diagnosis from extracapsular fracture.

Fig. 415.—Hip-joint dislocation upon the dorsum of the ilium (Cooper).

Treatment.—The chief obstacle to reduction in dislocation upon the dorsum of the ilium, Bigelow states, is the untorn portion of the capsule, especially the Y-ligament. The iliofemoral, Y, or Bigelow's ligament resembles an inverted Y, arises from the anterior inferior spine of the ilium, is inserted into the anterior intertrochanteric line, and is incorporated into the front of the capsule. To reduce a dislocation this ligament must be relaxed by manipulation or be torn by extension. Manipulation makes the head of the bone retrace its steps over the same route it took in emerging. Give ether; place the patient supine upon a mattress on the floor; flex the leg on the thigh (to relax the hamstrings), flex the thigh on the pelvis; increase the adduction over the middle line; strongly abduct; perform external rotation and extension. This treatment may be summed up as flexion, adduction, external circumduction, and extension; or, as Pick puts it, "bend up, roll out, turn out, and extend." Allis's advice is to fix the pelvis to the floor, lift the head of the bone to the level of the socket, rotate outward by carrying the leg toward the pubis, and extend the femur. If extension and counterextension are employed, make extension in the axis of the dislocated limb and obtain counterextension by a perineal band. The extension band is fastened to the thigh by a clove-hitch. After reduction put the patient to bed and use sand-bags (as in fracture of the hip) for four weeks. We may tie the knees together instead of using the sand-bags. Passive motion is made in the third week. The pulleys must not be used in reduction. They may inflict great or even fatal injury. If the surgeon fails to reduce the deformity, there are two courses open to him. He may let it alone. He may operate. If he lets it alone, the limb will almost certainly become ankylosed, though probably useful. If he determines to operate, he must recognize that tenotomy is useless. It is necessary to make a free incision in order to restore the bone.

Dislocation Onto the Border of the Sciatic Notch.—In this dislocation the head of the bone passes backward and a little upward, and rests upon the ischium at the margin of the sciatic notch (not in the notch), below the tendon of the obturator internus muscle. The *causes* are the same as those given for the previous dislocation.

The *signs* in dislocation by the sciatic notch are like those of dislocation upon the dorsum of the ilium, but they are not so marked. There

are flattening and broadening of the hip; ascent of the trochanter above Nélaton's line; shortening to the extent of an inch; relaxation of the fascia lata. If the knee of the injured side is vertical, the sole of the foot touches the bed. Flexion, inward rotation, and adduction exist, but the axis of the femur of the injured side passes through the knee of the sound side, and the ball of the great toe of the injured side rests upon the great toe of the sound side (Fig. 416). Other symptoms are identical with those of dislocation upon the dorsum of the ilium, but are less pronounced. Allis's signs of this dislocation are of value: if, with the patient recumbent, the thighs are brought to a right angle with the body, shortening on the affected side is materially increased; if the dislocated thigh is extended, the back arches as in hip disease.

Fig. 416.—Hip-joint dislocation onto the sciatic notch (Cooper).

Diagnosis and Treatment.—The signs of dislocation on the border of the sciatic notch are similar to, but are less marked than, those of dorsal dislocation, and, being a backward dislocation, the reduction and treatment are the same as for dislocation backward upon the dorsum of the ilium.

Dislocation Downward Into the Obturator Foramen (Fig. 417).—Downward dislocation is the primary position of most dislocations of the hip, the bone rarely remaining in the thyroid foramen, but usually mounting up as a result of muscular action or of the initial violence. The *cause* is a violent abduction by falls or by stepping from a moving car.

Signs.—Dislocation downward into the obturator foramen is indicated by flattening of the hip; the head of the bone is felt in its new position and is missed from the acetabulum; rigidity exists; passive motion is only possible in the direction of deformity, and that to a slight extent; a hollow is noted over the great trochanter, which process is well below Nélaton's line and nearer than normal to the middle line. The gluteal crease is lower than is the crease of the opposite side; there is lengthening to the extent of 1 to 2 inches; the body is bent forward by the traction upon the psoas and iliacus muscles, and is also deviated to the side, thus causing great apparent lengthening; the limb is advanced partially flexed and abducted, and the foot is pointed straight ahead or is a little everted (Fig. 417); when the patient is recumbent extension is impossible, the knees cannot be pushed together without great pain, and the abductor muscles are hard and rigid. Allis's signs are absent. Unreduced dislocations do well, the patient obtaining a very useful hip-joint (Sédillot).

Fig. 417.—Hip-joint dislocation into the obturator or thyroid foramen (Cooper).

Treatment.—In treating dislocation downward into the obturator foramen give ether and effect reduction, if possible, by manipulation, and, if this fails, by extension. To reduce by manipulation, flex the leg on the thigh and the thigh on the pelvis, and then perform, in the following order, abduction, internal circumduction, and extension. Allis's rule of reduction is as follows: fix the pelvis to the floor; pull the head of the femur outward and above the socket; fix the head; push the knee toward sound knee and extend the femur. If extension is made, make traction in the axis of the limb by means of muslin fastened around the thigh by a clove-hitch. Do not use pulleys; incise rather than use them.

Dislocation upon the pubis is a very uncommon accident. The head of the bone usually rests just internal to the anterior inferior spine of the

ilium. The primary position of the bone is in the thyroid foramen; the pubic dislocation, when it occurs, is always secondary, and is due to the initial force and to muscular action.

Symptoms.—In pubic dislocation the head of the bone can be felt and seen in its new position; the hip is flattened; there is a hollow over the great trochanter, this process being found below the anterior superior spine of the ilium; there is shortening to the extent of 1 inch; the limb is in abduction with eversion (Fig. 418), and the knees cannot be approximated without great pain.

In the *treatment* of pubic dislocation give ether and employ manipulation as for thyroid dislocation. If this fails, employ extension. The limb is well abducted, extension is made downward and backward, and the head of the femur is pulled outward "by a towel around the thigh, just beneath the groin" (Keetley). The after-treatment is the same as that for the previous forms.

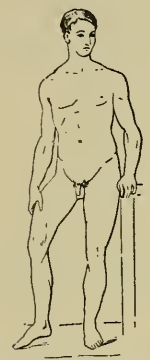

Fig. 418.—Dislocation on pubis (Cooper).

Central or Internal Dislocation (Fig. 419).—By this term we mean that the head of the femur has been displaced and perhaps forced through a fractured acetabulum into the pelvis. It is not a genuine dislocation. There is neither tearing nor stretching of the capsule and the acetabular floor may remain in contact with the femoral head. Skillern and Pancoast ("Annals of Surgery," Jan., 1912) point out that "the injury varies from a slight depression of the floor of the acetabulum . . . to the passage of the femoral head into the pelvic cavity." For the first injury they suggest the term *fractura acetabuli perforans;* for the second, *fractura acetabuli perforata.* This injury is due to violent force. The usual cause is a fall upon the great trochanter. The symptoms vary with the degree of depression or fracture of the floor of the acetabulum. If there is only slight depression of the floor, there may be no appreciable shortening and very slight approach of the trochanter toward the symphysis pubis. The x-rays may be needed to make a diagnosis. If the head has perforated, shortening will be evident, there will be marked approach of the trochanter toward the midline, and vaginal or rectal palpation will discover the displaced femoral head. In both injuries there are pain, tenderness, and impaired mobility. There may be serious damage within the pelvis. Intrapelvic hemorrhage is common. The peritoneum may be lacerated, the bowel may be damaged, the bladder injured, or the obturator nerve bruised (Skillern and Pancoast, Ibid.).

Treatment.—If complications such as are mentioned above exist, at once open the abdomen and repair the injury. Reduce the deformity by extension and counterextension. Treat by "extension in the axis of the limb in conjunction with lateral traction upon the femoral neck" (Ibid.). After a week, if there is no contra-indication, apply a plaster-of-Paris dressing from the toes to the chest.

Skillern and Pancoast (Ibid.) state that the injury was first described by Callisen in 1788, and that, with their 4 cases, 55 have been reported.

Anomalous Dislocations of the Hip.—In *supraspinous dislocation* the dislocation of the hip is backward, the head of the femur resting upon the ilium above or even anterior to the anterior superior spine. In *ischial dislocation* the dislocation is downward and backward, the head of the femur resting on the ischial tuberosity or in the lesser sciatic notch. *Monteggia's dislocation* is a supraspinous dislocation with eversion of the limb. In *perineal dislocation* the head of the femur is in the perineum. In *suprapubic dislocation* the head of the femur passes above the pubes. In *subspinous dislocation* the femoral head rests on the horizontal ramus of the pubes.

Dislocation with Catching Up of the Sciatic Nerve During Reduction.— This accident causes severe pain. The leg is flexed on the thigh and the thigh is flexed on the pelvis. Allis tells us that the task of reduction is very unpromising. We must strive to put the neck of the femur in such a position that the nerve will "drop off," and yet often the nerve cannot drop off because it is held by adhesion to the injured muscles. Allis attempts reduction by the following plan:

1. Place the patient upon his back and redislocate the femur.
2. Extend the thigh.
3. Flex the leg on the thigh.
4. Turn the ankle out until the leg is horizontal (this causes the head of the bone to look downward).
5. "Shake, shock, jar, adduct, and abduct," to disengage the nerve.
6. Rotate into socket without flexing leg (without making nerve tense).
7. If this fails, make an incision above the popliteal space, and draw the nerve out of the wound. Detach the head of the bone from its entanglement and rotate it into the socket.[1]

Fig. 419.—Dislocation of left hip. Fracture of acetabulum, ischium, and pubes (right), with central dislocation of hip. Separation of pubic arch.

Dislocation of the Head of the Femur with Fracture of the Shaft of the Bone.—We may incise, replace, and plate the fragments. We may use McBurney's hooks as in the shoulder. We may be forced to do a resection of the head.

Allis maintains that it is possible to reduce it by manipulation. He states that the upper fragment is the entire lever, and the lower fragment "is only the agent through which we apply our force." The fragments are not completely separated, but are connected at one side by material which is "partly periosteal, partly tendinous, and partly muscular." This connecting material enables us to make traction upon the upper fragment, but does not allow "rotation, circumduction, and leverage through the agency of the lower frag-

[1] Allis's views will be found in "An Inquiry Into the Difficulties Encountered in the Reduction of Dislocations of the Hip," by Oscar H. Allis, M. D. This highly original and valuable treatise received the Samuel D. Gross Prize of the Philadelphia Academy of Surgery in 1895.

ment." Hence "the only agency at our command is traction." If the dislocation is inward (forward), draw the head outward and have an assistant make direct pressure upon the head of the bone. If this fails, the assistant holds the head of the bone to prevent its slipping into the thyroid depression, and the surgeon makes traction inward or inward and downward. If the dislocation is outward (backward), make traction directly upward to lift the head of the bone to the level of the socket, and try to place the head over the socket by traction obliquely upward and inward. During all these manipulations an assistant presses upon the trochanter to prevent the head of the bone slipping back. Traction is now made downward and inward, and the tightened ligament may drag the head of the bone into place.

Dislocation of the Knee.—It is a rare injury. There are four forms—forward, backward, outward, and inward. Any one of the four may be complete or incomplete; the commonest dislocations are lateral. The *cause* is violent force, such as a fall, or in jumping from a moving train, or in being caught by the foot and dragged.

Fig. 420.—Old dislocation of the patella outward.

Dislocation Forward of the Knee-joint.—In the *complete* form of forward dislocation the deformity is obvious. The limb is usually extended, but it may be flexed. Much shortening exists; the condyles are felt posterior and below; the head of the tibia is felt anterior and above; the patella is movable and the quadriceps is lax; pressure of the condyles upon the contents of the popliteal space arrests the tibial pulse and causes edema and intense pain. In *incomplete* dislocation the symptoms are identical in kind, but are less pronounced.

Treatment.—Compound dislocation of the knee-joint often demands excision or amputation. In simple dislocation give ether, have one assistant extend the leg while another makes counterextension on the thigh, and the surgeon pushes the bone into place. Reduction is easy because of ligamentous laceration. Place the limb on a double inclined plane, and combat inflammation by the usual methods (see Synovitis, page 617). Begin passive motion in the third week. The patient must wear a knee-support for months. Very extensive laceration of ligaments calls for incision and suturing. If the popliteal vessels are much damaged, gangrene will supervene and amputation will be demanded.

Dislocation Backward of the Knee-joint.—In the *complete* form of backward knee-joint dislocation displacement is not so great as in dislocation forward. The head of the tibia projects posteriorly and above, the femoral condyles anteriorly and below; the leg is, as a rule, partly flexed, but it may be extended, and there is moderate shortening. In *incomplete* dislocation the symptoms are less marked.

The *treatment* of backward dislocation of the knee-joint is the same as for forward dislocation.

Dislocation outward of the knee-joint is usually incomplete. The inner tuberosity of the tibia in outward dislocation lies upon the outer condyle of the femur (Pick); the inner condyle of the femur projects internally; the outer tibial tuberosity and fibular head project externally, the former having a depression below it, and the latter above it; the leg is semiflexed, but shortening is absent.

Dislocation inward of the knee-joint is usually incomplete. The outer tuberosity of the tibia in inward dislocation lies upon the inner condyle of the femur; the outer condyle of the femur forms an external prominence, and the inner tuberosity of the tibia forms an internal prominence. Pick cautions us not to mistake a separation of the lower femoral epiphysis for lateral dislocation (the former is reduced easily, the deformity tends to recur, and there is soft crepitus).

Treatment.—In treating lateral dislocation of the knee-joint, effect extension and counterextension as in anteroposterior dislocations. The leg is moved from side to side and attempts are made at rotation. The after-treatment is the same as that for anteroposterior luxations.

Dislocation of the patella is seldom congenital. There are 35 congenital cases on record (Bajardi). There are three forms of dislocation of the patella: outward, inward, and edgewise. The so-called dislocation upward is, in reality, rupture of the ligamentum patellæ (see page 718).

Fig. 421.—Dr. Morris Booth Miller's case of outward dislocation of the patella from direct force six months after the fall. Failed of reduction under ether anesthesia.

Dislocation of the patella outward (Fig. 420) may be due to muscular action or to direct force, and occurs during extension of the leg. It occasionally happens in a person with knock-knee. If dislocation is complete the bone lies upon the external surface of the external condyle; if incomplete, the patella rests upon the anterior surface of the external condyle. The leg is extended, flexion is impossible, and attempts at flexion produce great agony. In the patient shown in Fig. 420 flexion became possible in an unreduced dislocation, but not until months after the accident. The knee is wider than normal. There is a hollow in front of the joint. The bone is felt in its new position.

Dislocation of the patella inward is very rare (Fig. 421). The signs are like those of dislocation outward, except that the patella rests upon the inner condyle.

Treatment of Lateral Dislocations of the Patella.—Give ether. Raise the

body upon a bed-rest and flex the thigh. Grasp the patella and depress the margin which is farthest from the center of the joint (Pick). The muscles may pull the bone into place. Extend the extremity and immobilize for three weeks, and then begin passive motion. Incision may be necessary in order to effect reduction.

Dislocation of the Patella Edgewise.—The patella rotates vertically, one edge resting between the condyles. As a rule, the outer border is in the intercondyloid notch. This condition is produced by direct force when the extremity is partly flexed. Twisting and muscular action have been assigned as causes. The condition is obvious at a glance.

Treatment.—Give ether. Pick recommends "sudden and forcible bending of the knee." In some cases the bone can be pushed into place, the limb being extended and flexed as in the reduction of a lateral dislocation. In some cases incision will be necessary.

Dislocation of the Semilunar Cartilages of the Knee-joint (*the Internal Derangement of Hey; Subluxation of the Knee-joint*).—The condition was described by Hey, of Leeds, in 1803. The interarticular cartilages of the knee-joint are attached in front of and behind the tibial spine, and the convexity of each cartilage is attached to the edge of the corresponding tibial tuberosity by means of the coronary ligament. The internal cartilage is fastened to the internal lateral ligament and has a moderate freedom of movement. The outer cartilage is not connected with the external lateral ligament and is not freely movable. It has been stated that the outer cartilage is more frequently dislocated than the inner, but modern experience indicates that this is not true, and that the internal cartilage is the one most apt to suffer. In 17 cases operated upon by Barker the internal cartilage was involved in every case ("Lancet," Jan. 4, 1902). Those persons whose occupations force them to pass considerable time upon their knees are predisposed to this accident (Annandale). The derangement of the cartilage is usually caused by a sudden external rotation of the tibia while the knee-joint is in partial flexion; for instance, when the patient stumbles over an obstacle, the knee-joint being partially flexed, the tibia is twisted outward. When the joint is flexed a normal cartilage moves backward, and when it is extended moves forward again. When the cartilage is thrown out by the sudden eversion and flexion of the tibia it is caught and does not move into place readily when the leg is extended. The tear takes place in the direction of the fibers of the cartilage.

Symptoms.—The first indication of interarticular cartilage displacement is a sudden, violent, sickening pain in the knee, which may be so severe as to cause the patient to fall to the ground. The knee is in a position of fixed semiflexion. Further flexion is possible, but extension is impossible. In some cases the patient can voluntarily make further flexion; in others, the pain is so severe that he either cannot or will not do it; but increase of flexion can be obtained by passive motion. The joint is, however, blocked both to passive and to voluntary extension. Attempts at passive motion are productive of fierce pain. If either cartilage is displaced away from the tibial spine, a prominence may be found on one or the other side of the knee-joint. If the displacement takes place toward the tibial spine a prominence may be found on one side of the ligament of the patella. Subluxation is rapidly followed by inflammation of the synovial membrane of the joint and inflammation of the cartilage itself; and swelling quickly masks the projection of the cartilage. This accident is frequently mistaken for the blocking of the joint by a floating cartilage; but a dislocated cartilage always remains in the same position, and a loose cartilage changes its position from time to time (Turner). Loose bodies in a joint produce pain of a shifting character and interference with both flexion and extension, or with either flexion or extension in an

irregular way (Cotterill). In regard to the diagnosis, Cotterill points out that in a sprain of the joint extension is not painful, but flexion is interfered with; whereas, in the dislocation of a cartilage of the joint, flexion is still possible, but extension cannot be carried out ("Lancet," Feb. 22, 1902).

Treatment.—To reduce a displaced semilunar cartilage I have used with satisfaction a method described by Henry W. Jacob ("Brit. Med. Jour.," March 7, 1908). It is not followed by severe synovitis unless the patient has walked or has made repeated efforts to reduce the displacement, and as it is a painless method ether is not required. Jacob describes it as follows:

"The patient lies on a bed or couch, the surgeon standing on the outer side of the limb affected, with his face toward the patient's foot; the patient then raises his leg off the couch in the semiflexed position, the surgeon grasps the patient's leg in both hands, and using his own thigh as a fulcrum, by means of a steady pulling movement draws the patient's leg outward while the surgeon's thigh keeps the patient's femur in a fixed position; directly this movement is effected the patient must steadily extend the limb, and the displaced cartilage will probably go back with a slight click; if the first movement of extension is not successful the maneuver must be repeated without any hurry or unnecessary force, and after a few attempts the cartilage can usually be felt to slip in without pain or inconvenience."

In treating dislocation of a semilunar cartilage of the knee it is customary to give ether and reduce by forced flexion and external rotation. Extension becomes possible if the cartilage is freed. During these maneuvers an assistant endeavors to push any projection of cartilage into place. After reduction apply a splint for two weeks and combat inflammation by proper remedies (see Synovitis); then begin passive motion. At the end of two weeks apply a firm knee-cap made of leather and let the patient get about on crutches. After a couple of weeks the crutches can be laid aside. As recurrence of the displacement is usual, the patient should wear a knee-cap during the day for many months. A partial tear may entirely heal when thus treated by rest and support; an extensive tear will not, although even in such cases a useful but somewhat stiff joint may be obtained. If it is found impossible to unlock the blocked joint, or if the tear is extensive and redislocation is prone to occur, an operation is advisable. The joint is opened and the loose cartilage is pushed into place and held by stitches to the periosteum, or the loosened portion is excised. Annandale, in 1885, sutured through a transverse incision. Freeman and others used sutures to fix the cartilage. Excision is just as satisfactory as suturing, and after excision recurrence of the trouble is impossible. After excision the extremity is placed upon a posterior splint. Passive motion is begun in two weeks.

Dislocation of the Fibula at the Superior Tibiofibular Articulation.—This injury is rare. The head of the fibula may go forward or backward. The *causes* are direct force and violent adduction of the foot with abduction of the knee (Bryant).

Symptoms.—After dislocation of the fibula the position is one of semiflexion of the knee, voluntary extension and flexion being impaired or lost. A distinct movable projection is readily noticed in front or behind, which is found to be continuous with the fibula. There is a depression over the normal position of the head of the fibula.

Treatment.—In treating dislocation of the fibula bend the knee to relax the biceps, and proceed to push the bone into place. Put a compress over the head of the fibula, apply a bandage, and put the limb on a double inclined plane. The peroneal nerve passes over the fibula just below the head of the bone and care must be taken to avoid making injurious pressure upon the nerve. At the end of three weeks put a lacing knee-support upon the knee and let the

patient up. Displacement being liable to recur, a knee-cap must be worn for a year.

Dislocation of the Ankle-joint.—This injury is not unusual. Fracture is a frequent complication. There are five forms of ankle-joint dislocation—outward, inward, forward, backward, and upward.

Lateral dislocation of the ankle-joint is either outward or inward, and may be complete or incomplete. In these dislocations the astragalus rotates. In incomplete dislocation "there is no great separation of the trochlear surface of the astragalus from the under surface of the tibia, but the outer or inner margin of this surface is brought into contact with the articular surface of the tibia, and the whole foot presents a lateral twist" (Pick). The *causes* of these dislocations are twists of the joint.

Symptoms.—Incomplete outward dislocation of the ankle-joint occurs in *Pott's fracture* (see page 612). Complete outward dislocation, in which the articular surface of the astragalus is completely displaced outward from the articular surface of the tibia, and which condition is associated with a fracture of the fibula and separation of the inferior tibiofibular articulation, is known as *Dupuytren's fracture.* In incomplete dislocation the foot goes outward and upward, the fibula is fractured, and the tibiofibular ligaments are torn off. In Dupuytren's fracture the ankle is broad, the inner malleolus projects and looks lower than natural, the outer malleolus ascends with the foot, the foot rotates outward, and crepitus can be detected. In inward dislocation which is associated with fracture of the inner malleolus there is inversion, the outer malleolus projects, and crepitus can be detected. In incomplete separation the symptoms are similar, but are not so marked.

Treatment.—In treating a case of dislocation of the ankle-joint the deformity is reduced by flexing the leg on the thigh and the thigh on the pelvis; an assistant makes counterextension from the knee; the surgeon makes extension from the foot, and at the same time rocks the astragalus into place. Dupuytren's fracture is treated in the same manner as Pott's fracture (see page 613). Dislocation inward is treated in a fracture-box for the same period as Pott's fracture.

Anteroposterior dislocation of the ankle-joint is rare. The *cause* is the catching of the foot in jumping or falling—direct violence. In dislocation forward the foot is lengthened, the heel is not conspicuous, the tibia and fibula project against the tendo Achillis, and the relation of the malleoli to the tarsus is altered. In incomplete dislocation the symptoms are similar, but less pronounced. In dislocation backward the foot is shortened, the tibia and fibula project in front, the heel is prominent, and the relation between the malleoli and the tarsus is altered. In incomplete dislocation the symptoms are similar, but less marked.

Treatment.—In anteroposterior dislocation of the ankle-joint reduce as in lateral dislocations. Sometimes the tendo Achillis must be cut. Apply a plaster-of-Paris dressing and let it be worn for two weeks; then begin passive motion, and let the patient wear side-splints for a week longer.

Dislocation upward of the ankle-joint, or *Nélaton's dislocation,* is a very rare injury. The astragalus is wedged between the widely separated tibia and fibula. This dislocation is usually associated with fracture. The *cause* is a fall upon the feet from a great height.

Symptoms.—Upward dislocation of the ankle-joint is indicated by the widening of the ankle and by the flattening of the foot. The malleoli are nearly on a level with the plantar surface of the foot, and there is absolute rigidity.

Treatment.—In treating upward dislocation of the ankle-joint give ether, and try to reduce by powerful extension and counterextension. Treat the injury afterward in the same manner as an anteroposterior luxation.

Dislocation of the Astragalus.—The astragalus may be displaced from the bones of the leg and at the same time be separated from the rest of the tarsus. The displacement may be forward, backward, outward, inward, or rotary.

Dislocation of the astragalus forward or **backward** is caused by falls or twists.

Symptoms.—In forward dislocation the astragalus projects strongly; there is shortening of the foot, and the malleoli approach the plantar aspect of the foot; the foot is deviated to one side or to the other, and there is absolute rigidity of the ankle-joint. In incomplete luxations the symptoms are similar, but less marked. This dislocation may be obliquely forward. In backward dislocation of the astragalus the foot is not deviated to either side; the astragalus projects between the malleoli and above the os calcis, and the tendo Achillis is stretched over the projection. Rigidity is absolute. This dislocation may be obliquely backward.

Lateral and Rotary Dislocations of the Astragalus.—Lateral dislocations of the astragalus are rare, are always compound, and are always associated with fracture. In rotary dislocation the astragalus remains in its normal habitat after rotating on its own axis, either horizontal or vertical. The *causes* of rotary dislocation are twists of the foot when it is at a right angle to the leg (Barwell). The *symptoms* of rotary dislocations are obscure. There is rigidity, but sometimes the position of the astragalus may be made out.

Treatment of Dislocation of the Astragalus.—In treating astragalus dislocation reduce under ether by flexing the knee to relax the gastrocnemius, extending the foot, and pushing the bone into place. It may be necessary to cut the tendo Achillis. After reduction put up the foot and leg in a plaster-of-Paris dressing for two weeks, and then begin passive motion and apply side-splints, which are to be worn for one week more. If reduction fails, support the limb on splints, combat inflammation, and endeavor to bring about union between the dislocated bone and the tissues. Often, in unreduced dislocation, the skin sloughs over the projecting bone. Excision is demanded the moment sloughing is seen to be inevitable. Cases of compound dislocation of the astragalus require immediate excision.

Subastragaloid Dislocation.—This condition is a separation of the astragalus from the os calcis and scaphoid, without separation from the bones of the leg. Pick states that the usual classification for these dislocations is forward, backward, inward, and outward, but that the displacement is, as a rule, oblique, the foot passing backward and outward or backward and inward. The *cause* is twisting.

Symptoms.—In subastragaloid dislocation the astragalus projects on the dorsum; the foot is everted in outward dislocation and inverted in inward dislocation; the relation of the malleoli to the astragalus is unaltered; the ankle-joint is not absolutely rigid; the foot "is shortened in front and is elongated behind" (Pick).

Treatment.—To treat subastragaloid dislocation make extension in the direction opposite to that of the displacement. In dislocation of the tarsus backward fix a bandage around the foot, on a level with the heads of the metatarsal bones, which bandage the surgeon ties around his shoulders. The surgeon puts one knee in front of the ankle and thus fixes the leg, raises himself up to make extension upon the tarsus, and molds the bone into position. Tenotomy may be necessary. After reduction apply a plaster-of-Paris dressing and have it worn for three weeks. The ankle-joint, fortunately, is not involved, and stiffness of this articulation need not be apprehended. If reduction is impossible, take the same course as in luxations of the astragalus.

Dislocations of the other tarsal bones are very rare. Single bones may be dislocated, or the luxation may occur at the mediotarsal articulation.

Symptoms and Treatment.—Projection is an obvious *symptom* in dislocation of the other tarsal bones. The *treatment* is to reduce by extension and molding, the part being put up in plaster-of-Paris dressing for two weeks.

Dislocations of the metatarsal bones are rare.

Symptoms and Treatment.—Shortening of the toes and projection of the dislocated bone are *symptoms* of dislocation of the metatarsal bones. To *treat* these dislocations reduce by extension under ether and put up in a plaster-of-Paris dressing for two weeks. If reduction fails, the functions of the foot will not be much impaired.

Dislocations of the phalanges are very rare. The first phalanx of the big toe is the one most liable to dislocation.

Symptoms and Treatment.—Dislocations of the phalanges are obvious. The *treatment* is by reduction and fixation, as in dislocation of the thumb. Immobilize for two weeks.

Operations Upon Bones and Joints

Osteotomy.—By the term *osteotomy* the modern surgeon means literally the sectioning of a bone for the purpose of straightening a limb ankylosed in a bad position, correcting a bony deformity, or amending a vicious union

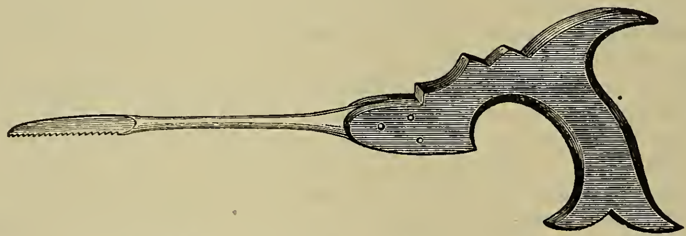

Fig. 422.—Adams's large saw. (In this day of surgery the saw has a metal handle.)

of a fracture. In a *linear osteotomy* the bone is transversely or obliquely divided at one spot; in a *cuneiform osteotomy* a wedge-shaped portion of bone is removed. The operation of osteotomy may be performed with a saw (Fig. 422) or with an osteotome. The saw creates dust, draws much air into the wound, and lacerates the tissues to a considerable degree. Most surgeons prefer the chisel or the osteotome. The osteotome slopes down to a point from each side (Fig. 423); the chisel is straight on one side and on the other is bevelled to a point.

Fig. 423.—Osteotome.

Osteotomy for Genu Valgum, or Knock-knee (*Macewen's Operation*, Fig. 424).—The patient lies upon his back, being rolled a little toward the diseased side. The leg of the diseased side is partly flexed upon the thigh and the thigh upon the pelvis, and the extremity is laid upon its outer surface, a sand-bag being pushed between the extremity and the bed, opposite to the site of section. The flexion of the knee relaxes the popliteal vessels and saves them from injury. The surgeon, if operating on the right leg, stands outside of that extremity; if operating on the left leg, he stands opposite the left hip (Barker). The knife is inserted into the tissues and carried to the bone at the inner side of the knee, just in front of the adductor tubercle of the inner condyle and on a level with the upper border of "the patellar articular surface of the femur" (Barker). An incision is made upward 1 inch in length, in the direction of the axis of the femur. The knife is left in as a guide until the osteotome is inserted at the lower

angle of this wound. After the insertion of the osteotome the knife is withdrawn and the blade of the osteotome is turned to a right angle with the shaft of the femur, ½ inch above the epiphysis (Fig. 424). The osteotome is struck several times with a mallet; the handle is moved several times toward and from the body, so as to widen the cut in the bone (Fig. 425); the osteotome is again struck with the mallet several times; it is again moved to and fro, and this process is continued until the bone is cut two-thirds through. If the osteotome becomes tightly fixed, it should be withdrawn and a smaller one introduced. In the soft bone of a young girl this to-and-fro movement of the chisel, if carefully executed, is not liable to break the instrument. In dense bone it may break the instrument; hence, when doing an osteotomy in dense bone, the osteotome is moved to and fro across the limb and slight downward pressure upon the handle will to a great extent prevent binding. When the bone is cut two-thirds through the osteotome is withdrawn, a piece of wet antiseptic gauze is held over the wound, and the surgeon fractures the femur by strong adduction. The wound is neither sutured nor drained, but is dressed aseptically, the entire extremity is wrapped in cotton, and a plaster-of-Paris dressing is applied and carried up to the groin. The dressing may be removed in two weeks, and the patient may subsequently be treated with sand-bags, as for an ordinary fracture of the thigh, but without extension. This operation is scarcely ever fatal.

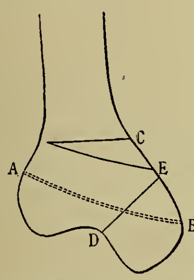

Fig. 424.—Osteotomy of the right femur in a case of knock-knee: A B, Epiphyseal line; C, section of Macewen; D E, section of Ogston.

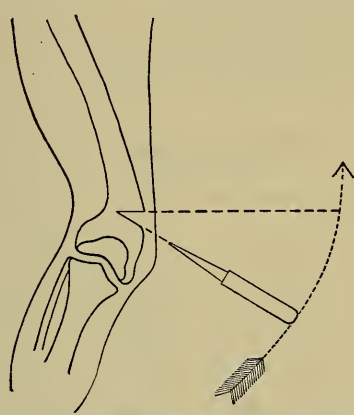

Fig. 425.—Macewen's operation for genu valgum. The chisel is held in the line for striking with a mallet; the arrow shows the direction in which the chisel is levered up and down so as to make a wide gap in the bone (after Barker).

Ogston's Operation for Knock-knee (Fig. 424).—In this operation the internal condyle is sawed off obliquely with an Adams saw—a proceeding which permits the straightening of the knee. The objection to the procedure is that it opens the knee-joint, and that this cavity fills up more or less with a mixture of blood and bone-dust. Macewen's operation is decidedly the safer.

Osteotomy for a Bent Tibia.—The tibia is divided transversely or obliquely (linear osteotomy), or a wedge-shaped piece is removed (cuneiform osteotomy). The oblique incision is the best. If the convexity of the tibial curve is inward, cut the bone from above downward and from in front backward; if the curve is forward, section the bone from above downward and from within outward. The fibula need rarely be interfered with. After the osteotomy the limb is treated just as it would be for a fracture.

Osteotomy for Faulty Ankylosis of the Hip-joint.—This operation is performed in order to allow straightening of a limb that has undergone bony ankylosis in a faulty or an inconvenient position. In some cases an attempt is made to obtain a movable joint, but in most cases the surgeon must be

satisfied with ankylosis in extension. Osteotomy may be performed through the neck of the femur or through the shaft of the femur below the trochanters.

Osteotomy through the neck of the femur is performed (1) with a saw (Adams's operation) or (2) with an osteotome.

Adams's Operation (Fig. 426, A).—The patient lies upon his sound hip; the surgeon stands upon the side to be operated upon, and back of the patient. The knife is entered a finger's breadth above the great trochanter, is pushed in until it strikes the neck of the bone, is then carried across the front of and at a right angle with the neck, and is withdrawn, enlarging the wound, in the soft parts as it emerges, to the extent of 1 inch. The saw is then introduced and the neck of the femur is entirely divided. After the osteotomy dress the wound antiseptically and place the extremity straight. To straighten the limb it may be found necessary to cut contracted tendons and fascial bands. After securing extension and applying dressings use the weight-extension apparatus and the sand-bags. Begin passive movements from the start if a movable joint is desired; few patients can tolerate the pain necessary to bring this about. If it is determined to aim for a stiff joint, treat the case as an intracapsular fracture would be treated.

With an Osteotome.—The position of the patient is the same as that for Adams's operation. An incision 1 inch long is made, starting just above the great trochanter, ascending in the axis of the femoral neck, and reaching to the bone. An osteotome is introduced, is turned to a right angle with the neck of the bone, and is struck with a mallet until the bone is *completely* divided. (It is not to be divided partially and then broken.) The after-treatment is the same as that for Adams's operation. The operation by the osteotome is to be preferred to that by the saw.

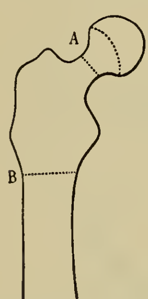

Fig. 426.—Osteotomy through the neck of the femur: A, Adams's operation; B, Gant's operation.

Osteotomy of the Shaft of the Femur Below the Trochanters (*Gant's Operation*).—In this operation (Fig. 426, B) the saw may be used, but the osteotome is to be preferred. The position in Gant's is like that in Adams's operation. A longitudinal incision 1 inch long is made upon the outer aspect of the femur and on a level with the lesser trochanter. The osteotome is inserted and the bone is completely divided below the lesser trochanter. The after-treatment is the same as that for Adams's operation. Gant's operation is the best method for correcting faulty position in bony ankylosis, and Adams's operation can only be employed in those cases in which the femur still has a neck which is practically unchanged.

Osteotomy for Faulty Ankylosis of the Knee-joint.—This operation is performed for bony ankylosis of a knee in a position of flexion. In these cases it is nearly always necessary to cut contracted tendons and fascia. These contractures tend to draw the tibia backward as in a posterior dislocation. The patient lies upon his back with his thighs flat upon the bed, the legs hanging over the end of the bed. The surgeon stands on the patient's right side. Just above the patellar articular surface upon the femur a transverse incision is made, 1 inch in length and reaching to the bone. The osteotome is introduced and the bone is cut *nearly* through. The leg is then forcibly extended. It must not be extended too violently or the popliteal vessels may be injured. In cases in which the structures of the popliteal space are tense and have not been divided the leg must not be brought at once into extension, but this position should be attained gradually by means of weights. The wound is dressed aseptically, and the extremity is placed upon a double inclined plane and is treated as for fracture near the knee-joint.

Osteotomy for vicious union of a fracture is performed in case of angular deformity, and is carried out in the same manner as are the above procedures. It is best, when possible, to enter the osteotome upon the concavity of the bent bone, so that the periosteum will not rupture when extension is made, and the patient will in consequence gain a longer limb.

Osteotomy for Hallux Valgus.—In this operation a linear osteotomy is made through the neck of the metatarsal bone of the great toe, the toe is forcibly adducted, and a splint is applied to the inside of the foot and the toe. A cuneiform osteotomy may be done instead of a linear osteotomy. The osteotomy is made through the neck of the metatarsal bone. A wedge-shaped piece of bone (the base of which is to the inner side of the foot) is removed. Charles H. Mayo makes a flap of the bursal sac and capsular ligament, divides the metatarsal bone with a Gigli wire saw, sutures the flap over the bone end, closes the skin incision, and fixes the toe in the adducted position.

Osteotomy for Talipes Equinovarus (*After Barker*).—The patient lies upon his back, the thigh is semiflexed, the knee is bent, and the sole of the foot rests upon the table. The surgeon stands to the right side if it is the right limb which is to be operated upon, and to the left side if it is the left limb. He feels for the outer surface of the cuboid bone, and cuts away from over the latter a piece of skin corresponding in size with the bone-wedge intended to be removed (this piece of skin must include the bursa which forms in these cases). The foot is then turned outward, the astragaloscaphoid articulation is located, and over this an incision is made "from the lower to the upper dorsal border of the scaphoid bone" (Barker), reaching through the skin only; the foot is placed again in the first position, all the soft parts are raised from off the superior surface of the tarsus, and a triangular surface corresponding with the base of the wedge to be removed is cleared; a "kite-shaped" director (Fig. 427) is passed into the external wound and projected from the internal wound; the saw is pushed through the groove of the director nearest the toes, and is made to cut through the tarsus, from the dorsum to the sole, at right angles to the metatarsal bones; the saw is pushed through the groove of the director nearest the ankle, and is made to cut from the dorsum to the sole, at right angles to the long axis of the calcaneum; the wedge-shaped piece of bone is grasped by sequestrum forceps and cut out by scissors, by bone-forceps, or by a blunt bistoury. The wound is well irrigated, the foot is straightened, the internal wound is sewed up, the external wound is sutured except at its lowest portion, where a drainage-tube is to be retained for twenty-four hours, and dressings are applied to the wound. The foot is put up in plaster or upon a Davy splint. Some surgeons insert the wedge of bone into the opening made by a linear osteotomy on the inner side of the foot.

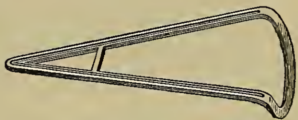

Fig. 427.—Davy's director (Pye).

Osteotomy for Talipes Equinus.—This operation is described by Mr. Davy, who devised it, as follows:[1] "Taking the line of the transverse tarsal joint as a guide, on the outer and inner sides of the foot, and immediately over the joint, two wedge-shaped pieces of skin are removed, equal in extent to the amount of bone demanded. The soft structures are freed on the dorsum of the foot in the way previously described; but, as the base of the osseous wedge for equinus cases is at the dorsum and its apex at the sole, the parallel wire director, instead of the kite-shaped varus one, is used. The saw is successively inserted in its grooves, and by keeping in mind the idea of a keystone a clean wedge of bone is cut out from the dorsum to the sole of the foot."

[1] Barker's "Manual of Surgical Operations."

The wedge is extracted, and the foot is straightened and is put up in plaster of Paris or is placed on a Davy splint.

The Question of Operation for Recent Fractures.—(See page 533.)

Operation for Recent Simple Fracture.—Very early after the injury is a fairly safe period for operation. Lane favors very early operation. During the first week, excluding the early hours after the injury, is a dangerous period to operate because the area of injury has a low resistance to infection. About the tenth day is a safer period for operation. Very careful sterilization is imperatively necessary. Make a free incision and expose the fracture. Remove all tissue from between the bone ends. König disagrees with Lane that all blood-clot should be removed. Arrest bleeding. Bring the fragments into apposition by extension and by using Lane's powerful forceps (see Fig. 283) as a lever. Apply nails, screws, or what apparatus we desire.

The Lane plate is an excellent device (see Fig. 281). Select a suitable plate, remove the lever, fix the plate and bones by Lowman's clamp (see Fig. 284), bore the bone by a drill (see Fig. 282) at each screw hole, insert and fix the screws, remove the clamp, and close the wound without drainage or with a cigarette drain. The part is placed upon a splint.

Figure 325 shows Lane's plate applied. If it does not loosen and does not give trouble a plate is not removed surgically.

Recent Transverse Fracture of the Patella.—(See page 604.)

Recent Fracture of the Olecranon Process of the Ulna.—(See page 568.)

Bone-grafting, or Transplantation.—(See pages 503 and 536.)

Operative Treatment of Ununited Fracture.—A method of operation long in vogue and still used is as follows: Incise longitudinally down to the

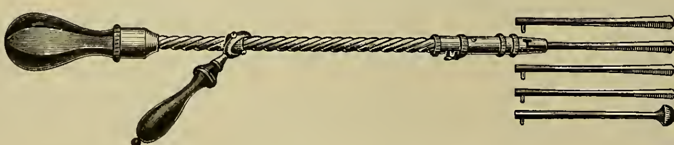

Fig. 428.—Hamilton's improved bone-drills.

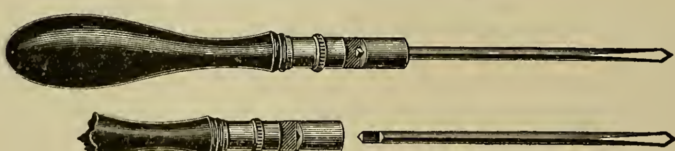

Fig. 429.—Brainard's drills with Wyeth's adjustable handles.

seat of fracture, retract the periosteum from the bone, drill the bones before cutting them, chisel away the material of imperfect union, saw through each bone end far enough from the seat of fracture to reach sound tissue, pass large silver wire through the holes (this wire should be $\frac{1}{10}$ inch in diameter for the femur, $\frac{1}{16}$ inch for the patella, etc.) (Fig. 430), twist the wires a fixed number of times (two complete turns) in the direction that the hands of a watch move (this is Keen's direction; in case removal of the wires should be demanded later we know how to untwist them; of course the surgeon must remember where he stood in relation to the limb and regard the hypothetical watch as being face up upon the part), sever the ends of the wires, and hammer their stems against the bones. The wires may never require removal. The soft parts are sutured, no drain or a cigarette drain is used, and the limb is encased in plaster of Paris. The objection to wire in fracture of a long bone is that the wire acts as a hinge and, as a consequence, alignment is apt to be disturbed. Various plans besides wiring have been employed in ununited

fracture. Gussenbauer's clamp is used by some. Clayton Parkhill's bone-clamp is a useful appliance, and holds the fragments firmly in contact. Some surgeons unite the fragments with kangaroo-tendon instead of wire (suturing of bone); others use nails of bone or ivory; others use screws. Senn asserted that the above methods will not hold fragments in contact if these fragments have a tendency to become displaced. Senn fastened the bones together by hollow cylinders of decalcified bone or ivory, the cylinders being perforated in many places (bone-ferrules). I regard the silver plate of Halsted and steel plate of Lane as the most satisfactory appliances in use.

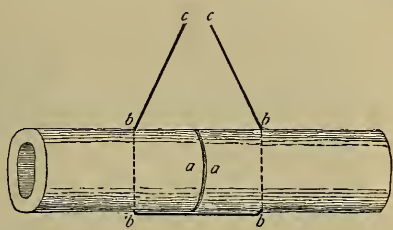

Fig. 430.—Wiring of bones for ununited fracture: *a*, *a*, Sawn surfaces approximated after removal of old material which was interposed between the fragments; *b–b*, *b–b*, perforations drilled completely across the bone; *c*, *c*, wires ready for twisting.

Ununited Fractures of the Femoral Neck.—Loreta did the first successful operation for this condition a number of years ago. The operation is not adapted to the aged, but should certainly be employed in youths and middle-aged individuals if the general condition of the patient or some particular diseased state does not forbid, and if pain is severe and disability is pronounced.

Leonard Freeman advises an anterior incision beginning below and external to the anterior superior iliac spine and extending downward, external to the sartorius, for 3 or 4 inches ("Annals of Surg.," Oct., 1904). When the fragments are exposed, the connective tissue between them is cut away by means of scissors, the surfaces of the fragments are freshened by a chisel or

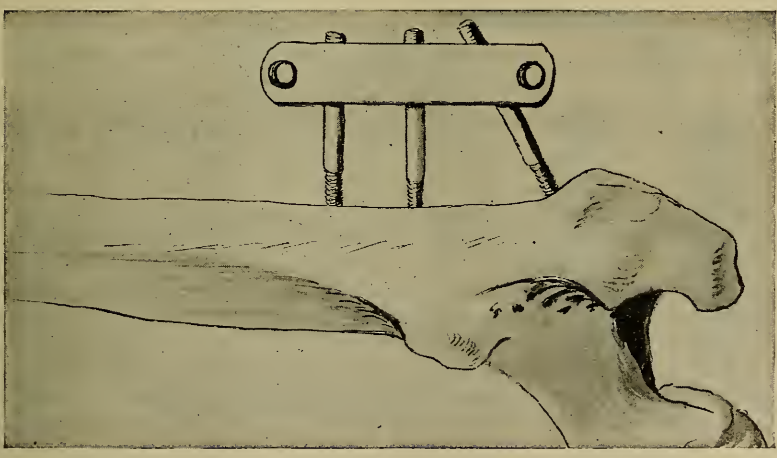

Fig. 431.—Method of securing screw of Freeman's apparatus in fracture of neck of femur; the wooden plates embracing screws (Freeman, in "Annals of Surgery," Oct., 1904).

a curet, oozing is arrested by pressure and hot water, and loose osseous splinters are removed (Freeman). Some surgeons have fixed the fragments together by nails, screws, or pegs of bone or ivory, access to the trochanter being best obtained for this purpose by making a second incision over the outer portion of that bony process. As Freeman points out, however, the head is often so very soft that none of these appliances will secure fixation.

Freeman has devised a clamp for this purpose (Figs. 431, 432). An additional incision is made over the trochanter and holes are bored for the clamp

screws, one hole being drilled "through the base of the trochanter, the external fragment of the neck, and into the head of the bone" ("Annals of Surgery," Oct., 1904). The wound is closed, dressings are applied, and extension is made on a long side splint, a pad being placed beneath the trochanter to prevent the disposition to pass backward, which movement, if it occurs, will

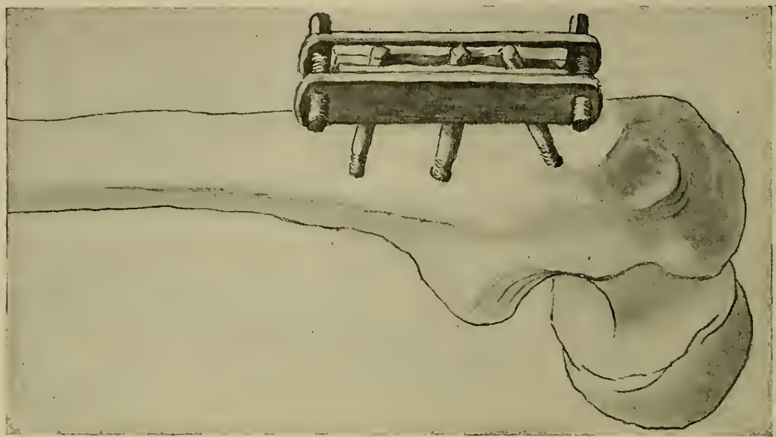

Fig. 432.—Completed screw and clamp of Freeman's apparatus for fixation of fracture of neck of femur (Freeman, in "Annals of Surgery," Oct., 1904).

cause external rotation of the limb and separation of the fragments. In about eight weeks the extension is removed and the patient is allowed about on crutches. Dr. H. Augustus Wilson has succeeded by simply nailing the fragments together without attempting to freshen their faces. He got his patient up on crutches in two weeks ("Amer. Jour. Orthopedic Surgery," Jan., 1908).

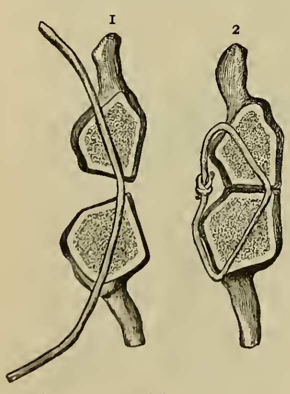

Fig. 433.—Wiring of the patella: 1, Fragments cut and cleaned and the wires passed; 2, wires twisted and hammered down upon the bone (after Barker).

In Freeman's case the screws were removed in two weeks because of infection of the cancellous tissue. A similar condition arose in Davis's case, in which two steel drills were used. Dr. H. Augustus Wilson has collected 36 cases of direct fixation of old intracapsular fractures (Ibid.).

Ununited Fracture of Patella.—A semilunar incision is made about the fragments, the convexity pointing up or down (this avoids the prepatellar bursa), or an incision is made in the long axis of the limb, over the middle of the space between the fragments, from well above the upper fragments to well below the lower piece. The soft parts are retracted, but the periosteum is undisturbed; each fragment is bored (Fig. 433, 1) in one or two places; the surfaces of the fragments are cut square through sound bone with a saw; all old reparative material is cut away; the wires are passed through the perforations, twisted, cut off, and hammered down (Fig. 433, 2). If the bone-fragments cannot be approximated, it may become necessary to incise the muscle around and above the patella or partially to separate the tuberosity of the tibia and bend this process upward. A small drain is inserted above the bone, the wound is sutured, aseptic dressings are applied, and the limb is put upon a Macewen splint.

Treves's Operation for Caries of the Lumbar and Last Dorsal Vertebræ, with Abscess in the Psoas Magnus or Quadratus Lumborum Muscle.—The patient lies upon his left side, with the knees drawn up and a sand-bag under the left loin. The surgeon stands behind the patient (Barker). An incision is made at the outer border of the erector spinæ mass, reaching from the last rib to the iliac crest and going down at once to the lumbar fascia. The lumbar aponeurosis is opened, the erector spinæ muscle is retracted inward, and the anterior portion of the erector spinæ sheath is incised. The quadratus lumborum muscle is next cut, and then the anterior leaflet of the lumbar aponeurosis is slit. The abscess is thus reached and opened and tuberculous pus flows out. The abscess-cavity is irrigated with quantities of warm corrosive sublimate solution (1 : 5000). The cavity is filled, the fluid is allowed to flow out, its exit being aided by pressure in front and changes of posture; the cavity is filled again, and so on, and, after all loose débris is removed, the bodies of the vertebræ are carefully examined with the finger and diverticula are opened. Loose pieces of bone are removed by spoons or forceps, and cavities are thoroughly but lightly curetted, as in some places the wall is very thin. By means of properly

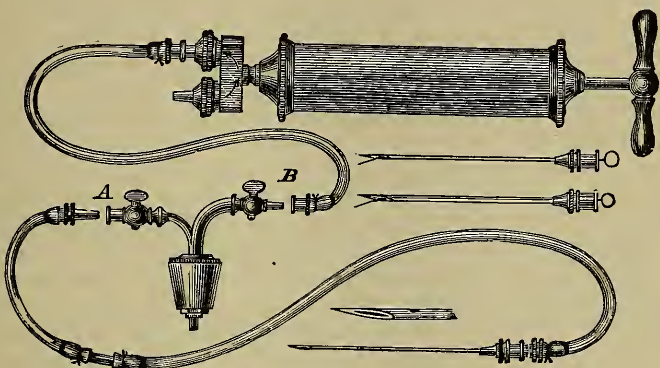

Fig. 434.—Aspirator and injector.

shaped spoons carious bone can be removed even from the anterior surface of the column (Treves). Thus the wall of the abscess is completely removed. Finally, all débris is washed out by irrigation with mercurial solution; any mercurial solution which might remain is washed out by warm water or salt solution, and the interior of the cavity is wiped dry. At this stage most operators introduce iodoform emulsion. Whether or not this is done, "the wound is closed by a series of silkworm-gut sutures, passed sufficiently deep to include the greater part of the muscular and tendinous structures with the skin" (Treves's "Operative Surgery"). Treves's operation gives a high mortality.

Aspiration of Joints.—In certain cases of joint-effusion from inflammation, tuberculous or otherwise, and sometimes in hemorrhage into a joint, it is desirable to remove the fluid by aspiration. The pneumatic aspirator (Fig. 434) is used. The trocar and cannula are thoroughly asepticized and the joint is prepared as for a set operation. The needle is entered at a surface free from vessels. The directions for using an aspirator are as follows: insert the stopper firmly into a strong bottle (preferably a clear glass one), then attach the short elastic hose to the stopcock *B* of the tube projecting from the stopper, and attach the other end of the same elastic hose to the exhausting or inward-flowing chamber of the pump. Next, attach one end of the longer elastic hose to the

stopcock A projecting from the stopper and the other end to the needle. Care should be taken that all the fittings or attachments are placed firmly into their respective places. Now close the stopcock A and open the stopcock B. By giving from thirty-five to fifty strokes of the pump a sufficient vacuum can be produced to fill with the fluid from the joint a bottle holding from a pint to a quart. After having formed the vacuum, close the stopcock B, and insert the needle in the joint. When the stopcock A is opened, suction through the needle draws the fluid from the joint. The trocar may also be used to inject antiseptic agents. After the completion of aspiration the part is dressed antiseptically and the extremity is put at rest upon a splint.

Excisions of Bones and Joints.—The ancients practised excision and resection for compound dislocations and fractures. For centuries surgeons removed pieces of diseased bone from joints. The operation was set forth as a definite procedure, and was first formally advised as a substitute for amputation in joint disease by Mr. Park, of Liverpool, in 1781. In 1782 the elder Moreau, of Bar-sur-Ornain, independently devised a like operation. The terms "excision" and "resection" are usually employed as synonymous, but such a use is not strictly accurate. According to Professor Ashhurst, the term *excision* means "the removal of an offending part without that total ablation of the affected portion of the body which is implied by the term 'amputation.' Hence we speak of excisions of tumors, of joints, of the eyeball, etc." *Resection* has a more restricted meaning; it signifies "an operation which takes away a middle portion and brings the ends together again, and is thus in strict surgical language limited to partial excisions of the long bones" ("International Encyclop. of Surgery," edited by John Ashhurst, Jr.). Excision of a joint is the removal of the articular portions of the bones of the joint, and also the cartilage and synovial membrane. In the hip-joint and shoulder-joint only the head of the long bone may be removed, and not the articular surfaces of both bones. In partial excision of a long bone, excision (resection) for bone disease, enough bone is known to have been removed only when the remaining bone bleeds. *Complete excision* of a bone is the removal of an entire bone. *Partial excision* or *resection* is the removal of a portion only of a bone. Excision is a conservative operation which often averts amputation.

Excision may be performed by the *open* method, in which the periosteum is not preserved, or it may be performed by the *subperiosteal* method, in which the periosteum is carefully separated by a rugine and the capsular ligament is preserved. This method was devised by Ollier, of Lyons. *Arthrectomy*, or *erasion*, is the excision of the diseased synovial membrane and ligament, and also small foci of disease of bone and cartilage.

Excision may be employed for compound dislocation, and in compound dislocations of the elbow and the shoulder it is usually performed. Excisions for compound dislocations in other large joints are very dangerous; they are rarely attempted in battlefield practice, and are to be avoided even in civil practice unless the patient is young and vigorous and every advantage can be given him during the operation and convalescence. Excision for deformity is rarely performed except upon the hip, the knee, and the shoulder, and these excisions must not be employed if the patient's condition leads one to fear the result of a protracted convalescence. Excision of the elbow, however, is usually a safe operation. In excising for deformity always consider the patient's trade and the demands of habitual position which it makes upon him.[1]

Excision is largely employed for joint-disease, especially for tuberculous joints. Bell states that attempts to preserve the limb without excision are

[1] Joseph Bell, in his "Manual of Surgical Operations."

more justifiable in the lower than in the upper limbs, because operation in the lower extremity is more dangerous than in the upper, and because a cure without operation in the lower limbs, if this cure can be brought about, gives as good a result as a cure by excision. In the upper extremity the danger from operation is less than is the danger from waiting. In a young subject an excision may remove the epiphysis, and thus lead to permanent shortening, which is productive of less inconvenience and deformity in the arm than in the leg. A danger of excision operations is that the section may be made through cancellous bony tissue; hence, if infection takes place, disastrous suppuration, phlebitis, myelitis, septicemia, or pyemia will follow; further, in excision the cut is often made through diseased tissue, and a protracted convalescence is then inevitable. Amputation is effected through healthy tissue, and the convalescence is short. Excision, however, when successful, gives the patient a very useful limb.

Erasion, or Arthrectomy.—This operation was suggested by Cross, of Bristol, and was perfected and established by Wright, of Manchester, between 1881 and 1888. *Erasion* is the complete removal of diseased synovial membrane, ligaments, and small foci of disease in bone and cartilage. This operation seeks to remove a depot of infection in an early stage of tuberculous synovitis, and it possesses the conspicuous merit of not interfering with the epiphysis. The term "erasion" is also used by some to designate the operation of removing healthy synovial membrane, ligaments, etc., for the purpose of producing fixation of a flail-joint due to infantile paralysis, but in such cases *arthrodesis* is the proper term for the operation. Erasion is oftenest practised upon the knee-joint.

Erasion of the Knee-joint.—The patient lies upon his back; the leg is flexed, with the sole of the foot planted upon the table, and an Esmarch bandage is applied at a point well up on the thigh. The surgeon stands to the right of the patient. The incision is begun in the midline of the thigh (on the side opposite to that occupied by the surgeon), about 3 inches above the patella; it is carried down across the ligament of the patella and up to a corresponding point on the opposite side of the thigh. This incision goes down to the bone; the flap is turned up and the joint exposed; the knee-joint is strongly flexed, and the synovial membrane and diseased ligaments are dissected away with scissors and forceps, great care being taken that the posterior ligaments (which, fortunately, are rarely implicated early in the case) are not divided and that the contents of the popliteal space remain intact. After removing the diseased ligaments and synovial membrane the cartilage is examined and any diseased portion is removed. The bone is then examined and any tuberculous foci are gouged away. Exposed vessels are ligated. The wound is irrigated by salt solution, the extremity is straightened, and the ends of the ligamentum patellæ are sutured, a drainage-tube is inserted at each angle of the wound, the skin is sutured, and antiseptic or sterile dressings are applied. The limb is placed upon a posterior splint for a few days, then the drainage-tubes are removed, the dressings are changed, and a plaster-of-Paris cast is applied, trap-doors being cut on each side, and the joint is kept immobile for two or three weeks. This operation is only suited to early cases in which the lesion involves chiefly or purely the synovial membrane and ligaments, and in these cases it frequently gives a good result, some capacity for motion being not unusually preserved.

Excision of the Shoulder-joint.—Bent, of New Castle, performed the operation in 1771 ("Manual of Operative Surgery," by Sir Frederick Treves). Syme really established the operation in surgical confidence. In the shoulder-joint *partial* excision is often performed, the head of the humerus being removed and the glenoid being undisturbed; but some patients require complete

excision, the entire glenoid depression, as well as the head of the humerus, being removed by the surgeon. Excision of the shoulder-joint is made, if possible, an intracapsular operation, the capsule being opened, but the capsular attachment to the anatomical neck of the humerus not being interfered with. In advanced cases, however, the capsular attachment must be destroyed. Excision of the shoulder-joint for trauma is a far less common operation in civil, than in military, practice. It is performed for gunshot-wounds, compound dislocations, tuberculous disease, and tumors of the head and upper portion of the humerus.

Operation by Anterior Incision.—The patient lies supine; a pillow is placed beneath the shoulders, and a sand-pillow is put beneath the shoulder to be operated upon. The arm is held to the side with the outer condyle forward and the bicipital groove inward (Barker's directions). The surgeon stands by the affected side. An incision 3 or 4 inches in length is made from just external to the coracoid process of the scapula, running straight down the humerus (Fig. 435, A). This incision divides the border of the deltoid muscle and brings into sight the long head of the biceps. The tendon of the biceps is retracted inward, unless it is diseased, in which case it is resected. The knife is carried up the groove and opens the capsule of the joint. The periosteum is lifted from the neck of the bone while an assistant rotates the elbow to make the muscles tense. In some places, if the periosteum tears, muscular insertions must be cut with a knife. The head of the bone is sawn off while the bone is in place, or the elbow is strongly pulled back, and the head of the bone is forced out of the wound, and is then sawn off at the point required. In ordinary cases only the articular head is removed; in other cases the section is made just above the surgical neck; in yet others a portion of the shaft must also be cut away. If the glenoid cavity is found slightly diseased, the dead bone must be removed by the chisel and mallet or by the cutting forceps. If the cavity is seriously diseased, the entire glenoid should be removed. Scrape away all damaged tissue; ligate bleeding points; irrigate the wound with corrosive sublimate solution; swab it out with a solution of chlorid of zinc (20 gr. to 1 oz.); dust with iodoform; close the upper portion of the wound and insert a drainage-tube in the lower angle; dress the wound antiseptically; place a small pad in the axilla; apply the second roller of Desault; and put the patient in bed with a pillow under the affected shoulder. In seven days the hand-sling is substituted for the bandage, and with the elbow hanging free the patient is permitted to get up and is advised to move his arm frequently. Drainage is maintained until the wound is well healed from the bottom. Great limitation of movement inevitably follows a shoulder-joint resection.

Excision by the deltoid flap is performed when the head of the bone is much enlarged (as by a tumor) or when the tissues are thick and indurated. The deltoid flap is in the shape of a U or is semilunar (Fig. 436, A). Raising this flap exposes the head of the bone most satisfactorily. Bell states that when the glenoid cavity is chiefly involved the incision should be posterior (Fig. 436, B).

Senn's Method.—Senn[1] described an incision which does not damage important vessels, muscles, tendons, or nerves, and which is followed by good functional results. A semilunar skin-flap is formed, the incision running from the coracoid process to the posterior border of the axillary space. The flap is turned up, exposing the upper half of the deltoid muscle. The acromion is sawn off and turned down with the attached deltoid. The capsule is now freely exposed; it is opened, and either arthrectomy or excision is performed, according to conditions. In closing the wound it is not necessary to bore the acromion and pass silver wires to join the fragments; it is enough to suture the periosteum with catgut.

[1] "Phila. Med. Jour.," Jan. 1, 1898.

Excision of the Elbow-joint.—This operation was suggested by Park in 1782, but the first employment of it was by Moreau in 1794. It is performed for wounds, faulty ankylosis, and chronic articular disease. Excision must be complete. Endeavor to make a subperiosteal resection; this maintains the shape of the articulation and gives the best chance for a movable joint. The patient is "supine, but inclining to the sound side, the affected arm being held almost vertical, with the forearm flexed and nearly horizontal" (Barker). The incision is made on the posterior surface of the joint. A single posterior incision is usually employed (Fig. 436, D). An incision is made a little internal to the long axis of the olecranon, beginning 2 inches above and terminating 2 inches below the tip of the olecranon. This incision goes down to the bone, and throughout the entire operation the surgeon must guard

Fig. 435.

A–G, Excisions: A, excision of shoulder-joint (deltoid flap); B, of shoulder-joint (posterior incision); C, of elbow-joint (H-shaped incision); D, of elbow-joint (linear incision); E, of hip-joint (Gross's); F, of os calcis; G, of scapula.

and shield the ulnar nerve. The periosteum and soft parts are well separated; the olecranon is sawn off; forced flexion exposes the joint-cavity freely, and enables the surgeon to lift the periosteum and soft parts from the humerus; the humerus is sawn through at the beginning of its condyloid processes; the radius and ulna are cleared and are sawn at a level below that of the base of the coronoid process of the ulna. Diseased tissues are cut and scraped away; the wound is irrigated, sutured, drained, and dressed. In some cases an H-shaped incision is employed (Fig. 436, C), but the cicatrix of a transverse cut will limit flexion of the limb.

After excision of the elbow the patient is put to bed and the arm is laid upon a pillow, the elbow being placed midway between a right angle and complete extension, the forearm being placed midway between pronation

and supination. No splint is used, as a rule. Esmarch used the splint shown in Fig. 437. The aim in treatment is to obtain a freely movable joint. Passive motion is begun in one week, at which time the patient gets up. The hand is carried in a sling for a time after healing of the wound is complete.

Excision of the Head of the Radius.—This operation is practised for irreducible dislocation of the radius. An incision is made through the supinator longus muscle down to the head of the radius, and the neck of the bone is divided by means of a Gigli saw or bone-cutting forceps. The musculospiral nerve lies to the inner side. Some bone is always taken from the external condyle in order to make a sufficient gap to prevent subsequent ankylosis ("The Operations of Surgery," by Jacobson and Rowlands).

Excision of the Wrist-joint.—This operation was first performed by Moreau in 1794. Bell states that, whatever method of excision is chosen, three cardinal rules must be borne in mind: (1) remove all the diseased bone, including the portions of the radius, ulna, carpus, and metacarpus which are covered with cartilage; (2) interfere with the tendons to the least possible degree, and (3) begin passive motion of the fingers very early. Many surgeons prefer the simple gouging away of diseased foci and the scraping of sinuses instead of a formal resection of the wrist, amputation being employed in severe cases or when scraping fails after several trials. Formal excision is not frequently performed, and the results cannot be regarded as very favorable.

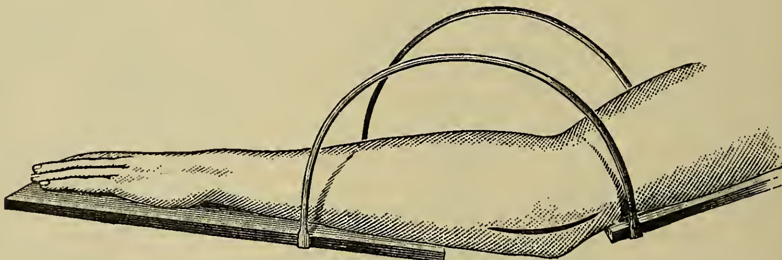

Fig. 437.—Esmarch's splint for the treatment of a limb after excision of the elbow-joint.

Lister's Open Method of Excision.—Break up adhesions as completely as possible by forcible movements. Apply a tourniquet or an Esmarch apparatus. The patient lies upon his back, the arm and the forearm being brought, from stage to stage, into the most desirable positions. Begin an incision over the middle of the dorsum of the radius, on a level with the styloid process; carry it downward in the direction of the inner edge of the articulation of the thumb with its metacarpal bone, and when the knife reaches the radial side of the second metacarpal bone alter the direction of the incision and carry it downward in the long axis of the metacarpal bone to about its middle (Fig. 438, A). This is known as the *radial incision*, and the only tendon divided is that of the extensor carpi radialis brevior muscle. The tissues upon the radial aspect of the incision are dissected up, the tendon of the extensor carpi radialis longior muscle is divided at its point of insertion (Bell), and all the soft structures are retracted outward, exposing the trapezium, which is cut off from the rest of the carpus, but which is left in place, as its removal at this stage endangers the radial artery (Barker). By extending the hand the tendons are loosened and the carpus is cleared in the direction of the ulnar border of the hand.

Another incision is made, starting upon the inner surface of the wrist, 2 inches above the articular surface of the ulna, and midway between the ulna and the flexor carpi ulnaris tendon. This incision, which is known

as the *ulnar incision*, is carried down until it is opposite the middle of the fifth metacarpal bone in the palm (Fig. 438, B). "The dorsal lip of this incision is raised" (Bell), and the extensor carpi ulnaris tendon is divided and dissected from its depression, but is not separated from the integument. The extensor tendons are lifted; the ligaments upon the dorsum and sides of the wrist-joint are cut; the flexor tendons are raised from the carpal bones; the pisiform bone is cut from the carpus, but is not yet removed; and the unciform process of the unciform bone is cut with forceps. The anterior radiocarpal ligament is divided, the carpometacarpal articulations are cut through, and the carpus is pulled out with bone-forceps. The ends of the radius and ulna are forced out of the ulnar incision. All that portion of the ulna which is crusted with cartilage is to be removed, the saw-cut is to be oblique, and the base of the styloid process is to be left behind. A thin section is to be sawn from the radius, and the tendon-grooves are not to be impinged upon. The articular surface of the ulna is cut away by pliers (Bell).

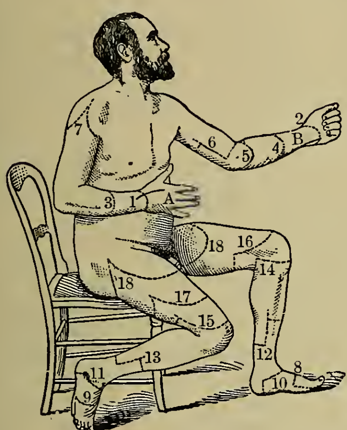

Fig. 438.

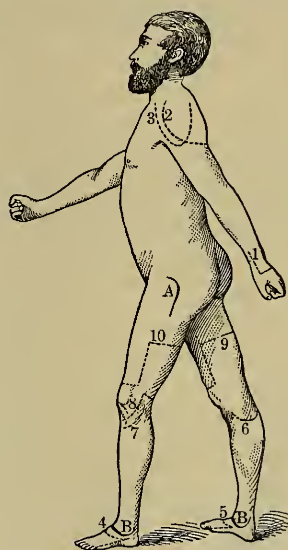

Fig. 439.

Fig. 438.—1–18, Amputations (Joseph Bell): 1, amputation at wrist-joint (dorsal incision); 2, at wrist-joint (palmar incision); 3, at forearm (dorsal incision); 4, at forearm (palmar incision); 5, at elbow-joint (anterior flap); 6, at arm (Teale's); 7, at shoulder-joint (first method); 8, 9, of metatarsus (Hey's); 10, 11, at ankle (Syme's); 12, 13, of leg, posterior flap (Lee's); 14, at knee-joint (Carden's); 15, of thigh (B. Bell's); 16, of thigh (Spence's); 17, of thigh in middle third; 18, 18, at hip-joint. A, excision of wrist (radial incision); B, of wrist (ulnar incision).

Fig. 439.—1–10, Amputations (Joseph Bell): 1, of lower third of forearm (Teale's); 2, at shoulder-joint by large postero-external flap (second method); 3, at shoulder-joint by triangular flap from deltoid (third method); 4, 5, through tarsus (Chopart's); 6, 7, at knee-joint; 8, by single flap (Carden's); 9, 10, of thigh (Teale's). A, excision of hip; B, B, of ankle-joint (Hancock's incision).

If foci of disease are discovered beyond these points, they are to be gouged out. The ends of the metacarpal bones are sawn off, and their articular facets are cut away by means of pliers. The trapezium is dissected out, the end of the first metacarpal bone is sawn off and its facet is cut away with pliers, and a portion of the pisiform bone is removed (the entire bone being removed if it be diseased). The wound is irrigated, vessels are tied, the radial incision is closed, the ulnar incision is partly closed, a drainage-tube is inserted by way of the ulnar incision, the wounds are dressed antiseptically, and the Esmarch apparatus is taken off. The forearm and hand are placed upon a splint which immobilizes the wrist and leaves the fingers semiflexed. Passive motion of the fingers is begun after thirty-six hours. The splint is worn for many months

until the wrist-joint is immobile and solid. Esmarch uses the splint shown in Fig. 440.

Excision of Metacarpal Bones and of Phalanges.—Excision of a metacarpal bone, except in cases of necrosis with the formation of large quantities of new bone, usually leaves a useless finger; hence amputation is usually preferred to excision. This rule does not apply to the metacarpal bone of the thumb, which is occasionally excised. The incision for this operation is made upon the dorsum, and is straight. Excision of the proximal phalanx of the thumb is sometimes performed. Excision for disease is rarely performed upon the finger-joints, amputation being preferred, though the operation is sometimes undertaken for compound dislocation. In the metacarpo-phalangeal joint of the thumb excision, if it can be performed, is preferred to amputation. The incision for resection of this joint is placed upon the radial aspect.

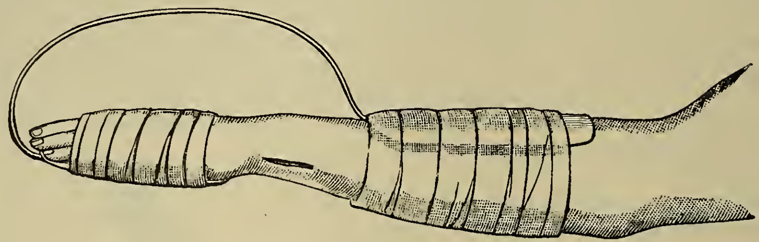

Fig. 440.—Esmarch's interrupted splint applied.

Excision of the Hip-joint.—Treves and Jonathan Hutchinson, Jr. ("Manual of Operative Surgery"), tell us that the operation was first performed by Anthony White, of the Westminster Hospital, in 1818. Sir William Fergusson established the operation in surgical confidence. Some surgeons advocate this operation; others, notably Marsh, are emphatically opposed to it. Excision should be performed in the early stage of tuberculous disease *if less radical treatment has failed.* In this stage the usual position of the limb is one of flexion, abduction, and eversion. In cases of long duration, especially where dislocation exists, excision is an easy and a comparatively safe operation; in recent cases it is difficult and carries with it decided dangers, but the peril of delay may be greater than the peril of an early excision. In cases of hip disease with involvement of the acetabulum the mortality is 50 per cent., whether operation is or is not attempted. Excision is performed especially for tuberculous disease and for gunshot-injuries.

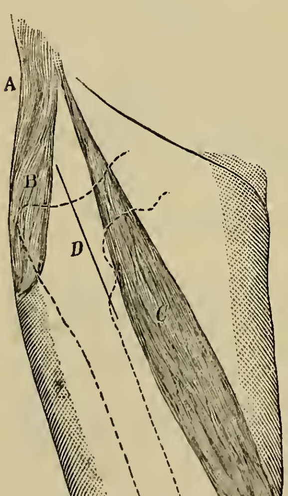

Fig. 441.—Excision of the hip-joint: A, Gluteus muscle; B, tensor vaginæ femoris muscle; C, sartorius muscle; D, anterior incision.

Operation by Anterior Incision (Fig. 441) (*Barker's Operation*).—In this operation the patient is supine, with the thighs extended as thoroughly as circumstances permit. The surgeon stands to the right of the patient. An incision is begun ½ inch below and ½ inch external to the anterior superior iliac spine, and it is carried downward and a little inward for about 3 inches (Fig. 441, D). If dislocation exists, the incision need not be so long. This incision is carried at once deeply between the muscles, and the capsule of the joint is

opened. The neck of the bone is divided from its upper surface downward by a saw or an osteotome, and without dislocating the bone through the wound by forcible extension and eversion. The head of the bone is removed. All tuberculous foci must be scraped away, and the flushing gouge is used upon tuberculous areas of the acetabulum. All sinuses should be thoroughly scraped. Bleeding is arrested, the wound is irrigated with normal salt solution, mopped with chlorid of zinc solution, and dusted with iodoform. A drainage-tube is inserted at the lower angle of the incision, and the upper portion of the cut is closed. The wound is dressed antiseptically. Extension is made by the extension apparatus until healing has obtained good headway, when a double Thomas splint is applied, so that the patient may be taken out daily in the air and sunlight. As a rule, rigid ankylosis results from resection of the hip, but occasionally a joint results with a small range of movement.

Operation by Lateral Incision (*Langenbeck's Operation*).—In this operation a straight incision 2 inches in length is made in the direction of the axis of the femur, and passing downward from the apex of the great trochanter. From the beginning of this incision a curved incision is carried toward the head of the bone, the convexity of the curve being backward (see Fig. 439, A). Bell advises the use of the saw after bringing the head of the bone into the wound by abduction and eversion of the thigh. Barker applies the saw with the bone *in situ*, and strongly opposes wrenching the bone out of the incision because of the danger of peeling off the periosteum, which peeling, if it takes place, favors necrosis.

Incision of Gross.—In Gross's operation a semilunar flap is made with the convexity backward (see Fig. 436, E).

Excision of the Knee-joint.—The complete operation was first performed by Park, of Liverpool, in 1781. In this operation a complete excision should be performed, and the patella ought to be removed. The operation is performed for tuberculous disease, some compound fractures and compound dislocations, and some cases of angular ankylosis. It is rarely employed for gunshot-injuries.

Operation by Anterior Semilunar Flap.—The patient lies upon his back, and the joint, if not ankylosed in extension, should be semiflexed. The surgeon stands to the right side. An incision is made which at once opens the joint. The incision begins at one condyle and reaches the other condyle by a curve which passes through the ligamentum patellæ midway between the tuberosity of the tibia and the inferior margin of the patella (see Fig. 435, B). The flap is dissected up, the knee is thrown into forced flexion, the lateral ligaments and crucial ligaments are cut, and the end of the femur is well cleared. The blade of Butcher's saw is passed beneath the bone, which is sawn from below upward (Ashhurst). The end of the tibia is cleared and a portion is sawn off. If, after sawing, diseased foci are discovered, another section can be sawn off or the foci can be gouged away. Ashhurst, who had a vast experience with this operation, insisted that in sawing through the femur the natural obliquity of the bone must be borne in mind and the section must be made in "a line parallel to that of the free surface of the condyles." If the section is made transverse to the axis of the femur, "the limb, after adjustment, will be found to be markedly bowed outward." The same surgeon said that the epiphyseal line is somewhat higher on the front than it is on the back of the femur, and in consequence the following rule is formulated for section of the condyles: the section of the condyles should be "in a plane which, as regards the axis of the femur, is oblique from behind forward, from below upward, and from within outward." Ashhurst advocated section of the tibia "in a plane transverse to the long axis of the bone, with a slight anteroposterior obliquity, so as to correspond with that of the section of the condyles," and he further says that the

patella must be removed whether it is diseased or not, and quotes Pénière's observations to the effect that excision of the patella diminishes the risk of death one-third, and its retention doubles the probability of an amputation becoming necessary in the future.

After removing the patella the diseased synovial membrane is clipped away with scissors and all sinuses and diseased territories are well curetted. The posterior ligament of the joint is not removed unless it is diseased; its retention prevents displacement and guards the popliteal space. In some cases tenotomy is required to permit extension. In children the fragments should be wired together; in adults this need not be done. After hemostasis, irrigate by salt solution, insert a drainage-tube, suture, dress antiseptically, and adjust the limb upon Price's splint or Ashhurst's bracketed wire splint. Instead of the bracketed splint, a long fracture-box may be used. If the femur tends to project anteriorly, use an anterior splint. If there be a tendency to outward bowing, adopt Ashhurst's expedient of carrying a strip of adhesive plaster around the outside of the limb and fastening it to the inner side of the splint. The splint is kept on until bony union is complete, as in this operation a movable joint is never sought. Many surgeons use a fenestrated or interrupted plaster-of-Paris splint, which is employed until the parts have become apparently firm and solid (Fig. 442). Even for many months after the parts have apparently

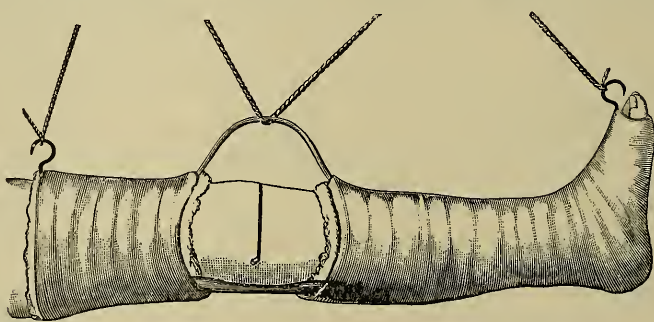

Fig. 442.—Watson's plaster-of-Paris swing-splint.

become solidly united bending may occur. How long fixation should be used has been much debated. In order to avoid the danger of flexion or other deformity fixation by some form of apparatus should be maintained for "at least a year and probably nearly two years after excision" (J. Torrance Rugh, "Am. Jour. Orthopedic Surgery," Feb., 1909).

Excision of the Ankle-joint.—Excision of the ankle was first performed by Moreau in 1792. This operation is performed chiefly for gunshot-wounds, compound dislocations, and in some cases of tuberculous joint disease. Excision of the ankle is an operation which is seldom performed.

Operation by Hancock's Method.—In this operation the patient lies upon his back, the foot rests upon its inner side, and the surgeon stands to the outer side of the damaged limb. Begin an incision just behind and 2 inches above the external malleolus, and carry it across the front of the joint to a corresponding point above and behind the internal malleolus (see Fig. 439, B); this incision goes only through the skin, and the flap thus marked out is reflected. "Cut down upon the external malleolus, carrying the knife close to the edge of the bone both behind and below the process, dislodge the peronei tendons, and divide the external lateral ligaments" (Joseph Bell). Cut the fibula 1 inch above the malleolus by means of pliers; divide the tibiofibular ligament; turn the foot upon its outer side; dissect from their

habitat back of the inner malleolus the tendons of the posterior tibial and the common flexor of the toes; carry the knife around the inner malleolus close to the bony edge; separate the internal lateral ligament, and dislocate the lower end of the tibia through the wound by turning the sole of the foot downward; saw off the lower end of the tibia and the articular process of the astragalus, sawing away from the tendo Achillis, and removing the fragments by bone-forceps. Cut away diseased synovial membrane, and curet all sinuses and tuberculous areas. Arrest bleeding, irrigate, and drain. Sew up the wound, insert a tube at the outer angle, and cause it to emerge at the inner angle. Apply antiseptic dressings, and put up the foot in fixed dressing or in splints at a right angle to the leg (Fig. 443). In Langenbeck's operation the excision is subperiosteal. If, in an excision of the ankle-joint, the astragalus is found extensively diseased, remove the entire bone.

Excision of the Os Calcis.—In caries limited to the os calcis most surgeons prefer to gouge away the dead bone, leaving the periosteum and, if possible, a shell of healthy bone, and draining thoroughly. Others advocate excision in some cases. Extensive disease limited purely to the os calcis is rare, and most surgeons advise gouging for limited caries, and Syme's amputation in the event of the disease extending beyond the periosteum or reaching adjacent bones.

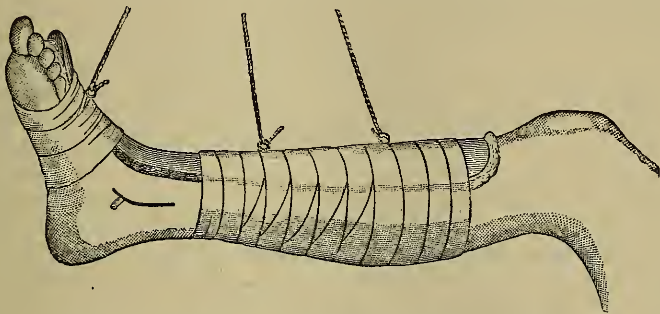

Fig. 443.—Volkmann's dorsal splint for excision of the ankle.

Operation by Subperiosteal Method.—In this operation the position assumed by the patient is supine, with the leg extended and the foot resting on its inner side. The incision, which cuts the tendo Achillis and reaches the bone at once, is begun at the upper border of the os calcis and the inner margin of the tendo Achillis, and is taken outward and horizontally forward to a point in front of the calcaneocuboid articulation (see Fig. 436, F). A vertical incision is begun near the forward termination of the initial incision, is carried across the outer edge and plantar surface of the foot, and terminates at the external margin of the inner surface of the os calcis. Some surgeons carry the vertical incision a little upward, toward the dorsum. The periosteum is entirely stripped by an elevator, the os calcis is removed, the cavity is packed with iodoform gauze, the wound is stitched, a drain is inserted posteriorly, the foot is dressed antiseptically, is placed at a right angle to the leg, and plaster of Paris is applied, trap-doors being cut for drainage.

Astragalectomy, or excision of the astragalus, is seldom performed. Astragalectomy is employed occasionally for relapsed and inveterate cases of club-foot. The indications are pointed out by Willard ("International Clinics," vol. iii, 12th series): "(1) Adults with great bony deformity; (2) neglected children of five to fifteen years, who have markedly distorted their tarsi by locomotion; (3) relapsed cases which have resisted the milder forms of operation, or which have been neglected by parents after previous operation; (4)

only occasionally, young children in whom from infancy the bones of the foot have been exceedingly rigid and unyielding, and where there is practically but little motion either at the ankle-joint or in the tarsus."

Operation by the Subperiosteal Plan.—Barker advises an incision going at once to the bone, from the "tip of the external malleolus forward and a little inward, curving toward the dorsum of the foot." The foot is extended and turned inward, the periosteum is lifted, the astragalus is removed, and the wound is treated and the foot is dressed as is done after excision of the os calcis.

In cases of *paralytic calcaneus* Whitman ("Orthopedic Surgery") recommends removal of the astragalus through a curved external incision; freeing the malleoli and making new sockets for them beside the cuboid and scaphoid bones. He puts the foot in marked plantar flexion and holds it by plaster.

Excision of the Metatarsophalangeal Articulation of the Great Toe.—In this operation make a lateral incision and cut off or saw off the proximal end of the first phalanx and the distal third of the first metatarsal bone. (See Mayo's Operation for Bunion, page 691.)

Excision of the Metatarsal Bone of the Great Toe (*Butcher's Method*).—In this operation a lateral straight incision is made, the periosteum is elevated, and the shaft is sawn from each extremity and removed.

Excision of the clavicle may be required for dislocation, caries, necrosis, gunshot-wound, tumor of this bone, as a preliminary to ligation of the artery and vein in certain cases of amputation at the shoulder-joint, or in cases of removal of the entire upper extremity. In excision of the clavicle the position of the patient is the same as that for ligation of the third part of the subclavian artery (see page 475). An incision is made down to the bone, from the sternoclavicular joint to the acromioclavicular articulation. If the case is suitable, the periosteum is stripped and the bone is sawn and removed; if not, the bone is sawn and each half is separately disarticulated. The wound is sutured and dressed, and the limb is put up in a Velpeau bandage. McCreary, of Kentucky, in 1811 performed the first complete excision of the clavicle.

Excision of the Scapula.—Complete excision of the scapula is usually performed for tumors. Partial excision requires no detailed description. In excision of the scapula the patient lies upon his sound side. Treves suggests the following incisions: one outside the vertebral border of the scapula, from its superior to its inferior angle; another from over the acromioclavicular joint, along the acromion process and spine of the scapula, to meet the first incision. Syme used an incision carried transversely inward from the acromion process to the vertebral border of the scapula, and another cut directly downward from the center of the first incision (see Fig. 436, G). In the method of Treves[1] the upper flap is reflected and the trapezius muscle is divided; the lower flap is reflected and the deltoid muscle is divided. The patient's hand is placed on the sound shoulder; the muscles of the vertebral border are divided, the posterior scapular artery is tied, and while the vertebral border of the scapula is pulled toward the surgeon, the serratus magnus muscle is cut, the upper border of the shoulder-blade is cleared, and the suprascapular artery is tied. The hand is now brought down to the side; the acromioclavicular joint is disarticulated; the conoid and trapezoid ligaments are divided; the muscles of the coracoid process are cut; the capsule is incised, with the supraspinatus and infraspinatus, the subscapularis, and the scapular origins of the biceps and triceps muscles; and finally the teres major and minor muscles are divided, the subscapular artery is tied, and the bone is removed. The wound is stitched, a drain is introduced, and antiseptic dressings are applied. The patient lies upon his back until healing is well under way, when the arm is placed in a sling.

[1] "Manual of Operative Surgery."

The drainage-tube may be removed in twenty-four hours. Langenbeck, of Berlin, in 1855 performed the first complete excision of the scapula.

Excision or Resection of a Rib (Fig. 572).—In *caries* the gouge and rongeur may remove the disease. In other cases excision is performed. In this operation the patient lies upon his sound side unless the operation is performed for empyema, in which case he lies on his back or only partly on the sound side. (See Empyema, Operation for.) The surgeon faces the patient. Make an incision down to the bone, in the long axis of the rib. The periosteum, if not diseased, is lifted from the bone, and the intercostal artery is lifted out of the way with the periosteum and is thus saved from being cut. After dividing the bone beyond the limits of disease, remove it. During the sawing a metal retractor is held beneath the rib, between the rib and the periosteum. It is better to saw it than cut it with ordinary biting forceps, because the latter splinters the bone. The author usually uses a forceps known as a *costotome*, which cuts the rib without splintering. If the periosteum is diseased, remove it after tying the intercostal artery. It should be removed in a case of empyema, otherwise bone-formation may interfere with drainage. In *empyema*, after removing the periosteum, open into the pleural cavity, allow pus to flow out slowly, remove fibrinous masses, employ a finger to feel if there are adhesions and if the lung will probably expand, and insert a drainage-tube. In resection for rib disease curet sinuses and pack with iodoform gauze for some days. Sew up the wound except at one end. Dress antiseptically and apply a binder. (See Operations Upon the Chest and Estlander's Operation.)

In *removing a cervical rib* make an incision along the posterior edge of the sternocleidomastoid, avoid the pleura, subclavian vessels, and brachial plexus, and remove the periosteum with the rib in order that the bone will not be reproduced.

Complete Excision of One-half of the Upper Jaw.—The whole upper jaw has been removed, but in what follows only resection of one-half the jaw will be described. This operation is performed for malignant tumors of the superior maxillary bone or its antrum. Up to 1826, at which time Lizars, of Edinburgh, suggested the operation, tumors of the antrum were treated by scraping them away with a sharp spoon. Gensoul, of Lyons, in 1827 performed the first operation for resection of the upper jaw. Heyfelder, in 1844, removed both superior maxillary bones. Excision of a superior maxillary bone is not justifiable except as a palliative measure, if the orbit is invaded, if the skin and subcutaneous tissues are infiltrated, or if the disease extends widely beyond the superior maxillary and palate bones.

Preliminary Closure of the External Carotid Artery.—Some surgeons ligate the external carotid artery or compress it temporarily. In a number of excisions of the upper jaw I have always found the hemorrhage readily controllable as soon as the bone is removed, and have never felt it necessary to resort to preliminary ligation or compression.

Operation by Median Incision.—The patient, whose face has been shaved, is placed in the Trendelenburg position, thus avoiding the possible need of instant tracheotomy; or, what is even better, he lies horizontal or with the head a little raised and takes ether by intratracheal insufflation (see page 1199). The surgeon stands to the right side of, and faces, the patient. The incisor tooth on the diseased side is pulled out. The incision, which is really Weber's incision (called by some Nélaton's, by some Fergusson's, by some Liston's) (Fig. 444, line A–B), is begun $\frac{1}{2}$ inch below the inner canthus of the eye, and is carried along the side of the nose, around the ala of the nose, by the margin of the nostril, and through the middle of the lip. While the lip is being incised the assistant arrests hemorrhage by grasping the corners of the mouth, and after the lip has been divided the coronary

arteries are at once ligated. Some operators approach the mucous membrane cautiously and ligate the vessels before opening the cavity of the mouth. The upper portion of the wound having been compressed by another assistant during these manipulations, pressure is now removed and bleeding points are ligated. Another incision is now carried outward from the beginning of the first incision, along the orbital margin to well over the malar bone. The flap is lifted from the periosteum, and the bleeding from the infra-orbital artery and the small vessels is restrained by pressure. The nasal cartilage is separated from the bone, and the nasal process of the superior maxillary is sawn (line A–B, Fig. 445). The orbital periosteum is lifted up, and the orbital plate is cut by forceps from the saw-cut in the superior maxillary bone to the sphenomaxillary fissure (line B–C, Fig. 445). The malar bone is sawn or is bitten through about its center, the cut running into the sphenomaxillary fissure and taking a downward and outward direction (line C–D, Fig. 445). The soft parts covering the hard palate are incised in the median line, a corresponding incision is made along the floor of the nose near the septum, and the soft palate is separated from the hard palate by a transverse cut.

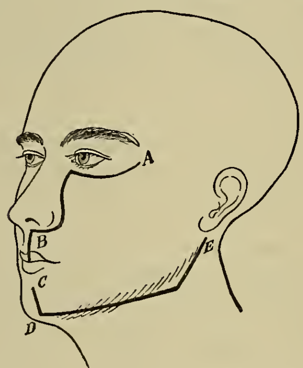

Fig. 444.—*A–B*, Incision of the soft parts preliminary to excision of the upper jaw; *C–D–E*, incision of soft parts preliminary to excision of the lower jaw.

Fig. 445.—1, Excision of the upper jaw: A–B, Section of the nasal process; B–C, section of the orbital plate; D, section of the malar bone and orbital plate; E, section of the alveolus and hard palate. 2, Excision of the lower jaw: G, Section of the inferior maxillary; H, section of the ramus in partial resection.

The saw is introduced through the nose, and the palate is sawn (line E, Fig. 445). The upper jaw-bone is grasped by Fergusson's lion-jaw forceps and removed, the removal being aided by the use of the scissors and bone-cutters; the latter are used to separate the upper jaw from the pterygoid process (Treves). Every vessel that can be seen is tied, and severe bleeding from bone is arrested by antiseptic wax. Oozing is controlled by hot water and pressure or by Paquelin's cautery. Examine carefully to see if all the diseased area is removed; if it is not, use the gouge, scissors, chisel, and saw until healthy tissue is reached. The wound is packed with iodoform gauze, and the end of the strip is so placed as to be accessible through the mouth. The wound is sutured (the mucous membrane of the lip must be stitched, as well as the skin) and is dressed antiseptically (the eye being protected by aseptic gauze), and a crossed bandage of the angle of the jaw is applied. After this operation it is common to have the eye sink to a lower level (causing double vision), to have persistent swelling of the lower lid, and to have the tears flow over the lid instead of down the duct.

Excision of One-half of the Lower Jaw.—In some rare instances the entire inferior maxillary bone is removed. The lesions necessitating removal of the

lower jaw are of the same nature as cause us to remove the upper jaw. The names of many surgeons are connected with this operation, viz., Deadrick, White, Dupuytren, Sir Astley Cooper, and Valentine Mott.

In this operation the patient is placed in the same position as for excision of the upper jaw, the chin having been previously shaved. A vertical cut is made through the chin-tissue, starting below the margin of the lip and reaching to below the border of the jaw (C–D, Fig. 444). From the point D an incision is carried outward below the border of the jaw and then back of the ramus, as shown in the line D–E (Fig. 444). Treves's advice is to carry this incision down to the bone, except at the line of the facial artery, at which point it must go through the skin only. The facial artery is now to be sought for, tied in two places, and divided. Except in malignant cases the periosteum is lifted from the external surface of the bone, from the symphysis outward. Hemorrhage is arrested. The buccal mucous membrane is cut from the alveolus. A lateral incisor tooth is pulled, and the bone is sawn in the line G (Fig. 445). The bone is grasped in a lion-jaw forceps and is drawn outward. The mylohyoid insertion is cut; the internal pterygoid muscle is cut or the periosteum at this spot is lifted; the inferior dental artery is cut and tied; the jaw is pulled down; the insertion of the temporal muscle upon the coronoid process is cut away, and the external pterygoid muscle is divided. The capsule of the joint is opened, and the bone is separated from the ligaments which still hold it in place. Bleeding is arrested, the wound is sutured, a tube is introduced in the posterior portion of the wound and retained for twenty-four hours, and antiseptic dressings and a Gibson or a Barton bandage are applied. Partial excisions of the alveolus may be performed through the mouth by means of chisels and rongeur forceps, and Wyeth has thus removed half of the jaw; but if any considerable part of the body of the jaw is to be removed, it is usually best to make an incision below the inferior maxillary.

Partial Excision.—This operation is frequently made necessary by epithelioma involving the periosteum or bone. After this operation, unless means are taken to prevent deformity, there will be asymmetry of the two portions of jaw bone remaining and malrelation of the teeth. Various attempts have been made to fill up this gap at the time of operation by some material, or to hold the two portions of the mandible in symmetrical relation by the insertion of trusses of silver wire, or by fastening each piece of bone to a metal plate.

John B. Murphy suggested the use of a bridge of silver wire. All of my trials with such a bridge failed. It always ulcerated out and usually through the skin, but did some good by keeping the bone ends further apart than they otherwise would have been.

Stanley Stillman ("Annals of Surgery," July, 1912) advocates bone-grafting as the only proper method, in order to prevent contraction during healing after the removal of the jaw bone. "When the teeth on the sound side are numerous and firm enough to stand the strain, they may be prepared beforehand with the aid of a dentist, so that a few days after the operation they may be clamped firmly to those of the upper jaw" (Ibid.). When the wound heals, Stillman separates the flap, freshens the bone ends, and wedges a section of rib between them. The clamps are left in place until the bones unite, which requires six to eight weeks. In cases in which the teeth cannot be used to clamp, a silver bridge is inserted, which is left in place until the parts are ready for the insertion of the bone.

Barker's Operation for Dislocation of the Semilunar Cartilages of the Knee-joint.[1]—Begin the incision over the ligament of the patella, $\frac{1}{2}$ inch above the articular surface of the tibia, and carry it in a curve downward and outward to the anterior edge of the internal ligament. The periosteum should be divided

[1] "Lancet," Jan. 4, 1902.

by the cut. This incision forms a flap the lower edge of which is ½ inch below the border of the articular surface of the tibia. The flap is lifted until the cartilage is seen "under the attachment of the meniscus, which if partially attached will rise with the flap until its under surface is seen." If partially torn anteriorly it is stitched to periosteum by a few silk sutures. The periosteum is then stitched in place, no drain is used, the joint is immobilized, and for one week ice is kept upon the part. If the meniscus is found completely separated and curled up, it may, if the injury was recent, be reduced. If the injury was old and if the cartilage is shrunken, it should be completely cut away (Barker).

Operation for Congenital Dislocation of Hip.—*Lorenz's Bloodless Method of Reduction.*—The method of reducing by manipulation a congenital dislocation of the hip was advised by Paci and modified and improved by Lorenz. It has long been known that reduction is easy at birth because an acetabulum, though probably a shallow one, exists, and the head of the bone is not firmly held in its new situation. In an older child the problem is far more difficult, because, even if reduction is effected, the acetabulum may be extremely shallow or absent, and redislocation may readily occur. Lorenz aims to effect thorough reduction and then fixes the limb in abduction for months, so that the acetabulum will deepen and the bone will become firm in its proper socket. This operation is rarely successful in children over six years of age. The child is anesthetized and an attempt is made to draw the femoral head on to a line with the acetabulum. If the child has never walked, this is readily accomplished. If it has walked, the procedure may be very difficult, and it may be necessary to make extension by a fillet fastened above the knee, and counterextension by a screw and a perineal band. The drawing down of the head is made easier by stretching and massaging the adductor muscles. The next step is to strongly flex the thigh, rotate it a trifle internally, and then abduct it while flexion is maintained. This causes the head of the femur to pass around the posterior margin of the acetabulum and frequently produces reduction. "Full abduction being kept up, the thigh is rotated out, thus forcing the head of the femur more firmly into the socket." (See the description of the Lorenz method in J. Jackson Clarke's "Orthopedic Surgery.") The strongly abducted limb is put up in plaster of Paris. In about three months the plaster is removed, the abduction is diminished, the plaster is reapplied, and is retained for another three months. During the continuance of immobilization of the hip the child walks about, with the knees bent. When the plaster is finally removed, manipulation, massage, and exercise strengthen the muscles and give freedom to the joint. In a double dislocation one joint may be cured before the other is operated upon, or both may be operated upon at the same séance. In double dislocation plaster must be worn more than six months. The Lorenz operation is safe when applied to very young children, but has elements of danger which increase with the years of the subject. A patient may suffer grave lacerations of muscles and ligaments, and even vessels and nerves. Death

Fig. 446.—Lorenz method. Unilateral congenital dislocation of hip (reduced). Cast applied with leg in "frog position."

may result from shock, and extensive deep-seated hemorrhage may occur. In fact, it is a mistake to call it a bloodless method. The blood flows, though we do not see it. An untrained man may do fearful mischief by this operation, and it should only be attempted by an experienced, skilful manipulator and upon properly selected cases, when it is a very successful procedure. I am satisfied that, except in the case of a very young child, in whom reduction is easy, one who performs the Lorenz operation should be something more than skilful and experienced. He should be physically strong, so that traction and abduction will be powerful and steady. A weak man will jerk, will throw his weight upon the part, and will be apt to tear structures instead of stretching them. Sudden forcible movements are apt to break the bone.

Hoffa's Cutting Operation.—Make the external incision of Langenbeck to open the joint (see page 703). The capsule is incised at its insertion into the neck, and the periosteum and muscles are lifted from the great trochanter. Hoffa claims that in children less than five years of age the head of the bone can be readily replaced into the acetabulum by flexing the thigh and making direct pressure upon the head of the bone. After replacing the femoral head it is held in place while an assistant extends the leg in order to stretch the muscles. In children over five years of age cut with a tenotome the muscles which spring from the ischial tuberosity and also the adductors; cut the fascia lata and muscles which arise from the anterior superior iliac spine by incision; open the joint and liberate the head of the bone; remove the ligamentum teres; scrape out the acetabulum, removing "cartilage, fat, and considerable spongy tissue" (Tubby); and replace the head of the bone in the acetabulum. The limb is maintained in inversion, abduction, and extension for several weeks, when it is straightened. Massage and passive motion are begun in the fifth week. The patient now gets about, wearing an apparatus for many weeks. This apparatus permits the head of the bone to move in the socket, but prevents redislocation.

Lorenz's Cutting Operation.—This is a modification of Hoffa's. The muscles inserted into the greater and the lesser trochanter are not cut; the sartorius, the hamstrings, and the external portion of the fascia lata are cut (Tubby).

The incision of Lorenz is longitudinally from the anterior superior spine. Another incision is carried inward from this at the level of the lesser trochanter. The capsule is opened by a crucial cut; the acetabulum is enlarged; the head of the bone, if it remains, is inserted into the acetabulum; if there is no true head, a new one is formed and inserted into the cavity. The limb is immobilized in a position of moderate abduction. Massage and passive motion are begun in the fifth week, and are continued for months.[1]

Reduction by Means of Mechanical Appliances.—As the chief factor in the reduction of a congenital dislocation is thorough stretching of the muscles and ligaments before attempting replacement, numerous forms of levers have been devised to accomplish this. The best-known one is that of Bartlett, of Boston. It consists of a pelvic rest with perineal support, rods to fix the pelvis and traction rods to make extension. Great care is necessary in the use of all such appliances because of the danger of injury to vessels and nerves or of fracturing bony parts. After the parts have been thoroughly stretched replacement is accomplished by manipulation, as in the usual methods of manual reposition.

[1] I have drawn upon the very lucid description of these operations in A. H. Tubby's treatise upon "Deformities."

XXI. DISEASES AND INJURIES OF MUSCLES, TENDONS, AND BURSÆ

Myalgia, or **muscular rheumatism,** is a painful disorder of the voluntary muscles and of the fibrous and periosteal areas where they are attached. The term "muscular rheumatism" is not strictly correct. It is possible that in some cases the muscular structure is inflamed, but it is certain that in many cases the pain is distinctly neuralgic. Muscular rheumatism may be due to cold and wet, to overexertion and strain, to acute infectious disorders, to syphilis, to chronic intoxications (lead, mercury, and alcohol), and to disturbances of the circulation. Gouty and rheumatic persons are especially predisposed, men being more liable to the disease than women. The disease is usually acute, but it may be chronic.

Symptoms.—Muscular rheumatism is apt to come on suddenly. The pain, which may be very acute and lancinating or dull and aching, is in some cases constantly present; in other cases it is awakened only by muscular contraction, and it is frequently relieved by pressure, though there is often some soreness. The skin above the muscle is sometimes tender to light pressure. The disease usually lasts for a few days, but it tends to recur. There is little, if any, fever.

Lumbago is myalgia of the muscles of the loins. *Rheumatic torticollis* is myalgia of the muscles of the neck. Usually one side of the neck is attacked. The chin is turned from the affected side and the neck is stiff. *Pleurodynia* is myalgia of the intercostal muscles. The pain is very severe, is aggravated by deep respiration, by coughing, and by yawning, there may be tenderness, and the patient tries to limit chest-movement. In *intercostal neuralgia* the pain is limited, is not constant, but occurs in distinct paroxysms, and is linked with the presence of the tender spots of Valleix. Pleurodynia lacks the physical signs of pleurisy. *Cephalodynia* is myalgia of the muscles of the scalp. The muscles of the shoulder, upper dorsal region, abdomen, and extremities may also be attacked by myalgia. Myalgia must not be confused with the pains of locomotor ataxia.

Treatment.—Remove any obvious cause. Treat any existing diathesis, such as gout or rheumatism. Rest is of the first importance. For lumbago, put the person to bed. For pleurodynia, strap the side of the chest. A hypodermatic injection of morphin and atropin into the affected muscles at once allays the pain, and a deep injection of distilled water is sometimes curative. Relief may be afforded by painting the surface with 30 drops of a mixture of equal parts of guaiacol and glycerin and covering the painted area with cotton. The introduction of four or five aseptic needles into the muscles, and their retention for a few minutes, sometimes acts most favorably. Ironing the skin above the painful muscles with a very warm iron, a piece of flannel being interposed, is a useful domestic remedy. Vigorous rubbing of the area with a piece of ice allays the pain. Hot poultices do good. If the pain is widely diffused, alters its seat, or is very obstinate, order hot baths or Turkish baths and administer diuretics. In chronic cases employ blisters or counterirritation by the cautery, give iodid of potassium and nux vomica, and have the patient take a Turkish bath every week. The constant electric current finds advocates. In an ordinary severe case order a hot bath, put the patient to bed with a hot-water bag over the part, and administer 10 gr. of Dover's powder; the next morning order to be taken four times daily a capsule containing 5 gr. of salol and 3 gr. of phenacetin, until the pain disappears. Citrate of potassium, citrate of lithium, chlorid of ammonium, or the salicylate of colchicin may be ordered instead of salol and phenacetin.

Infective myositis is a widespread inflammation of the voluntary muscles, due to an unknown infective cause. It is a disorder accompanied by pain and stiffness, by cutaneous edema, and by various paresthesiæ. Myositis resembles trichinosis, and can be distinguished from it only by spearing out a bit of muscle and examining it microscopically. Occasionally diffuse suppuration occurs.

Ordinary myositis arises from injuries, from syphilis, or from rheumatism, and it presents the usual inflammatory symptoms. Contraction and adhesions may follow. I operated upon a case of myositis of the rectus abdominis in a boy of eight. There was a large mass like a full bladder. There had not been an attack of typhoid and there was not hereditary syphilis. Caseation existed. The condition was possibly tuberculous, although no bacilli were found.

Treatment of Myositis.—Infective myositis is treated by anodynes, stimulants, nutritious food, hot applications, and rest. If pus forms, it should be evacuated. Rheumatic myositis calls for the administration of the salicylates, the alkalis, or salol. Syphilitic myositis is treated with mercury and iodid of potassium. The remedies employed for myalgia are used in traumatic myositis.

Hypertrophy of the muscles may arise from their increased use. In *pseudohypertrophic paralysis* the muscle is greatly augmented in bulk, but it contains less muscle-structure and more fat or connective tissue.

Atrophy of the muscles arises from want of use, from injury, from continuous pressure, from interference with the blood-supply, from disease of the nerves or their centers, or from lead-poisoning.

Degeneration of Muscles.—The muscles may undergo granular degeneration, waxy degeneration, fatty degeneration and calcareous degeneration, and may become pigmented.

Local Ossification and Myositis Ossificans.—It is not unusual for a small portion of bone to form in the periosteal insertion of a muscle which is subjected to frequent strain. In persons who ride many hours a day there not infrequently develops the *riders' bone*, which is an area of ossification in the adductor muscles of the thigh. *Myositis ossificans*, a widespread ossification of the muscles, is a rare disorder the cause of which is unknown, and which, though not congenital, usually begins in early life. In some local cases a traumatic origin seems certain. It is seen more often among males than females. Columns of inflammatory swelling and induration slowly develop, each column running in the direction of the muscular fibers, and ossification of the indurated columns takes place. It is stated that the thumbs and great toes shorten (J. Jackson Clarke's "Orthopedic Surgery"). In traumatic cases the condition is localized. I operated upon a traumatic case by removing an ossified area in the thigh muscles. The laboratory report was myositis ossificans. Growth quickly recurred after operation, but the new growth showed very little ossification. The laboratory report was spindle-celled sarcoma. This case and also another one reacted to Coley's fluid. It seems possible that local myositis ossificans may, in some cases at least, be a sarcoma in which rapid ossification occurs.

Tumors of the Muscles.—Primary tumors of the muscles are rare. Among those which may occur are sarcoma, fibroma, lipoma, osteoma, angioma, myxoma, and enchondroma. Most cases of supposed primary sarcoma of muscle are, in reality, cases of syphiloma (Esmarch).

Syphilis may cause inflammation. Gummata may form, or gummatous infiltration may take place.

Trichinosis or **trichiniasis** is a disease due to the embryos of the Trichina or Trichinella spiralis. Sir James Paget recognized the nature of the pre-

viously known encysted or larval form. It was long believed that the Trichina spiralis was a harmless parasite, but in 1860 Zenker, of Dresden, proved that it might be responsible for dangerous epidemics. The trichina is normally a parasite of the rat. Man is infected by eating flesh which contains trichinæ and has been insufficiently cooked. The flesh of the pig is the medium of infecting man. The pig becomes infected by eating rats suffering from the disease or offal and slaughter-house refuse containing trichinallized flesh. Dr. Joseph Leidy discovered the trichina in pork. People are most commonly affected by eating raw sausage, smoked sausage, or underdone pork. Imperfectly boiled ham may be responsible. Albert reported 14 cases from eating boiled ham. W. Gilman Thompson found records of 52 sporadic cases occurring in New York City during six years ("Amer. Jour. Med. Sciences," August, 1910). These nematodes are carried into the intestine, there to develop and multiply. In from seven to nine days a horde of embryos develop in the bowel, and leave the alimentary canal by passing through the peritoneum or by means of the blood, and finally reach the connective tissue of the muscles. From the connective tissue the embryos migrate into the primitive muscle-fibers, where they dwell and enlarge. Myositis develops, and in the course of five or six weeks the parasites become encapsulated and devlop no further. The cyst-walls may calcify and the worms may become calcified, or may live for years. The eating of infected meat is not inevitably followed by the disease, and a few embryos lodged in muscle may cause no symptoms.

The **symptoms** of trichinosis often appear in a day or two after eating infected meat. The symptoms of acute gastro-intestinal catarrh or of cholera morbus are common, but in some cases no gastro-intestinal manifestations usher in the disease. In from seven to fourteen days after the infected meat is eaten the migration of the parasites develops obvious symptoms. A chill may be noted; there is usually fever; muscular pain, tenderness, swelling, and stiffness are complained of. This condition may be widespread. Involvement of the muscles of mastication interferes with chewing; of the larynx, with talking and respiration; of the intercostals and diaphragm, with respiration. Skin-edema and itching are marked. In some cases delirium exists. The writer saw in the Philadelphia Hospital one fatal case which was mistaken for erysipelas because of the high fever, the delirium, and the edematous redness of the face and neck. Dyspnea is frequent. Mild cases get well in a week or two; severe cases may last many weeks. The mortality varies in different epidemics from 1 to 30 per cent. (Osler). The diagnosis is made by spearing out a piece of muscle, which is then examined for trichinæ under a microscope; or the worms may perhaps be detected in the feces by means of a pocket-lens. In a case under the care of the author, in St. Joseph's Hospital, there was no record of any attack of gastro-intestinal disturbance and the first manifestation was enlargement of the calf of the left leg. In most cases of trichinosis there is eosinophilia, but in the author's case, previously referred to, eosinophilia was not present.

Treatment.—To treat trichinosis employ purgatives (senna and calomel) early in the case, and give glycerin, and also santonin or filix mas. When muscular invasion has taken place, sedatives, hypnotics, nourishing diet, and stimulants are indicated.

Ischemic Myositis, or Volkmann's Contracture (*Volkmann's Paralysis; Ischemic Paralysis; Ischemic Muscular Atrophy, with Contractures and Paralysis*, Fergusson calls it).—It is occasionally noticed, particularly in children, after prolonged fixation of the forearm, especially after prolonged fixation of the elbow-joint by some appliance that impedes the freedom of circulation in the part. Contracture of the fingers occurs and per-

haps rigidity and flexion of the wrist. In 1875 Volkmann described severe contractures of the hand observed in some cases as a result of the use of tight bandages to hold splints in place in treating fractures of the arm. He believed that the condition was due to deprivation of arterial blood, that the muscles perished for want of oxygen, and that rigor mortis occurred. He pointed out that paralysis and contracture occur simultaneously, whereas in primary nerve lesion paralysis precedes contracture. The condition may come on after the application of an Esmarch band, after a severe injury in the neighborhood of the elbow-joint, may follow ligation of the main artery of a limb, venous embolism, venous thrombosis from injury or infectious disease, Raynaud's disease, or exposure to cold. One of Jones's cases followed a rapidly developing traumatic myositis ossificans; two followed crushes; in one an elastic tourniquet had been kept on a child's arm to prevent bleeding after an operation for webbed-fingers; in one pad pressure had been maintained for twenty-four hours to check bleeding ("Amer. Jour. Orthop. Surg.," April, 1908). A case of mine resulted from embolism of the brachial artery. There are two forms, one due to almost complete arterial ischemia, lasting for several hours at least; another due to interference with venous return. Volkmann's contracture is due to muscular degeneration, infiltration, induration, and contraction, the result of marked and prolonged arterial ischemia or interrupted venous return, and it is frequently spoken of as ischemic myositis (Dudgeon, "Lancet," Jan. 11, 1902). In some cases distinct neuritis with paralysis also exists. One characteristic of ischemic contracture is the rapidity with which it comes on. Dudgeon points out that in half a day, or even in less time in some cases, the symptoms appear, these symptoms being paralysis of the part with contracture. Pain is unusual, unless the nerves are seriously involved. In some cases the fingers and hand swell and become discolored. The absence of pain frequently prevents the recognition of the condition; therefore, the causative splint or bandage pressure may be maintained for days after the trouble has become serious. When the splints and bandages are removed and the forearm is examined, there is almost always tenderness over the muscles and the nerve-trunks; and in the majority of cases in which a splint was the cause a portion of the skin will have sloughed. Dudgeon points out the characteristic position of the deformity as follows: When the wrist is extended, the metacarpophalangeal joints are also extended; but the interphalangeal joints of the fingers and the terminal joint of the thumb are so strongly bent that the tips of the fingers touch the palm, and this position cannot be corrected by any justifiable amount of force. As soon as the wrist-joint is bent to a right angle, the interphalangeal joints can readily be extended. In a very severe case the wrist itself will become markedly flexed, and it will be impossible to extend it. The forearm is usually semiflexed and the hand pronated. The ulceration or sloughing so frequently present causes a *splint-sore*. There is always marked induration about a splint-sore. The flexor muscles themselves are indurated and usually wasted. The condition of sensation depends upon the state of the nerves of the part. When neuritis is absent, sensation will be normal; but in accordance with the amount of neuritis and degeneration there will be hyperesthesia, partial anesthesia, or complete anesthesia. A curious feature of these cases that is dwelt upon by Dudgeon and commented upon by Turner is the fact that in young children there is a cessation of growth of the bone. Robert Jones (Loc. cit.) reports that 19 cases out of 40 were associated with fracture. In 13 of the 19 cases there was pronounced malunion.

Treatment.—The old view of this condition was that it is practically hopeless. Anderson and Dudgeon, however, maintain that restoration may usually be obtained, the treatment consisting in regular, active motion, passive move-

ment, massage, and electricity. Forcible extension under ether is of no benefit whatever.

Jones's plan of treatment is very beneficial ("Amer. Jour. Orthop. Surg.," April, 1908).

Operative procedures on arms that necessarily have deficient circulation are hazardous, and Jones has discontinued all operative correction and relies upon purely mechanical and manipulative routine, as follows:

Five splints are cut out of zinc, tin, or sheet wire, to fit each finger and thumb. The wrist is forcibly flexed and held while each finger is separately splinted. It will be observed that in the fully flexed position of the wrist the fingers are all relaxed.

Fig. 447.—Rugh's splint for Volkmann's contracture. Splint applied. Looking at the palmar surface.

When the finger splints have been applied the wrist is released, and the patient is directed to systematically extend the metacarpophalangeal joints. In a few days the second splinting may usually be employed by embedding the entire hand to the wrist and the already splinted fingers in plaster of Paris, while the wrist is again flexed. Several days are devoted to systematic voluntary efforts at extension of the hand in a similar manner employed for the metacarpophalangeal joints.

The third splinting embraces that already employed and in addition embraces the wrist in the fullest extension possible, which in a few days may be increased until full extension is obtained. The latter position of full extension of wrist, hand, and fingers is maintained for some weeks until all contractible elasticity has disappeared.

It is usually observed that when the hand can be held in hyperextension without tendency to relapse, the circulation will almost invariably improve and the fingers resume their normal function and appearance except in cases of nerve destruction. Jones has found that in many cases in which the nerves had lost their function during contracture, the extension of the hand was the starting-point of recovery.

In making any splint pressure to straighten the fingers the greatest care must be exercised. The skin of the dorsum of the fingers will not endure prolonged pressure. I have used Rugh's splint with much satisfaction (Figs. 447, 448). It is best in the beginning to apply the splint for five or ten minutes twice a day. The time of each séance is gradually increased as the tissues develop resistance. Frequent bathing with alcohol aids the skin to bear pressure.

R. H. Sayre ("Volkmann's Ischemic Paralysis and Contracture," "Amer. Jour. Orthop. Surg.," Nov., 1908, p. 221) advocates the Jones method in all cases, inasmuch as cutting operations may be employed later if the results of Jones's treatment are not entirely satisfactory. The improvement in the

circulation and function obtained by the Jones method will make the operative field more capable of rapid recovery.

In a persistent and long-continued case an operation may be necessary. The operation may consist in dividing in the forearm the flexor muscles of the fingers, as advised by Davies Colley, and then, at a later period, dividing the flexor tendons. The objection to his procedure is that it destroys the capacity to flex the fingers for all time. Another suggestion has been to excise a piece from both the radius and the ulna, and wire the fragments together. The best surgical treatment is probably exposing the nerves, separating them from adhesions, stretching them, and then doing tendon-lengthening, but this should not be done until all the improvement possible to secure by conservative treatment has been obtained by at least three months of effort.

Wounds and Contusions of the Muscles.—*Wounds* of muscles may be either *open* or *subcutaneous.* In a longitudinal wound the edges lie close together, and hence drainage must be provided for by the surgeon. In a transverse wound the edges separate widely, and catgut stitches must be inserted. *Contusions* of muscles, like contusions of other tissues, vary in extent and in severity. There are pain (which is increased by attempts to use the muscle), loss of function, swelling beneath the deep fascia, and discoloration, which may appear at once because of superficial damage from

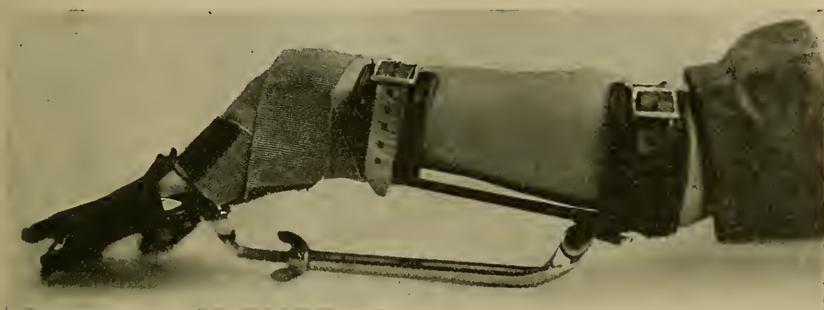

Fig. 448.—Lateral view of splint shown in Fig. 447.

the initial injury, or which may appear in dependent parts after many days because of gravitation of blood and blood-stained serum. As a result of contusion, suppuration, inflammation, or atrophy may arise.

Treatment.—In a longitudinal wound, drain; in a transverse wound, suture the muscle. The further indications in wounds and contusions of muscles are to obtain rest by means of splints and to secure relaxation. Limitation of swelling is secured by bandaging. Inflammation is combated first by cold and lead-water and laudanum; later by iodin, blue ointment, ichthyol, and intermittent heat. To prevent loss of function employ, as soon as the acute symptoms subside, massage, passive motion, and stimulating liniments, and, later in the case, electricity (galvanism if the reactions of degeneration exist; faradism, if they are absent).

Strains.—A muscular strain is a stretching of a muscle with a small amount of rupture. It is caused by traction in the long axis of the muscle. The muscle becomes swollen, tender, stiff, weak, and sore, and attempts at motion produce sharp pain. A strain of a tendon is a trivial or partial rupture. It leads to the development of acute thecitis, with fluid swelling and pseudocrepitation. Strains are common in the deltoid, the ham-string muscles, the back, the calf, the biceps, and the great pectoral. *Strain of the psoas muscle* causes pain on voluntary flexion of the thigh, and is associated

with tenderness in the iliac fossa. Strain of the right psoas may be mistaken for appendicitis, but it lacks the intense local tenderness, the abdominal rigidity, and the constitutional symptoms. *Lawn-tennis arm* is a strain of the pronator radii teres muscle. *Riders' leg* is a strain of the adductor muscles of the thigh. A strain of the long head of the biceps flexor cubiti produces the condition called by ball players a *glass arm.* A strain may be the only injury, or may be associated with some other condition (fracture of bone, dislocation, sprain, contusion, etc.). A strain may be followed by periostitis at the point of insertion of the muscle. Atrophy of the muscle occasionally follows a strain.

A strained muscle is usually rigid, is tender, and pains greatly when an attempt is made to use it. The skin over it, especially over its point of insertion, is usually tender.

A *strain of the back* is a very common accident, which is often associated with sprains of the vertebral articulations. There is great pain when the patient voluntarily straightens up. If the vertebral ligaments are not damaged, the patient can be straightened by passive motion without pain. The skin is tender in certain areas. The muscles are often rigid. There may be unilateral rigidity. In a back injury make a careful examination to be sure no damage has been inflicted upon the vertebræ or cord.

Treatment.—Relaxation by suitable position; rest by the use of splints or by putting the patient to bed; bandages for compression; hot fomentations or a hot-water bag, and ichthyol. As soon as acute symptoms subside, employ friction and massage. Strapping with adhesive plaster is of service in strain of the back and of the calf. If there is severe pain after a strain, administer Dover's powder, or even morphin.

Rupture of Muscles and Tendons.—**Rupture of a muscle** is announced by a sudden and violent pain and by loss of function, arising during powerful muscular contraction or strong traction in the long axis of a muscle. The rupture may be announced by a clearly audible snap (A. Pearce Gould). A distinct gap is felt between the ends; great pain develops on movement; there are tenderness, loss of power, and swelling. Rupture may be followed by atrophy, as is a contusion. Among the muscles which occasionally rupture we may mention the quadriceps, biceps, triceps, deltoid, plantaris, etc.

Rupture of the biceps flexor cubiti or its tendon is not very common; 72 cases have been collected (W. W. Keen, in "Annals of Surgery," May, 1905). It is much more common in men than in women. Loos's table of 66 cases contains records of only 2 women (Doane, in "Jour. Amer. Med. Assoc.," May 16, 1908). The rupture may be where the muscular belly passes into the lower tendon, through the muscular belly, in the muscular part passing either to the long or short head, or at the part where the muscular belly joins the long or short head. The tendon of the long head may be torn through or the long head may be torn from the glenoid cavity. The muscular portion is far more often injured than the tendinous. In rupture of the muscle belly a part of the muscle, in rupture of the long head the entire muscle, becomes soft and relaxed. In rupture of the belly there is a gap between the two portions and each portion causes a lump. In rupture of the tendon there are not two lumps with a gap between, but there will be a single muscular lump. In rupture of the long head the muscular belly is much nearer the elbow than in health (Figs. 449 and 450). If rupture takes place at the lower part of the belly, the muscle passes toward the shoulder. *Rupture of the long head of the biceps* allows the humerus to pass somewhat forward and upward.

Flexion with the forearm supinated is much less powerful than flexion with the forearm pronated (*Hüter's sign*).

In a case of my own in the Blockley Hospital the accident had occurred while carrying a heavy bucket. Forearm flexion was possible, but slow, feeble, partial, and incomplete. On flexion the short head contracted, but the muscular "bunch" of the belly was nearer the elbow than normally. *Rupture of the plantaris muscle* (*coup de fouet; lawn-tennis leg*) is an injury which is frequently not diagnosticated. It occurs during exercise (walking, bicycling, jumping, playing tennis) or is first complained of after exercise. It

Fig. 449.—Author's case of rupture of the long head of the biceps.

produces sudden pain in the middle of the calf, swelling, and often ecchymosis and inability to walk except with a rigid ankle and everted toes. *Rupture of the quadriceps extensor femoris tendon* results occasionally from force which in other cases fractures the patella. The rupture is just above the patella. The patient cannot extend the thigh and cannot walk or stand and there is severe pain. A gap can be felt just above the patella, unless it is hidden by synovial effusion, and the muscle is bunched above.

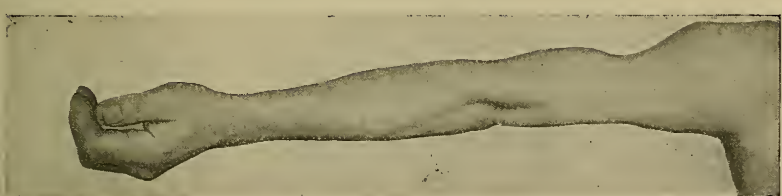

Fig. 450.—Author's case of rupture of the long head of the biceps.

Treatment.—In limited rupture treat as a severe strain. In treating extensive rupture of an important muscle, when the ends are widely separated, expose by incision, unite the divided ends by sutures of chromicized catgut (Fig. 109), and sew up the skin with silkworm-gut. Treat the part in any case by rest and relaxation and combat inflammation by appropriate means. Passive motion and massage are employed as soon as union is firm. In rupture of the quadriceps extensor femoris, operation should be undertaken, because mechanical treatment frequently gives a bad result and confines the patient to bed for weeks. *Rupture of the biceps* requires incision and suture.

In a case in the Blockley Hospital (Figs. 449, 450) I operated and found that the long head with a portion of periosteum had been torn off from the glenoid cavity. A portion of the upper end of the tendon was cut away and the tendon was fastened to the short head by splitting and suture. Nine months later the result was perfect (Keen, in "Annals of Surgery," May, 1905). *Rupture of the plantaris* is treated at first by rest on a posterior splint and compression and later by massage and the use of an elastic bandage. The patient is allowed to walk with the aid of a cane in one week, but he should not raise the heel for several weeks.

Hernia of Muscles.—When a tear takes place in a muscular sheath, a portion of the muscle protrudes.

The **treatment** is incision, restoration or extirpation of the protruding mass of muscle, and suturing of any muscle wound and of the sheath.

Contractions of muscles may result from injury, from joint disease, from malposition of parts (as in old dislocation or torticollis), or from diseases of the nervous system.

The **treatment** in some cases is sudden extension, in other cases gradual extension, tenotomy, or myotomy. Macewen recommends the making of a number of V-shaped incisions in the muscle. In some cases of spasmodic contraction nerve-stretching is of value.

Dislocations of Muscles and Tendons.—The long head of the biceps is oftenest displaced. The flexor carpi ulnaris, the peroneus brevis, the peroneus longus, the tibialis posticus, the sartorius, the plantaris, the quadriceps extensor femoris, and the extensors back of the wrist may be dislocated. What is known as dislocation of the latissimus dorsi, a condition in which that muscle no longer lies upon the angle of the scapula, is, in reality, paralysis of the serratus magnus (see page 751). Most of these accidents are associated with chronic joint disease or with fracture, but displacement may exist as a solitary injury. *Dislocation of the long head of the biceps* may occur tolerably early in the progress of rheumatoid arthritis of the shoulder-joint, and the displaced tendon may be absorbed.

Symptoms.—After dislocation of a tendon the muscle of the tendon can still contract, but it acts at a disadvantage; thus the corresponding joint exhibits partial loss of function. The displaced tendon can be felt, and a hollow exists where it normally resides.

When the muscle contracts, the tendon is felt to slip from its groove. When the tendon of the biceps is dislocated, the head of the bone passes forward (so-called *subluxation of the humerus*).

Treatment.—In tendon dislocation reduction is easy, but the displacement is apt to recur because of laceration of the sheath. The treatment usually advised is to effect reduction by relaxation of the limb and manipulation of the tendon, to place the part upon a splint so that the muscle belonging to the tendon will be relaxed, and to apply pressure over the point of injury. This treatment generally fails, and if the tendon does not become firmly anchored in its proper situation in four weeks we should operate. In some tendons it is enough to incise, freshen the edges of the torn sheath, and sew up with kangaroo-tendon or chromicized catgut. In a tendon lying in a long groove make a halter for the tendon by incising the periosteum and suturing it over the tendon.[1] Passive movements are begun at the end of the first week. Even if the tendon will not remain reduced, a useful joint will probably be obtained.

Wounds of Tendons.—Subcutaneous wounds of tendons are usually inflicted by the surgeon, and they heal well. Open wounds require rigid antisepsis and suturing of the tendon. In wounds of the wrist especially always

[1] Walsham's case of dislocation of the proneus longus, "Brit. Med. Jour.," Nov. 2, 1895.

suture the divided tendons (see Fig. 110), and be sure to bring the proper ends into apposition.

Rupture of Tendons.—A violent muscular effort may rupture a tendon, and as the accident occurs a snap may often be heard.

The **symptoms** are sudden pain and loss of power, fulness of the associated muscle from retraction, and absolute inability to bring the tendon into action. A gap may often be felt in the tendon (see page 718).

Treatment.—The best procedure in treating rupture of a tendon is exposure by incision and the introduction of sutures. Some surgeons relax the parts and apply splints (see page 718).

Thecitis, or **tenosynovitis,** is inflammation of the sheath of a tendon.

Acute thecitis may arise from a contusion, from a wound, from repeated overaction in working or while engaged in some sport, from rheumatism, from gonorrhea, from pyogenic infection, from influenza, from a continued fever, or from syphilis. In early syphilis certain tendon-sheaths may rapidly develop effusion because of hyperemia of the sheaths (Taylor).

Symptoms.—In *non-suppurative* cases of thecitis the symptoms are pain, swelling, tenderness, and moist crepitus along the tendon-sheath, due to inflammatory roughening. The crepitus disappears as the swelling increases, but it reappears as the swelling diminishes. In *suppurative* cases (*phlegmon of the tendon-sheaths*) the symptoms are great swelling, pulsatile pain, dusky discoloration, inflammation spreading up the tendon-sheaths, and often the constitutional symptoms of sepsis.

Treatment.—In treating non-suppurative thecitis employ splints, use the hot-air oven, and apply locally iodin, blue ointment, or ichthyol, and administer suitable remedies to combat any causative constitutional disease. In the suppurative form inject 1 c.c of formalin-glycerin (2 per cent.) after withdrawal of part or all of the exudate. If this fails, make free incisions, irrigate, drain, dress with hot antiseptic fomentations, and employ Bier's method (see page 112). (See Felon, page 724.)

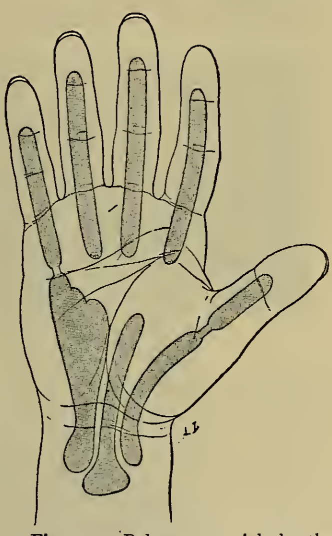

Fig. 451.—Palmar synovial sheaths (vaginæ tendinum), normal adult type (Poirier and Charpy).

Palmar Abscess.—We mean by this term an abscess beneath the palmar fascia and not a superfical collection of pus. Palmar abscess may arise after wounds, abrasions, burns, or inflammations of the skin of the palm. A thecal abscess in a flexor tendon of a finger travels rapidly upward and may produce a palmar abscess. A thecal abscess of either the index, ring, or middle finger is usually arrested at the lower end of the palm, but suppurative thecitis of the thumb or the little finger conducts pus along the tendon sheath and up the arm (Fig. 451). If the theca ruptures, pus is diffused over the palm. Abscess produces great swelling of the hand and fingers, the dorsum being swollen as well as the palm. The fingers become flexed and rigid. Violent pulsatile pain and decided constitutional disturbance exist. Discoloration is late in appearing. Related lymph-glands enlarge. Palmar abscess is a most serious affection. The pus may dissect up all the structures of the palm, may pass between the bones and reach the dorsum, or may pass beneath the anterior annular ligament into the connective-tissue planes of the forearm. In some cases it leaves a clawed, stiff, and useless hand.

Treatment.—A palmar abscess demands radical treatment at the earliest possible moment; delay will be responsible for stiff and contracted fingers and hyperesthetic skin, a damaged and perhaps a useless hand. The patient should be placed under the influence of ether. The incision is made in the line of the metacarpal bone and, if possible, below the palmar arches. A line transverse with the web of the thumb is below the palmar arches. In an incision above this line try not to cut either arch; but if one should be cut, at once take means to arrest the hemorrhage (see page 449). In a severe case it may be necessary to make several palmar incisions, to open the tendon-sheaths on the flexor surface of the forearm above the wrist, and to make counter-openings in the back of the hand, and it is sometimes necessary to introduce tubes, and drain through and through the hand. After operation apply hot antiseptic fomentations and put the part upon a splint. Bier's passive hyperemia is very useful. When granulations begin to form, dry dressings are substituted for hot moist dressing. It may be necessary to give morphin for pain, and stimulants may be needed. There is great danger of stiffness of the fingers occurring, the tendons becoming adherent to their sheaths. Hence passive movements are inaugurated as soon as granulations begin to form.

Chronic thecitis may follow acute thecitis, but may be due to injury, to rheumatism, to gummatous infiltration, to rheumatoid arthritis, or to

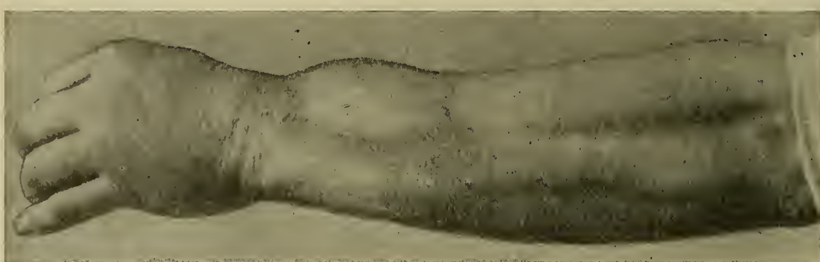

Fig. 452.—Tuberculous thecitis (compound ganglion).

tuberculous inflammation of a tendon-sheath. Chronic thecitis is commonest in the tendons at the wrists, the ankles, and the knees; it may spread to a joint or it may arise from a tuberculous joint. This condition causes very little pain. In ordinary non-tuberculous thecitis the part is weak, tender, painful and stiff, crepitates on motion, and is swollen. In *tuberculous thecitis* there is at first distention of the tendon-sheath with serum. The serum contains *rice*, *riziform*, or *melon-seed* bodies, and the wall of the tendon-sheath is here and there thickened and caseating. Later in the case the interior of the tendon-sheath becomes lined with tuberculous granulations and a tuberculous abscess may form. Rice bodies are sometimes fibrinous masses, are sometimes pieces of separated and dead recently formed fibrous tissue, and are sometimes masses of proliferating cells. In tuberculous cases the swelling is firm or doughy when due to granulation tissue, but is fluctuating when due to fluid. Grating is marked. Tubercle bacilli are present in the fluid or in the granulation tissue. Tuberculous thecitis is most common about the wrist, constituting the so-called *compound ganglion* (Fig. 452).

Treatment.—*Tuberculous cases* are treated as follows: If there is a fluid effusion and no rice bodies, make a small incision, wash out with salt solution, introduce iodoform emulsion or formalin-glycerin, and close the wound. In cases in which there are rice bodies, open the sheath, evacuate the con-

tents, scrape the walls thoroughly, inject iodoform emulsion or formalin-glycerin, and close the wound. (If the annular ligament requires division, stitch it before closing the wound—Fig. 453.) In cases with extensive thickening apply an Esmarch bandage, make a large incision, and remove all infected tissue from the sheath, around the sheath, and from the tendon. In tuberculous thecitis Bier's method (see page 112) may be of service and so may the x-rays. In *ordinary traumatic thecitis* use for the first few days rest associated with applications of ichthyol. Later employ hot and cold douches, massage and passive movements, strapping of the part, inunctions of ichthyol, and the hot-air bath. If effusion is persistent or rice bodies exist, make an incision and scrape the interior of the tendon-sheaths. In rheumatic cases give antirheumatic remedies and employ the hot-air bath. In syphilitic cases administer mercury and iodid of potassium.

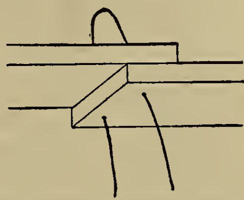

Fig. 453.—Method of suturing the annular ligament of the wrist.

Simple Ganglia.—In connection with tendon-sheaths and joints simple ganglia may develop. They are small, tense, round swellings, which are firm, grow progressively though slowly, are painless when uninflamed, and contain a fluid of the appearance and consistence of glycerin-jelly (Bowlby). Ganglia are commonest upon the dorsum of the wrist and they occur especially in those who constantly use the wrist muscles. Ganglia are occasionally seen on the dorsum of the foot. Paget states that a *simple* ganglion is due to cystic degeneration of a synovial fringe inside a tendon-sheath, and that the fluid of the ganglion does not communicate with the fluid of the tendon-sheath. Other pathologists have maintained that a simple ganglion is a hernia of synovial membrane through a rent in a tendon-sheath, all communication between the

Fig. 454.—Ganglion of extensor tendon-sheaths of the wrist.

herniated part and the tendon-sheath being soon obliterated. The belief is now general that a ganglion is due to cystic degeneration of an area of connective tissue adjacent to a joint or a tendon, this area of tissue having been rendered extremely cellular by traumatism. A number of minute cysts form and they coalesce into one cyst. The cyst may form a secondary communication with the interior of a tendon-sheath or joint. Ganglia occasionally diminish in size or even disappear spontaneously.

Treatment.—A ganglion is treated by aseptic puncture by a tenotome, evacuation, scarification of the walls, antiseptic dressing, and pressure. An old-time method of treatment was subcutaneous rupture brought about by

striking with a heavy book. Duplay treats a ganglion by injecting a few drops of iodin through a hypodermatic needle. The cyst is not evacuated before injection. The parts are dressed antiseptically, and cure is obtained in one week. Recurrent ganglia, very large ganglia, and ganglia with very thick contents should be dissected out.

Felon, or **whitlow,** is a violent, rapidly spreading pyogenic inflammation of a finger or a toe which resembles cellulitis, and which is sometimes followed by gangrene of the soft parts or by necrosis of bone (Fig. 455). An injury precedes the whitlow—an abrasion of the surface which admits pus-organisms or a contusion which creates a point of least resistance. The commonest seat of a felon is the last digit of a finger or the thumb. An abrasion of the surface at this point absorbs pus-organisms and the superficial lymphatics carry the bacteria directly inward, the micro-organisms lodging, it may be, in the skin, in the subcutaneous tissues, in the tendon-sheath, or beneath the periosteum. The perpendicular direction of the fibers of the subcutaneous tissue favors this passage inward.

Fig. 455.—Deep felon, with sloughing of soft parts and necrosis of bone.

Felons are very rare in infants, but may occur in children. Women are more liable to them than men. The fingers are much more prone to infection than the toes, because they are more exposed to injury. Several fingers may be attacked at once or successively in persons of dilapidated constitution. Whitlow is most apt to occur and is most severe in persons broken down by disease, alcoholism, overwork, or worry. In certain cases of neuritis painless suppuration may arise. In syringomyelia *painless felons* are common, and they are apt to be associated with necrosis of bone. Painless and destructive whitlows constitute a characteristic part of *Morvan's disease.*

There are two forms of felons, the *superficial* and the *deep.*

Superficial Felons.—One form of superficial felon is between the cuticle and the true skin and is rarely followed by involvement of deeper parts. The infection is in the skin. The point of infection becomes dark red, swollen, painful, and tender. The epidermis is lifted up into a pustule by the seropus which forms, and a considerable area may be attacked before the spread of the process is arrested. The commonest form of superficial felon is subcutaneous suppuration, the pus collecting in the fibrofatty pad at the palmar surface of the last digit (G. B. Mower White, in "Brit. Med. Jour.," Feb. 24, 1906). This form often spreads deeply. If the subcutaneous tissues only are involved the symptoms are those of an ordinary cellulitis. There is severe pain, increased by motion, pressure, and a dependent position. Swelling and discoloration are early and marked. Pus forms within forty-eight hours. *Paronychia,* or *ring around,* is cellulitis starting at the end or side of the digit, and involving the parts around and below the nail. The pus-organisms obtain entrance by means of an abrasion, a puncture, or an ulcerated "step-mother."

In paronychia pain is throbbing and violent; is increased by motion, pressure, or a dependent position; the skin is dusky red, but the swelling is slight. In about forty-eight hours pus forms in the superficial parts, the epidermis being lifted into pustules or blebs, and pus may also form under the nail. A portion of the nail or the entire nail may be lost.

If the tendon-sheath becomes involved as well as the subcutaneous tissue, the symptoms are those of suppurative thecitis, with more marked discoloration of the skin.

Deep Felons (Fig. 455).—There are two forms of deep felon. One is a thecal suppuration involving the flexor tendon-sheath, arising secondarily to subcutaneous suppuration and spreading widely. In suppurative thecitis of the three middle fingers the process seldom reaches the palm; in suppurative thecitis of the theca of the thumb or little finger the pus may pass above the wrist and a true palmar abscess may form (see Fig. 451). Another form is suppuration beneath the periosteum. This form is the so-called *bone felon.* It is occasionally primary, but more often arises secondarily to suppurative thecitis or to subcutaneous suppuration. In some cases a deep felon involves most of the structures of the finger (periosteum, bone, tendon, tendon-sheath, and cellular tissue), and may destroy the digit or the finger. The bacteria causative of a deep felon are lodged in the deeper parts. The pain is agonizing, entirely preventing sleep, pulsatile in character, associated with excruciating tenderness, greatly aggravated by motion or a dependent position, and often extending up the hand and forearm. The skin is dusky red and edematous, and the part is enormously swollen. Pus forms quickly; diffuse cellulitis may arise; sloughing of the tendon and subcutaneous tissue may take place; necrosis of one or more bones may ensue, and in some cases gangrene of the finger follows.

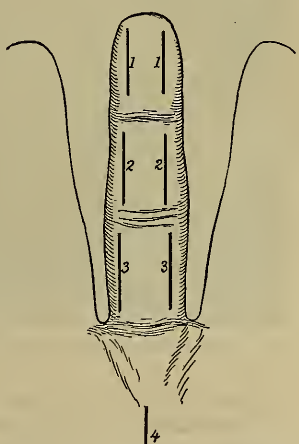

Fig. 456.—1, 2, and 3, Incisions for felon of finger and for ordinary suppuration; 4, palmar incision.

In deep whitlow lymphangitis of the forearm and arm is not unusual, adenitis of the axillary glands is common, and almost always there is fever. In superficial felon constitutional symptoms are slight or absent, and lymphangitis and adenitis arise in a minority of cases.

Treatment.—In a subcuticular felon, after cleansing, soften the parts well in an antiseptic fluid and then pare off the cuticle with a very sharp knife. This plan of White's is an excellent one; it gives vent to pus and prevents the inoculation of the deeper tissues which may follow incision. In subcutaneous suppuration incise the abscess, but be careful not to open the tendon-sheath or periosteum, as this would diffuse infection (White, in "Brit. Med. Jour.," Feb. 24, 1906). In neither of the above instances is it necessary to give an anesthetic. After operating, the parts must be irrigated, dressed with hot antiseptic fomentations, the hand must be placed upon a splint, and Bier's passive hyperemia is to be induced daily. In a deep felon I am convinced that we should operate immediately. Allay tension and prevent pus formation by early incision. Do not waste time with poultices; to wait means agonizing pain, sleepless nights, constitutional involvement, and, perhaps, sloughing of tendons or death of bone. Incision and drainage constitute *the* treatment, but incision conducted in a particular manner. I have only lately learned how to treat a deep felon. I formerly treated all cases by incisions down to

the bone alongside of the tendon (Fig. 456), and was frequently disappointed by a spread of the suppuration in spite of incisions, by necrosis of bone, or by extensive sloughing of tendons. I obtained new light upon this subject from an article on "Whitlow," by G. B. Mower White ("Brit. Med. Jour.," Feb. 24, 1906). I immediately put in practice the common-sense suggestions in this valuable article and have seen a surprising improvement in results. The chief points in White's plan of treatment are as follows: To plunge a knife through an area of infection into a tendon-sheath, if that sheath is not infected, will lead to infection, and the way to be sure whether it is or is not infected is to look through a carefully made incision and see. After careful sterilization, anesthetize, drain the extremity of blood by elevation, and apply an Esmarch band to the arm. This enables us to see what we are doing. Slowly and carefully make an incision by the side of the tendon-sheath (Fig. 456), and on reaching it see if it is distended. If in doubt, insert a hypodermatic needle and withdraw fluid. If we get turbid serum, the theca is infected. If the theca is not infected, do not open it, but incise the subperiosteal area of suppuration if it exists. If the theca is infected, remember that this infection has surely ascended more or less, and we must not only open at the lower point, but must also incise at the upper point. Do not incise the theca over the length of the tendon, as sloughing will follow. If one of the three middle fingers is involved, incise the distal end of the theca and also the proximal end over the head of a metacarpal bone in the midline, wash from opening to opening, and drain. If the theca of the thumb or little finger is involved, open distally and then proximally above the wrist. To reach the proximal end ot the theca of the thumb cut at the radial side of the tendon of the flexor carpi radialis. Also open the palmar sac of the flexor longus pollicis, making the cut along the inner border of the outer head of the flexor brevis pollicis.

To reach the proximal end of the theca of the little finger begin an incision at the upper margin of the annular ligament and carry it up along the inner border of the flexor sublimis. Retract the tendons and pus will usually be found between the tendons of the superficial and deep flexor. Look beneath the profundus tendons for the bursa and open it. Then open the palm by an incision in the line of the axis of the ring-finger. Thus three openings are made in either case, and the theca can be thoroughly washed and drained. If either the thumb or little finger bursa is found infected, the other must be exposed and examined, as they usually communicate at their proximal ends or a communication may form as a result of suppuration. Rupture of either bursa may diffuse pus widely. White, in order to prevent secondary hemorrhage, ligates the radial artery in two places and removes 1½ inches of it (if operating on the thumb bursa); and ligates the superficial arch and removes 1 inch of it (if operating on the palmar expansion of the little finger theca). These arterial ligations seem a serious and perhaps unnecessary addition to the operation and I have not *practised* them. After thorough irrigation apply antiseptic fomentations, splint the extremity, and induce Bier's passive hyperemia daily. If the patient cannot sleep, give morphin. See that the bowels are moved once a day. Give quinin, iron, and milk-punch. As soon as granulations begin to form, use dry dressings and make passive motion daily. If bone undergoes necrosis, let it loosen and then remove it. Amputation is sometimes necessary.

Bursitis is inflammation of a bursa. *Acute bursitis* arises from strain, from traumatism, or from infection. The symptoms of acute bursitis are pain, limited swelling, moist crepitus, fluctuation, and discoloration in the anatomical position of a bursa. In *chronic bursitis* there is intermittent pain, tenderness, and progressive, fluctuating swelling. *Bursitis of the retrocalcaneal bursa* (*Albert's disease*) is a painful affection which is often overlooked. It is rather

common in storekeepers who rise often on the toes to reach shelves, in motormen who use a foot gong, in street-car conductors, and in clerks who stand at desks. It may follow gonorrhea and may be tuberculous. Walking causes great pain in the heel. Raising up on the toes is exceedingly painful. It is usually associated with flat-foot. In these cases osteophytes often form within the bursa. There are numerous bursæ about the hip. Some anatomists count twenty-one.[1] The two most important bursæ and the ones usually affected are the iliac and the deep bursa over the great trochanter.[2] Inflammation of the *iliac* or *iliopsoas bursa* produces swelling below Poupart's ligament, which swelling is tense, but exhibits fluctuation on careful examination. Often the swelling attains large size. In some cases the sac can be emptied by pressure, the fluid passing into an adjacent bursa or into the joint. The swelling is beneath the femoral artery and consequently lifts that vessel (F. B. Lund, in "Boston Med. and Surg. Jour.," Sept. 25, 1902). The enlargement often presses on the anterior crural nerve and causes spasmodic pain throughout the nerve's trajectory. The limb, according to Zuelzer, is usually slightly flexed, abducted and rotated outward, and movement in an opposite direction causes pain. Inflammation of the bursæ about the hip may produce symptoms resembling those of incipient coxalgia, but in bursitis the symptoms do not remit, as in hip-disease. Iliopsoas bursitis occasionally results from gonorrhea. The bursa is sometimes involved in joint-disease. In inflammation of the iliac bursa flexion is not so marked as in coxalgia, and the trochanter is never above Nélaton's line. In inflammation of the deep trochanteric bursa the position is the same as in iliac bursitis, and resembles that of coxalgia. In coxalgia, however, there is pain on pressure upon the front of the joint or directly on the trochanter or on tapping the sole of the foot. These manipulations do not cause pain in bursitis (Zuelzer). In inflammation of the *gluteal bursæ* there is moderate pain back of the thigh and knee, which disappears when the patient is at rest; there are a marked limp, limitation of motion, and an area of deep fluctuation in the buttock (Brackett).

Fig. 457.—Olecranon bursitis.

It is difficult to differentiate between inflammation of a deep bursa and synovitis; indeed, in bursitis the joint is apt to be secondarily affected. This difficulty is especially vexatious in distinguishing between joint-injury and injury of the bursa beneath the deltoid. In subdeltoid bursitis there is a tender spot over the bursa when the arm is by the side. When the surgeon abducts the patient's arm the bursa slips up under the acromion and no tender spot can be found. Suppuration may take place in a bursa. Direct force may rupture a bursa. The bursa beneath the deltoid is frequently ruptured. When this accident happens, there are pain, marked swelling, a large area of moist crepitus, and later extensive discoloration from blood. Chronic bursitis may follow acute bursitis, or the disease may be chronic from the start. It may be due to tuberculosis. Bursæ particularly apt to become tuberculous are those about the hip, the subdeltoid, the olecranon, the prepatellar, and the retrocalcaneal. In tuberculous bursitis during the

[1] Synnestvedt, of Sweden. [2] Zuelzer, in "Zeit. f. Chir.," vol. l.

first stage the bursa is distended by fluid, due to oversecretion, the walls are thickened here and there, and perhaps contain caseous foci and rice bodies are found in the bursal fluid. In a more advanced stage the bursal wall is lined with caseating granulation tissue and the bursa may become a tuberculous abscess, the walls may give way with diffusion of the process, or mixed infection with pyogenic organisms may occur. In some cases of tuberculous bursitis tending to cure the bursal walls become enormously thickened by fibrous tissue.

Fig. 458.—Housemaids' knee.

The **symptom** of chronic bursitis is swelling but little or no pain unless acute inflammation arises. Chronic bursitis of the prepatellar bursa is known as *housemaids' knee* (Fig. 458). Chronic bursitis of the subhyoid bursa is known as *Boyer's cyst.* There are six bursæ about the ham, the largest of which is the bursa of the semimembranosus muscle.

Treatment.—Acute bursitis is treated by rest, pressure, and the application of iodin, blue ointment, or ichthyol. If the swelling persists, aspirate and apply pressure, or incise the sac and remove it partly or completely. If pus forms, incise, paint the interior of the sac with pure carbolic acid, and pack with iodoform gauze. Chronic bursitis may be cured by the use of pressure and the application of blue ointment, and with treatment of any causative diathesis, but most cases require incision and packing. A ruptured bursa is treated as an acute bursitis. In bursal tuberculosis the best treatment is excision. If we are dealing with a very deep bursa the proper treatment is incision, scraping with a sharp spoon, mopping with carbolic acid, and packing with iodoform gauze.

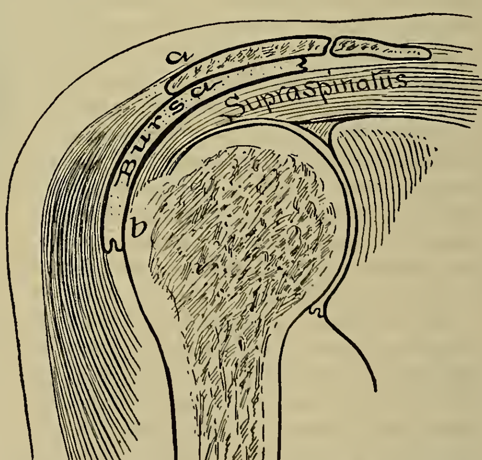

Fig. 459.—Diagram from a frozen section. Notice the deltoid and its origin, from the edge of the acromion. Notice the subdeltoid or subacromial bursa with its roof made by the under surface of the acromion and by the fascia beneath the upper portion of the deltoid. Its base is on the greater tuberosity and the tendon of the supraspinatus, which separates it like an interarticular fibrocartilage from the true joint (Codman).

Bursitis of the subacromial bursa has been considered by A. E. Codman ("Boston Med. and Surg. Jour.," Oct. 22 and 29, Nov. 5, 12, 19, and 26, and Dec. 3, 1908), who points out that the deltoid and the subacromial bursa are one and the same thing. When the arm is abducted, the entire bursa is subacromial; when it is adducted, a large portion of the bursa is

subdeltoid. Codman describes three types of conditions associated with inflammation of this bursa, first: The acute, or spasmodic type, in which there is local tenderness on the point of the shoulder, just below the acromion process and outside the bicipital groove. In some cases Dawbarn has shown that the tender point, which is the base of the bursa, disappears under the acromion when the arm is abducted. Codman goes on to show that in attempting abduction about ten degrees of motion can be obtained without moving the scapula. Then the scapula is locked by spasm and moves with the humerus. This spasm may be temporary in mild cases. Sometimes pain prevents the patient from voluntarily raising the arm, though it may be raised by passive motion. The pain may run down the outer side of the arm, even into the hand; the patient frequently locates the pain about the insertion of the deltoid, and may be able to note swelling of the bursa.

Codman describes type two, the subacute or adherent type, in which there are adhesions between the roof and floor of the bursa and a definite mechanical hindrance to abduction and external rotation. There may or may not be local tenderness, but Dawbarn's sign is absent, owing to the presence of the adhesions. Abduction is limited to such a great degree that, as a rule, the tuberosity will not pass beneath the acromion. Any movement in abduction beyond ten degrees causes the scapula to move. The pain is located as in type one, and frequently also passes into the neck. In some cases it is very severe.

Fig. 460.—Showing incision used for demonstration of the bursa (Codman).

Codman's third form is the chronic and non-adherent. In this the full arc of motion is retained, but motion is painful. The bursa is thickened and irregular. There may or may not be local tenderness; and if this is present, one will find Dawbarn's sign. Abduction and external rotation are limited little, if at all, but at some point during abduction there is severe tenderness, which disappears as soon as the tuberosity passes beneath the acromion. The scapula does not accompany the motions of the humerus. There is often considerable pain after motion.

Codman points out that the prognosis in type one is very favorable if treatment is correct. In type two the disability, even without treatment, seldom lasts more than two years. He says that even severe or adherent cases, if there are no secondary contractures in the forearm muscles, will recover in from one to two years. In infective cases the prognosis is far worse than in traumatic cases. In chronic cases, in which the arc of mobility is not affected, the prognosis is fairly good.

Treatment.—Acute cases of subacromial bursitis should be treated by keeping the arm abducted in a splint (Fig. 461). Monks suggests that the patient may sit by a table, the arm being abducted and placed upon a pillow that is on the table. This relaxes the short rotators and the deltoid, and keeps the base of the bursa from being in contact with the acromion. At night

Codman places the arm on a pillow, with its long axis at right angles to the patient's body as he lies recumbent. If the patient has to get about, he may use a sling most cautiously. He should take the arm out from time to time and rest it on a table. Massage should be used about the bursa, but not directly over it. In the more severe cases with adhesions one may employ massage, passive and active movements, baking, forcible movement and

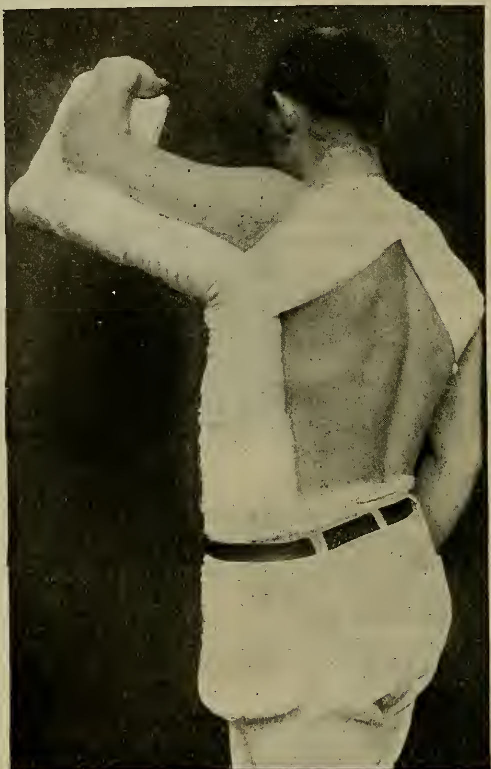

Fig. 461.—Showing the abduction splint in position, the patient standing. It is held by a figure-of-8 bandage, which crosses behind the shoulders and by a belt about the hips. The arm is at rest (Codman).

Description of Splint.—The frame of the splint which I use is made of iron wire (diameter, $\frac{1}{4}$ inch), stiff enough to maintain its form and to carry the weight of the arm securely. Sufficient cotton wadding to thoroughly pad it is bandaged over it and the whole covered with cotton or linen cloth. The general shape is shown in the photograph. It should be just long enough to extend from the axilla to the seat of the chair on which the patient sits. It is best held in position by a belt around the pelvis and a figure-of-8 flannel bandage about the shoulders crossing back of the neck. A pad should be placed in the opposite axilla to prevent excoriation of the skin by the bandage.

During the first twenty-four hours and afterward, if worn at night, the arm should also be lightly bandaged to the projecting part of the splint. Additional security is given by the application of a swathe, which may be pinned to the bandage of the axilla.

When properly adjusted it is perfectly comfortable. Unless it is comfortable it is useless. The use of the splint is not essential and is even harmful if not skilfully cared for.

manipulation under an anesthetic, followed by fixation in the position of abduction (Fig. 461), or perhaps incision of the bursa with division of the adhesions or excision of the subdeltoid portion of the bursa (Codman). In the cases in which there is irregularity of the surface of the bursa, one should excise and remove the thickened folds or other irregularities.

Housemaids' knee (see Fig. 458) is thickening and enlargement of the prepatellar bursa, the result of intermittent pressure. In effusion into the knee-

joint the fluid is behind the patella and the bone floats up; in housemaids' knee the fluid is above the bone and the osseous surface can be felt beneath it.

Fig. 462.—Bursitis of left olecranon bursa of three years' duration.

In **bursitis of the deep infrapatellar bursa** the swelling is under the ligament of the patella.

Miners' elbow (Figs. 457 and 462), which is a condition similar to housemaids' knee, affects the olecranon bursa.

Weavers' bottom is enlargement of the bursa over the tuberosity of the ischium. A bursa which is simply thickened and enlarged rarely gives rise to annoyance; but when it inflames, as it is apt to do, it causes the ordinary symptoms of bursitis.

The **bursa of the semimembranosus muscle** is the largest one about the ham. It lies between the inner femoral condyle and inner head of the gastrocnemius and the semimembranosus muscle. It communicates with the knee-joint. When the joint is flexed, it partly empties into the joint and becomes small and lax. When the joint is extended, it becomes large and tense.

Fig. 463.—Enlargement of the deep infrapatellar bursa; chronic and the result of traumatism.

Treatment of Special Forms.—Some few cases of housemaids' knee may be cured by rest and blistering, but in most cases it is necessary to incise and pack with iodoform gauze. In enlargement of the bursa beneath the ligamentum patellæ, if rest and blistering fail to cure, aspirate or incise. In enlargement of the bursa beneath the tendon of the semimembranosus and also in "weavers' bottom" and in "miners' elbow," incise and pack. In operating for iliopsoas bursitis I follow Lund's advice and make a vertical

incision below Poupart's ligament, and between the anterior crural nerve and the femoral artery. The fibers of the iliopsoas muscle are separated and the bursa is opened and drained. Some few cases of retrocalcaneal bursitis recover after rest, but most of them require incision and drainage. If osteophytic formations exist, the bony stalactites must be removed by means of the rongeur. Flat-foot, if it exists, is treated by a support (see page 742). The treatment of subacromial bursitis is considered on page 729.

A **bunion** is a bursa due to pressure, and it is most commonly situated above the metatarsophalangeal articulation of the great toe, but is occasionally seen over the joint of another toe. When the big toe is pushed toward the other toes by ill-fitting boots a bunion forms. When a bunion is not inflamed it may cause but little trouble, but when it inflames the bursa enlarges and the parts become hot, tender, and exceedingly painful. Suppuration may occur and pus may invade the joint, and the bone not unusually becomes diseased and very greatly enlarged.

Treatment.—In treating a bunion the patient must wear shoes that are not pointed, that have the inner border straight, and that have rounded toes (Jacobson). For a mild case a bunion-plaster gives comfort. Sayre advises the use of a linen glove over the toe, the toe being drawn inward by a piece of elastic webbing, one end of which is fastened to the glove and the other end to a piece of strapping from the heel. A special apparatus may be worn (Fig. 464). In many cases osteotomy of the first phalanx or of the first metatarsal bone is required; in some cases excision of the joint is necessary; in others amputation must be performed. Charles H. Mayo has operated on 65 cases successfully. He removes the head of the metatarsal bone and with it two-thirds of the hypertrophy on the inner side, and turns the bursa into the joint area in front of the bone. He sutures this bursa in place and now has a synovial membrane for a joint which becomes satisfactorily movable ("Annals of Surgery," August, 1908). When the bursa is not inflamed, but only thickened, blisters should be employed over it, or there should be applied tincture of iodin, ichthyol, or mercurial ointment. When the bursa inflames, ichthyol ointment is applied, and intermittent heat by foot-baths gives relief. Suppuration demands immediate incision and antiseptic dressing. If an ulcerated bunion does not heal by antiseptic dressing, stimulate it with nitrate of silver and dress it with unguent. hydrarg. nitrat. (1 part to 7 of cosmolin). Jacobson recommends skin-grafting for some cases.

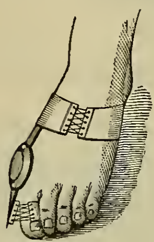

Fig. 464.—Bigg's apparatus for bunions.

Operations Upon Muscles and Tendons

Tenotomy is the cutting of a tendon. It may be *open* or *subcutaneous*, the open operation being preferred in dangerous regions.

Open Division of the Sternocleidomastoid Muscle for Wry-neck.—Subcutaneous tenotomy for wry-neck has been largely abandoned. It is not only more unsafe than the open operation, but it never completely divides all the contracted band.

The patient is placed recumbent, the chin being drawn more than is habitual toward the opposite side. A transverse incision is made over the muscle about ¼ inch above the clavicle. The superficial parts are divided, the muscle is exposed and sectioned, bleeding is arrested, and the skin is sutured. Avoid the anterior jugular vein, which is underneath the muscle, and also the external jugular, which is close to the outer edge of the muscle. Mikulicz advocates the removal of almost the entire muscle, leaving, however,

the upper and posterior portion where the spinal accessory nerve passes. After operation for wry-neck plaster of Paris is used to secure fixation for from four to eight weeks. Then inaugurate motions, active and passive.

Subcutaneous Tenotomy of the Tendo Achillis.—This operation is performed for club-foot, in which the heel is raised. The tendon is cut about 1 inch above its point of insertion. The instrument used for the first puncture is a sharp tenotome. The patient lies upon his back, "with his body rolled a little toward the affected side" (Treves), the foot being placed upon its outer side on a sand-pillow. The surgeon stands to the outer side. The tendon is rendered moderately rigid, and a sharp tenotome, with its blade turned upward, is inserted along the anterior border of the tendon until the surgeon's finger feels the knife approaching the outer side. The sharp-pointed instrument is withdrawn and a blunt-pointed tenotome is inserted in its place. The tendon is drawn into rigidity, and the surgeon turns the blade of his knife toward the tendon, places his finger over the skin, and saws toward his finger. The tendon gives way with a snap. Treves states that a beginner is apt not to push the knife far enough toward the outside, or he may in the first puncture push the knife through the tendon; in either case the tendon is not completely cut. Another method is to insert the tenotome between the skin and the tendon and cut the tendon by a sawing motion. In this method the danger of cutting through the skin is obviated. The little wound, which is covered by a bit of gauze, will be entirely closed in forty-eight hours. In club-foot cases after tenotomy some surgeons at once correct the deformity and immobilize the limb in plaster; some partially correct the deformity and apply plaster for one week, at which time they remove the plaster, correct the deformity further, reapply the plaster, and so on; other surgeons do not attempt correction of the deformity until the cut tendon has begun to unite, when they gradually stretch the new material.

Subcutaneous Tenotomy of the Tendon of the Tibialis Anticus Muscle.—The tendon is divided about $1\frac{1}{2}$ inches above its point of insertion. It can be made tense by extending and abducting the foot. The sharp-pointed tenotome is entered upon the outside of the tendon, and is passed well around it. The blunt-pointed tenotome is used to cut the tense tendon.

Subcutaneous Tenotomy of the Tendons of the Peroneus Longus and Brevis Muscles.—These two tendons are cut together back of the external malleolus, and $1\frac{1}{2}$ inches above the tip of the malleolus, so as to avoid the synovial sheath (Treves). The patient lies upon the sound side, the outer aspect of the deformed foot being upward and the inner aspect of the ankle resting upon a sand-pillow. A sharp tenotome is introduced close to the fibula, and is carried around the loose tendons. A blunt-pointed tenotome is now introduced, its edge is turned toward the tendons, and these structures are cut as they are made tense.

Subcutaneous Tenotomy of the Tendon of the Tibialis Posticus Muscle.—This tendon is sectioned above the point where its synovial sheath begins; that is, above the internal annular ligament (Treves). The tendon is made tense and the pointed knife is entered above the base of the inner malleolus. The knife is entered just back of the inner edge of the tibia, and is carried around the muscle and is kept close to the bone. The tendon is sectioned with a blunt knife.

Subcutaneous Fasciotomy of the Plantar Fascia.—The contracted bands are discovered by motions which render them tense, and they are divided just in front of the attachments to the os calcis. The sharp knife passes between the skin and fascia at the inner side of the sole of the foot. The fascia is cut from without inward by the blunt-pointed tenotome. It is usually necessary to section the fascia at more than one point.

Tendon-suture and Tendon-lengthening.—Chromicized gut, kangaroo-tendon, or silk is used for an ordinary case, silver wire for a suppurating wound. In performing tendon-suture make the part aseptic and bloodless. It is wise to apply a rubber bandage on the proximal side, the bandage being applied centrifugally, forcing the proximal end of the tendon into view (Haegler). If searching for the proximal end of a flexor of the finger, flex the injured finger and hyperextend the adjoining fingers (Filiget). If this expedient fails, enlarge the incision or, what is better, make a large flap in the skin. After finding the ends, approximate them, being sure the proper ends are brought into contact; stitch them together by a continuous suture or by one of the sutures shown in Fig. 465, 1, 2, and 3.

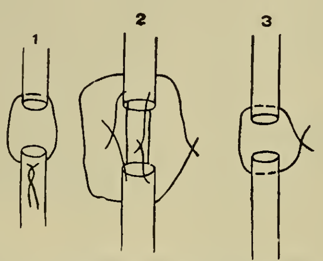

Fig. 465.—Tendon-sutures: 1, Of Le Fort; 2, of Le Dentu; 3, of Lejars.

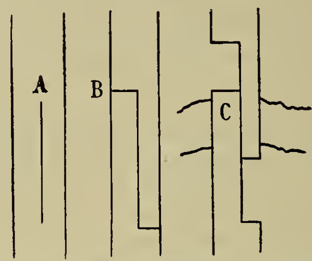

Fig. 466.—Anderson's method of tendon-lengthening.

In a suppurating wound suture by silver wire should be tried, though it usually fails. After suturing, remove the Esmarch apparatus, arrest bleeding, close the wound and dress it antiseptically, relax the parts, and place the limb on a splint. If, after suturing, there is much tension, stitch the cut tendon above the sutures to an adjacent tendon, and apply a splint, the finger which was injured being flexed, the others being extended. If only the distal end of the tendon can be found, graft it upon the nearest tendon with a like anatomical course and function. After a tendon has been sutured, begin gentle massage in two weeks. Positive passive motion is begun in three or four weeks. In old injuries, when the ends cannot be brought into apposition, lengthen one end or both ends, either by the method of Anderson (Fig. 466) or by the method of Czerny (Fig. 467). Dr. J. Neely Rhoads ("Med. News," Nov. 28, 1891) suggested that slight lengthening could be accomplished by "cutting half through the tendon at different levels and from opposite sides, leaving some longitudinal fibers to slip on each other, thus gaining slight elongation" (H. Augustus Wilson, in "International Clinics," vol. i, 4th series). Poncet makes several zigzag incisions on each side of the tendon, and when the tendon is pulled upon it elongates decidedly. Hibbs's method is shown in Fig. 468. One of these methods of lengthening may be used if there is deformity from tendon contraction. If the tendon cannot be lengthened sufficiently, make a bridge of catgut from one cut end of it to the other, or graft in another tendon from one of the lower animals, or graft the distal end to a tendon of like function (*tendon-grafting*).

Fig. 467.—Czerny's method of tendon-lengthening.

The annular ligament is sutured as shown in Fig. 453.

Tendon-transplantation and Silk Inserts.—Tendon-transplantation is the transplantation of the tendon of a healthy muscle to take the place of the tendon of a paralyzed muscle. Silk inserts are used to take the place of paralyzed muscles, "to lengthen normal tendons for the purpose of using them

in transplanting, and to reinforce joints as artificial ligaments, in place of arthrodesis" (James W. Sever, "Jour. Am. Med. Assoc.," May 11, 1912). Tendon-transplantation is usually said to have been devised by Nicoladoni in 1882; as a matter of fact, Duplay did the operation in 1876, endeavoring to secure function in an arm rendered nearly powerless by an injury (Elting, in "Albany Med. Annals," April, 1902).

The first American surgeon to do the operation was Parrish, of New York, who in 1892 transplanted tendons in a case of club-foot. In some cases in which a muscle has been paralyzed surgeons have divided the tendon of the paralyzed muscle and have united its distal end with the tendon of a normal muscle, the normal tendon being split to receive it. It has also been stated that when a muscle or the tendon of a muscle is sutured to a paralyzed antagonistic muscle, the transplanted structure will actually execute the functions of the paralyzed muscle. For instance, a flexor, when so transplanted, may become an extensor and act under the mental impulse of extension; a pronator may become a supinator (H. A. Wilson, in "American Med.," April 8, 1905). These principles have been utilized when some or many of the muscles of a limb have been paralyzed, the tendon of an unparalyzed muscle or the tendons of an unparalyzed group of muscles being fastened to the tendons of the paralyzed muscle. It has been shown that the success of the procedure depends upon the accuracy of diagnosis, the division of secondary contractures, the correction of existing deformities, and careful after-treatment. (See the article by Dr. J. Hilton Waterman, in "Med. News," July 12, 1902.) In a paralysis

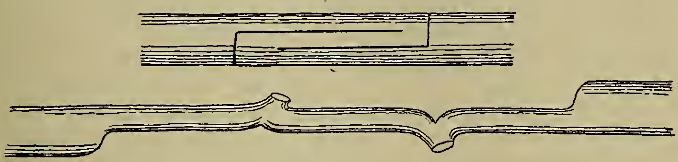

Fig. 468.—Hibbs's method of tendon-lengthening.

of the lower extremity, as Goldthwait points out, the sartorius usually retains power, and it may be advisable in such a case to divide the sartorius and suture its upper end to the quadriceps above the patella. A strip of the tendo Achillis may be grafted upon the peronei in certain cases. An artificial tendon may be made of silk, the silk being passed from the sound to the paralyzed tendon. This method was devised by Auger in 1875. The silk must have been boiled in paraffin, otherwise it will slough out. The silk eventually becomes surrounded by fibrous tissue. Some maintain that silk is eventually absorbed. Lange showed that tendon regeneration may take place along the strands of silk. Strands of silkworm-gut may be used for the same purpose (Kummell). It is useless to make a silk insert on a tendon in a patient under nine or ten years of age. Coöperation between surgeon and patient is essential if we would develop function, and coöperation is sure to be lacking before that period of life. The operation of tendon-transplantation is occasionally of distinct benefit, but I agree with Ridlon, and am not usually sanguine of results. Ridlon wisely reminds us that in such cases much good may perhaps result from the proper use of braces, tenotomy, and hand stretching, followed by prolonged retention in plaster, the patient using his limb actively.

Ridlon points out that most brace treatment is not curative because it only aims to prevent deformity developing, and tenotomy and stretching fail because they only seek to remove existing deformity. The object should be some restoration of function. This is often obtained by following Thomas's direction and "posturing" the limb so as to permit structural shortening of the paralyzed muscles and then fixing them for months.

XXII. ORTHOPEDIC SURGERY

This branch of surgery formerly dealt only with the treatment of deformities by means of mechanical appliances, but of recent years its domain has been enlarged to include the treatment, surgical and mechanical, of deformities, contractures, and many joint diseases.

Torticollis (wry-neck) is a condition in which contraction of certain of the neck muscles causes an alteration in the position of the head. The disease is one sided; the sternocleidomastoid is the muscle chiefly involved, though the trapezius, the splenius, and other muscles sometimes suffer. Acute torticollis, which is rare, is a temporary condition, and results from cold or from injury (see Myalgia). Chronic torticollis may be congenital (due to injury before birth or during birth), may be due to nerve irritation, to an assumed attitude because of eye defect, to polio-encephalitis (Golding Bird), to inflammation of the glands or to disease of the vertebræ, and it may be intermittent, but is usually persistent. The muscle stands out in bold outline, the head is turned to the opposite side, the ear of the disordered side is turned toward the shoulder, the chin is thrown forward, and spinal curvature may arise. The corresponding side of the face atrophies. There is no pain. In many cases the head may be restored to its normal position by passive movement or by voluntary effort, but it at once returns to its habitual position. Mikulicz asserts that torticollis is a chronic fibrous myositis, due often to compression during labor. He further says that the lesion known as hematoma of the sternomastoid, which occasionally follows labor, is not hematoma, but thickening due to myositis. D'Arcy Power reported the autopsy on a child one month of age. The sternomastoid muscle contained a fibrous mass, the result, Power believes, of a hemorrhage into the muscle prior to birth ("Med. Chir. Trans.," vol. lxxvi). Power, Clutton, and Owens have all traced cases of hematoma of the sternomastoid from early infancy to the time when tenotomy was required for torticollis. W. W. Richardson ("Surg., Gynec., and Obstet.," 1906) believes that interstitial myositis is always present, but doubts the causal influence of the lateral position of the head *in utero*. In some cases hereditary influence is evident. One woman gave birth successively to 7 wry-necked children (Nove-Jusserand and Vianny, in "Revue D'-Orthop.," 1906). Many writers advocate the ischemic theory as explanatory of the causation of torticollis. This theory is, that during labor lateral flexion of the head with elongation of the neck or lateral flexion with torsion produces occlusion of the sternomastoid branch of the superior thyroid artery, which vessel supplies the sternocleidomastoid muscle (see Tubby's "Orthop. Surgery"). In congenital torticollis the muscle and the cervical fascia are shortened, and the muscle does not relax under the influence of an anesthetic. In torticollis due to rheumatism and reflex causes the tonically contracted muscle relaxes when the patient is anesthetized. In spasmodic wry-neck the muscle is thrown repeatedly into clonic contractions.

Symptoms.—*Congenital* wry-neck is due to central nervous disease, to spinal deformity, or to injury during birth, and in this form the sternomastoid is shortened, hardened, and atrophied. It may not be noticed for some years because of the short neck of infancy. It is associated with asymmetrical development of the face, and is almost invariably upon the right side. *Spasmodic* wry-neck may present tonic spasm only, intermittent spasm alone, or both may appear alternately. It sometimes arises in those whose occupation demands frequent rotation of the head, but more often no such cause can be discovered. It is probably a disease of the cortical area which presides over rotation of the head. (See article by C. A. Hamann, in "Buffalo

Med. Jour.," Dec., 1901.) It is a disease especially of adults; in women it is often linked with hysteria. Pahl ("California State Med. Soc.," 1906) analyzed 68 reported cases. Men and women appeared equally liable, it was most frequent between the ages of twenty and thirty, and the right side was affected in twice as many cases as the left side. The exciting cause may be a cold, a blow, or a mental storm; the predisposing cause is the neurotic temperament. It may be due to enlarged glands, to carious teeth, or to eye-strain. In some rare cases bilateral spasm occurs, the head being pulled backward and the face being turned upward. Clonic spasms may come on unannounced, or they may be preceded by pain and stiffness; the head can be held still for a moment only; there is sometimes pain, always fatigue, but during sleep the contractions cease. The attack will probably pass away, but will almost certainly occur.

Treatment.—Congenital wry-neck is treated by myotenotomy through a superficial incision which is vertical or transverse (see page 732). The muscle is divided in a line parallel to and just above the clavicle or just below the mastoid attachment. The flaps are raised, access is free to the origin of the muscle, the muscle is readily divided, the wounds in the skin and fascia are closed. This incision leaves a trivial scar. After operation plaster of Paris is used to secure fixation and fixation is maintained from four to eight weeks. Early operation favors the establishment of muscular co-ordination before the development of permanent bony deformity of the vertebræ. Some surgeons cut the scalene muscles as well as the sternocleidomastoid. Gerdes Rowland lengthens the sternomastoid and carefully sutures it ("Practitioner," Sept., 1908). The old subcutaneous myotenotomy should be abandoned, as aseptic incision enables the surgeon to see and to feel all the contracted bands of fascia, muscle, and tendon, and to avoid vital structures (see page 732). In spasmodic wry-neck there is a fair chance of recovery. Pahl's table (Loc. cit.) shows that out of 68 cases, 28 recovered, 17 were improved, and 11 were not improved by treatment. Results in 12 were not stated. Treat the neurotic temperament and remove any obvious irritation (eye-strain, carious teeth, enlarged glands). Drugs usually are practically useless, although Chas. S. Potts reported a cure after the hypodermatic use of atropin. The rest cure is sometimes beneficial. Tenotomy is not to be employed. In 1890 Mayo Collier suggested ligation of the spinal accessory nerve with silver wire. In persistent cases stretch or divide and exsect a part of the spinal accessory nerve (Keen). To reach this nerve make an incision along the posterior edge of the sternocleidomastoid muscle, find the nerve as it emerges from under the middle of the muscle, about $1\frac{1}{2}$ inches below the tip of the mastoid process, retract the muscle at this point, and remove at least 1 inch of nerve. Neurectomy of the spinal accessory nerve paralyzes the sternocleidomastoid muscle, in spite of the fact that that muscle has also a nerve-supply from the cervical nerves. The paralysis is followed by atrophy, and if the spasm affected the sternomastoid muscle only the operation will cure the case. Unfortunately, other muscles are usually involved, and cure will only be obtained by performing neurectomy on the nerves which innervate the affected muscles. (For the treatment of rheumatic wry-neck, see Myalgia, page 712.)

Dupuytren's contraction is a contraction of the palmar fascia, of its digital prolongations, and of the fibers joining the fascia and skin. Fixed contraction of one or more fingers occurs (Fig. 469). The ring-finger and the little finger most often suffer, but any finger or the thumb may be involved. The condition may be symmetrical. It is far more common in men than in women. The disease arises oftenest in men beyond middle age, but is sometimes met with in youths. The **cause** of this disease is unknown; some refer it to gout, rheumatism, or osteo-arthritis; others, to traumatism, syphilis, organic

nervous diseases, arteriosclerosis, reflex irritation, or neuritis. In one-fourth of the cases heredity seems to be influential. If due to traumatism, the right hand should suffer most frequently; but it occurs in the left hand nearly as often as in the right (P. Jansen, in "Arch. f. klin. Chir.," Bd. lxvii, H. 4). Jansen examined specimens from 7 cases and found connective-tissue hypertrophy and circulatory disturbance, the contraction being a result of the above-named processes.

Fig. 469.—Dupuytren's contraction of the middle finger.

Symptoms.—Dupuytren's contraction is indicated by a small hard lump or crease which appears over the palmar surface of the metacarpophalangeal joint. This nodule grows and the corresponding finger is gradually pulled down. In some cases the tip of the finger is forced against the palm. The skin becomes dimpled or puckered.

Treatment.—Fibrolysin, which is a soluble combination of thiosinamin and salicylate of sodium, has been used hypodermatically in Dupuytren's contraction and, it is claimed, with success (Schwalbach). In treating Dupuytren's contraction subcutaneous multiple incisions may be made, the tense fascia and the fasciocutaneous fibers being cut. The finger is straightened and is placed upon a straight splint, which is worn continuously for a week or ten days and is worn at night for at least a month. A more satisfactory operation is that of Keen. He divides the skin by a V-shaped cut, the base of the V being downward, lifts up the flap, and dissects out the contracted tissue. A valuable method is that of McCurdy. He makes a long incision which crosses the contracture obliquely, stretches thoroughly, closes the wound, and keeps up mechanical fixation for a time. A cure is most certain to be obtained by Lexer's radical operation. This surgeon excises the entire aponeurosis and considerable portions of the palmar skin adherent to the aponeurosis.

Fig. 470.—Agnew's operation for webbed fingers (Pye).

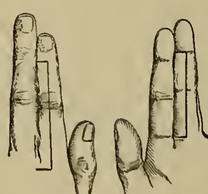

Fig. 471.—Diday's operation for webbed fingers (Pye).

In order to cover this wound it may be necessary to slide a pedunculated flap into the raw surface.

Syndactylism (webbed fingers) is always congenital, and may persist through several generations. Simple incision of the web is useless; the operation to be performed is that of Agnew or of Diday (Figs. 470, 471).

In Agnew's operation a flap of skin from the dorsum is inserted between the fingers and sutured in place.

In Diday's operation a flap is taken from the dorsal surface and another flap is raised from the palmar surface, and each flap is sutured to the finger to which it is attached.

Polydactylism (supernumerary digits) is always congenital, is often hereditary, and is usually symmetrical. There may be an incomplete digit, or there may be an entire and well-developed finger or toe with a metacarpal or metatarsal bone. The connection to the metacarpus or metatarsus may be by a fibrous pedicle only. If the digit is complete, with a metacarpal bone, no operation is required; if it is incomplete or is ill-developed, it should be removed.

Trigger-finger or Jerk-finger (Lock-finger, Snapping-finger).—The patient can usually close the fingers, but on trying to open them one finger remains closed. It can be opened by grasping it with the other hand, but flies open with a snap, like opening a knife (Abbe). In some cases two fingers are involved. In a reported case (Frederick Griffith, "Annals of Surgery," 1904) the ring and middle fingers of the left hand locked at the knuckle-joints on attempting flexion. The locking occurred when about one-third the amount of flexion necessary to grasp an object was achieved. By bending the fingers with the other hand unlocking was accomplished and flexion was finished voluntarily. In attempting extension blocking occurred at the same point and unlocking was accomplished in the same manner. In most cases, but not in all, there is pain when locking occurs. The condition is gradual in onset. Trigger-finger is often associated with rheumatism (in 52 cases out of 121, according to Necker). It is said by Tubby to be due to enlargement of the flexor tendon, or to contraction of the groove in the transverse ligament in the palm. It may be due to a ganglion, enchondroma, or tenosynovitis. Traumatism or irritation may produce it. The tendon-sheath may be thickened or, according to Marcano, there may be a nodule on the tendon which rubs against the sesamoid bone. It may result from occupation.

Treatment.—If a ganglion, a loose cartilage, or a tendon nodule exists, treat by excision. A sesamoid bone may be excised. If there is inflammation, use massage and counterirritation. If there is no obvious cause, put a compress over the tunnel in the ligament and apply a splint.

Mallet-finger.—This is called also *drop-finger* and *rupture of the extensor tendon.* It is due to a blow in the direction of flexion when the finger is extended. It is supposed to be due partly to stretching and partly to rupture of the extensor tendon at the point at which it is the posterior ligament of the distal interphalangeal joint. Abbe has shown that baseball players are liable to a condition which is the reverse of this, in which the last phalanx is dislocated backward. Drop-finger is treated by incision and suture of the tendon to the periosteum.

Genu valgum (knock-knee) results from an unnatural growth of the internal condyle, causing the shaft of the femur to curve inward and the internal lateral ligament of the knee-joint to stretch, the knees coming close together and the feet being widely separated. The condition may also be caused by curving of the tibial shaft just below the epiphysis. This deformity is usually noted when the child begins to walk, but it may not appear until puberty or even long after. Knock-knee may arise from rickets, from an occupation demanding prolonged standing, or from flat-foot. It may occur in one knee or in both knees.

Treatment.—Mild rachitic cases of knock-knee may remain in slight deformity, or may get well from improvement of the general health, though they seldom do. In an early case properly applied braces will correct deformity. In a later case operation will be necessary. In ordinary cases simply treat the

rickety condition. The patient is forbidden to stand or to walk, and the limb, after being put as straight as can be, is fixed on an external splint and a pad is put over the inner condyle. Later in the case plaster of Paris is used. Some surgeons prefer to immobilize while the leg is flexed to a right angle with the thigh. In a severe case the surgeon can immobilize after forcibly straightening (causing an epiphyseal separation) or after the performance of osteotomy (see page 688). Osteotomy is preferable to fracture by a mechanical appliance (osteoclasis).

Genu varum (bow-legs) is the opposite of knock-knee. It tends much more to self-correction than knock-knee because of the arrangement of the thigh muscles, the powerful adductors acting strongly on the knee and middle of the leg (J. Torrance Rugh, in "Am. Jour. Orthop. Surg.," April, 1908). Usually both legs are bowed *out*, the knees being widely separated, the tibiæ and femora, as a rule, being curved, and the feet being turned in. This disease in early life is due to rickets, the weight of the body producing the deformity. In older people incurable bow-legs may arise from arthritis deformans.

Fig. 472.—Club-hand.

Treatment.—Some mild cases of genu varum recover as a result of improvement in the health. Ordinary cases are treated by braces, by plaster-of-Paris bandages, and by attention to the general health. Braces usually suffice prior to three and a half years of age. Later, when the bones have hardened in severe deformity, osteotomy is necessary.

Club-hand (Fig. 472).—A congenital deformity in which the hand deviates from the normal relation to the forearm. It is usually associated with other deformities. In some cases the radius and possibly some of the carpal bones are absent.

Treatment.—By massage and passive motion, by immobilization, by tenotomy or osteotomy, or by bone-grafting.

Talipes (club-foot) is a permanent deviation of the foot into deformity. There are several forms: *talipes equinus* (Fig. 473) is a confirmed extension; *talipes calcaneus* (Fig. 474) is a confirmed flexion; *talipes varus* is a confirmed adduction and inversion, and *talipes valgus* is a confirmed abduction and eversion. Two of these forms may be combined, as in talipes equinovarus (Fig. 475), talipes equinovalgus, talipes calcaneovarus, and talipes calcaneovalgus. The **causes** of talipes are congenital or acquired. The congenital form is due to persistence of the fetal form of the foot. There are three theories of the cause of the deformity: viz., the nervous theory, the mechanical theory (intra-uterine pressure), and arrest of development. Acquired cases may arise from infantile paralysis, from spastic contractions, from cicatrices, from traumatisms, from arrest of bony growth following upon the inflammation of bone, or from hysterical contractures.

Talipes equinus is rarely congenital. In this condition the patient walks upon the toes and cannot bring the heel to the ground.

Talipes Calcaneus.—The patient walks upon the heel and cannot bring the toes to the ground. The true form is seen in congenital cases, the flexors of the foot being shortened and the tendo Achillis being lengthened.

Talipes varus is rarely met with without equinus. In this condition the patient walks on the outer edge of the foot.

Talipes valgus is met with in flat-foot. The patient walks on the inner edge of the foot.

Talipes Equinovarus.—The heel is raised and the patient walks upon the outer edge of the foot. This is the usual congenital form.

Talipes equinovalgus is very rarely congenital. The heel is raised and the patient walks upon the inner side of the foot.

Talipes calcaneovarus is a combination of calcaneus and varus.

Talipes calcaneovalgus is a combination of calcaneus and valgus.

Treatment.—In congenital cases the condition is usually manifest on both sides, and is nearly always talipes equinovarus. It is better that both sides should be affected, as the feet will then be symmetrical through life. Congenital club-foot should be treated in infancy, and when a restoration to position can be effected by the hands of the surgeon, is treated by plaster-of-Paris

Fig. 473.—Talipes equinis (Albert).

Fig. 474.—Talipes calcaneus (Albert).

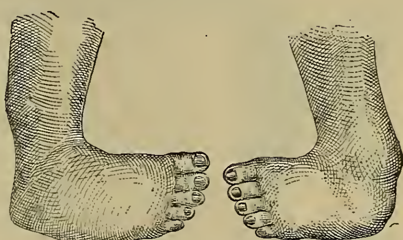

Fig. 475.—Double equinovarus ("American Text-Book of Surgery").

bandages. If a child has begun to walk, it may still be possible to correct the deformity eventually by manipulations, by plaster-of-Paris bandages, or by club-foot shoes, but most cases require tenotomy of the tendo Achillis before the application of the shoe or the plaster. The club-foot shoe may do good service, but in many instances it is painful and is not so efficient as plaster of Paris. In severe cases, before applying the plaster, the patient is given ether; the surgeon cuts the tendons of the anterior and posterior tibial muscles, the plantar fascia, the tendo Achillis, and the long flexor of the toes, in the order named, and forcibly corrects the deformity. In old cases, with alteration in the shape of the bones, cuneiform osteotomy, or the removal of the cuboid or other tarsal bones, may be indicated. In these cases Phelps advises an open transverse division of all rigid plantar soft parts. Buchanan employs subcutaneous division of all resistant structures. Occasionally, in relapsed and inveterate cases, *astragalectomy* is performed. It is seldom practised upon young children (see page 705). In some cases of talipes calcaneus shortening of the tendo Achillis is advised; but such an operation is only of temporary value, as stretching occurs after two years or more. In talipes due to infantile paralysis the operative treatment is the same, but we should not immobilize in plaster, but rather in some apparatus which can easily be removed to permit the use of massage and electricity. In paralytic cases tendon-transplantation is occasionally employed. This consists in transferring the tendon of an active

muscle so that it will take the place of the tendon of a paralyzed muscle. The transferred tendon should be always attached to the periosteum (Tubby and Jones on the "Surgery of Paralysis").

Pes planus (**flat-foot**) is a condition in which there is loss of the arch of the foot due to muscular paralysis or ligamentous weakness, to prolonged standing, or to trauma. Flat-foot is especially apt to occur in rickets. *Spurious flat-foot*, or *inflammatory flat-foot*, occurs in Pott's fracture and in inflammation of the ankle-joint or of the tendon of the peroneus longus muscle. *Paralytic flat-foot* is seen after infantile paralysis. *Static flat-foot* is due to disproportion between the body weight and the support of that weight. All children are born with pronated feet; the arch usually begins to form soon after birth, but in some individuals it never forms. Flat-foot, according to de Vlaccos, is thus produced: If we suppose a straight line prolonged downward from the center of the leg, most of the astragalus and os calcis will be external to it; hence the body weight presses on the inner side of the foot, and tends to flatten the arch and cause outward rotation, tendencies which are antagonized by the flexors of the toes and by the tibialis posticus muscle. The os calcis is pronated and is pushed to the side, the astragalus moves after the os calcis, and the ligaments are stretched ("Rev. de Chir.," Aug., 1901). A very common cause is contraction of the tendo Achillis. In childhood the condition is seldom recognized, but in an adult with contracted Achilles tendon long hours of standing will quickly precipitate the acute symptoms of flat-foot. Pes planus is productive of much pain upon standing or walking; in fact, the individual may be completely crippled. Pain is quickly relieved upon sitting down. Walking upon the toes is not painful. A marked flat-foot can at once be recognized by wetting the sole of the patient's foot with a colored fluid and causing him to step firmly upon a piece of paper (Fig. 476, B). Beginning flat-foot cannot be thus recognized and is frequently overlooked, the patient being treated for gout or rheumatism. Even a slight case can be detected by carefully observing the inner surface of the foot. When weight is placed upon it, it is seen to descend as the arch falls. A more accurate method is measurement, to find the middle of the foot. In flat-foot the extremity is lengthened. Golding-Bird points out that the middle of the normal foot is the point of articulation of the inner cuneiform and the metatarsal bone of the great toe. In flat-foot the greatest change is in the posterior half of this line. The extent to which the posterior measurement exceeds the anterior is the degree of flat-foot. The excess may reach $\frac{3}{4}$ inch.

A B

Fig. 476.—Print of a normal foot sole (A) and of a flat-foot sole (B) (Albert).

Treatment.—In *paralytic flat-foot*, which arises from infantile paralysis, employ exercise, electricity, and massage. To maintain a correct position of the ankle and to facilitate normal muscular action, apply suitable braces. In some cases of paralytic flat-foot it is advisable to permanently stiffen the ankle-joint by operation. Operation is not indicated before the twelfth year, because during the earlier years of life union will probably fail to occur. Goldthwait removes the cartilage from the articular surfaces of the astragalus, calcaneus, tibia, and malleoli, and seeks to obtain permanent bony ankylosis. In *static flat-foot* it has long been customary to advise rest in bed for two weeks, and then exercise for several hours a day to increase the arch. The usually recommended exercise has been to rise upon the toes and lower again and again, with the ankles turned outward. The patient rests for a time after each séance of exercise by sitting tailor-fashion with the legs crossed under him or by standing on the outer edges of the feet. Massage is ordered and a special shoe

is made to raise the arch of the foot. The shoe must fit the heel snugly and have a firm, broad heel. In some cases it is necessary to use a Thomas heel; in others, a steel shank. The patient's general health is, of course, attended to.

Many orthopedic surgeons have come to regard this usual treatment as unphilosophical and improper for many cases.

In static flat-foot it is essential to understand that a flat-foot may be a fully functionating foot, free from pain and disability, and, therefore, not a

Fig. 477.—H. Augustus Wilson's flat-foot correction screw.

subject for treatment. For convenience, flat-foot is divided into rigid and flexible. Either form may be from pain. The pain of flat-foot is usually the result of excessive use. It must be differentiated from Albert's disease (achillodynia), metatarsalgia, osteophytes on the under surface of the os calcis, and Raynaud's disease. Rigid flat-foot can be made flexible by manipulative measures (according to Whitman's method) or by the employment of H. Augustus Wilson's flat-foot correction screw (Fig. 477). This appa-

Fig. 478.—Whitman's plate to support the arch of the foot in flat-foot (Fowler's "Surgery").

ratus pulls down on the posterior part of the os calcis and the distal extremities of the metatarsal bones and pushes up beneath the tarsus. The force employed is very great and much care should be exercised when it is used upon a patient under anesthesia. It is preferable to use it without ether, relying upon the patient to state when the pressure becomes unendurable. A flexible flat-foot is capable of correction by exercises.

It was formerly customary to always prescribe various forms of steel plates

to correct the broken-down arch, but some orthopedic surgeons are discouraging their use, believing that they destroy the muscular control of the foot, and by weakening the foot render it susceptible to sprains and other injuries. It is my belief that steel plates should often be used, but never abused (Fig. 478). When plates are necessary because the patient is heavy or because he must continue a trying occupation, they must be fitted to the individual case and must be worn until such time as the use of exercise has enabled the patient to properly maintain the body weight with the strengthened arches. If the tendo Achillis is shortened it must be lengthened by operation or else the heel of the shoe must be raised to permit the fullest range of dorsal flexion the tendon allows. When muscle tone is low and there is small chance of restoring it, H. A. Wilson ("Amer. Medicine," May 6, 1905, page 725) advocates the employment of the method devised by Professor Müller ("Central. f. Chir.," January 10, 1903, page 40) for paralytic valgus. It consists of an arthrodesis of the astragaloscaphoid joint, and transplantation of the tendon of the extensor proprius hallucis into a hole drilled free from above downward through the scaphoid. Fixation in plaster of Paris in an overcorrected position is maintained for four weeks and then corrective exercises are employed. The anterior tibial tendon is supplemented in its action by the transplanted tendon.

Gleich shortens the foot and raises the arch by sawing through the os calcis and fastening the posterior part of this bone at a lower level. Trendelenburg advises supramalleolar osteotomy. This operation permits of adduction, and the adducted foot should be put up in an immovable dressing of plaster of Paris. Ogston resects the astragaloscaphoid joint. Golding-Bird and Davy remove the scaphoid bone. Stokes removes a wedge-shaped piece from the head and neck of the astragalus. Rugh has taken a wedge-shaped piece of bone from the inner side and inserted it in the outer side.

Pes cavus (hollow foot) is an increase in the arch of the foot, due, possibly, according to Golding-Bird, to paralysis of the peronei muscles. When the peronei muscles are paralyzed the adductors act unopposed, and secondary contraction of the plantar fascia occurs. Certain it is that a contracted plantar fascia is the chief obstacle to correction. In many cases the cause is the wearing of shoes which are too short for the feet. The pressure made upon the toes causes spasm of the plantar flexors and this spasm permits the fascia to contract.

Treatment.—A shoe is worn containing a plate of steel in the sole, and pressure is applied over the instep. Tenotomy, division of the plantar fascia, or excision of bone may be required. In paralytic cases apply electricity and massage to the paralyzed muscles. Transplantation of the tendons of the dorsal flexors into the ends of the metatarsal bones has proved very satisfactory.

Hallus valgus or **varus,** a displacement of the great toe outward or inward, may occur in the young, but it is most frequent in old persons, especially old women. It arises often from wearing pointed shoes, shoes that are too short, or high heels, but may be due to gout or to rheumatic gout. In many cases an exostosis forms in the inner portion of the distal end of the metatarsal bone. In hallux valgus a *bunion* (bursa) is apt to form over the metatarsophalangeal joint and it may inflame or ulcerate.

Treatment.—An arrangement may be worn to straighten the toe and to protect the bunion (see Fig. 464). The prominent and hypertrophied inner portion of the head of the metatarsal bone may be removed by means of a chisel, osteotomy may be performed upon the metatarsal bone, the joint may be excised, or amputation may be required. H. A. Wilson advocates lateral excision. By means of bone-forceps he cuts away that part of the distal extremity beyond the phalanx, and by a chisel removes the remaining

sharp line edge. He places the phalanx in normal position and holds it so for two weeks ("Am. Jour. Orthopedic Surgery," Jan., 1906). Mayo's operation is described on page 732.

Hammer-toe (Figs. 479 and 480) is a condition in which there is flexion of one or more toes at the first interphalangeal joint. Shattuck shows that this condition is due to contraction of "the plantar fibers of the lateral ligaments of the joint."[1] This disease usually begins in youth and may be congenital. A bunion is apt to form, and the joint may become dislocated.

Treatment.—Subcutaneous division of the lateral ligaments and flexor tendon usually allow of straightening of the toe. After the operation the toe must be held in extension for several months by means of a short splint and adhesive plaster. Terrier's plan of treatment consists in making a dorsal flap, removing a bursa if one is found, dividing the extensor tendon, opening the articulation, removing each articular surface by cutting forceps, suturing the soft parts, and applying a plantar splint for two weeks.[2] Some surgeons simply excise the joint. In some cases amputation of the toe is the best treatment.

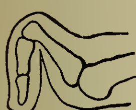

Fig. 479.—Hammer-toe.

Fig. 480.—*X*-ray of hammer-toe.

Metatarsalgia (Morton's Disease).—This disease was first described by Dr. Thomas G. Morton, of Philadelphia, in 1876. It is a painful condition of the foot, due to jamming of a nerve between the heads of the fourth and fifth metatarsal bones. The head of the fifth metatarsal bone is, by lateral pressure, forced against and below the neck of the fourth metatarsal, and as a result the superficial branch of the external plantar nerve and its two digital branches are squeezed. It is usually associated with flat-foot. Loss of the metatarsal arch will jam other nerves than that between the fourth and fifth metatarsals, and will produce a condition similar to Morton's disease, the pain being differently situated. Pain, in Morton's disease, is produced by walking, and the suffering may be so severe that the patient is obliged to sit down at once. When the shoe is removed and the foot is rested the pain soon abates. The pain is felt on the outer and inner sides of the little toe, the outer side of the fourth toe, and about the head of the fifth and the neck of the fourth metatarsal bones. Pain can be developed by grasping the foot in the hand and squeezing it. If flat-foot exists, there is also pain due to this trouble.

Treatment.—Mild cases may be cured by wearing well-fitting shoes and employing massage. The shoe should have a small elevation in the sole to restore the metatarsal arch and so relieve lateral pressure on the nerve. Some cases require a brace. Severe cases demand resection of the fourth metatarsophalangeal joint, or amputation of the fourth toe, and with it the head of the fourth metatarsal bone. Graham, of Washington, has cured cases by excising a portion of the superficial branch of the external plantar nerve.

Coxa Vara and Coxa Valga.—Coxa vara (*incurvation* or *infraction of the neck of the femur*) (Fig. 481) is a disease characterized by bending of the neck of the femur, the femoral neck being depressed below its normal obtuse angle with

[1] "American Text-Book of Surgery."
[2] "Rev. de Chir.," July, 1895.

the shaft, the hip-joint being perfectly healthy, and the condition, as a rule, being unilateral, but sometimes bilateral. This condition was described by Müller in 1889. Coxa vara is first noticed, as a rule, between the thirteenth and twentieth years, and the commonly accepted view has been that the deformity is rachitic, but Kredel has reported 2 congenital cases.[1] Traumatic coxa vara may follow impacted fracture of the neck of the femur in a child. An individual with coxa vara develops a limp, and grows tired after slight exertion, but there is no swelling, no tenderness, and little or no pain. Shortening after a time becomes apparent, the great trochanter can be detected above Nélaton's line, and the head of the bone is in the acetabulum. If the head is in the acetabulum it can be recognized as being there by locating the femoral artery $\frac{1}{2}$ inch below Poupart's ligament and making pressure directly backward at that point. The head, if in place, will be felt. The extremity is adducted and usually rotated outward. Abduction is limited. In some cases in which there is joint irritation all joint motions may be distinctly limited.

Fig. 481.—Congenital dislocation of the hip on one side and coxa vara on the other.

In a bilateral case there is lordosis, but shortening may not be detected because both legs are the same length. Each great trochanter, however, is above Nélaton's line and the head of each bone is in the acetabulum.

Coxa valga is a condition in which the angle of the neck to the shaft of the femur is more obtuse than normal. The neck may assume a position in line with the long axis of the shaft. It occurs particularly in children who have had infantile palsy, but it may be congenital, may occur in rickets and osteomalacia, and after a prolonged period of disuse of a limb. The patient has pain and a limp, the extremity is lengthened, abducted, and in external rotation there is limitation of adduction and the trochanter is flattened. Coxa valga is usually unilateral, but may be bilateral.

Without the *x*-rays the differential diagnosis in coxa vara and coxa valga is often very difficult, and the accompanying table will materially aid in contrasting the conspicuous features of the various conditions with which these two deformities of the neck of the femur may be confounded:

[1] "Centralbl. f. Chir.," Oct. 17, 1896.

	Hip Disease.	Infantile Paralysis.	Congenital Dislocation.	Psoas Abscess.	Coxa Vara or Valga.	Knee Disease.
Age.	Four to six.	Four to six.	Any age.	Four to six.	Any age.	Four to six.
Onset.	Insidious.	Sudden.	From birth.	Insidious.	Childhood.	Insidious.
Pain.	Referred to knee.	None.	None.	Referred to abdomen.	None.	Referred from knee.
History.	Tuberculous.	Inflammatory disease.	Limp from birth.	Tuberculous.	Limp.	Tuberculous.
Posture.	Flexion, abduction, external rotation.	Uncontrolled.	Shortening and adduction.	Flexion, adduction, external rotation.	Great trochanter higher in vara and lower in valga.	Knee flexed.
Muscular rigidity.	Present in all directions.	Absent.	Absent.	In one direction.	None.	About knee.
Temperature.	1 degree high.	Normal.	Normal.	1 degree.	Normal.	1 degree.
Local tenderness.	In hip.	None.	None.	In spine.	None.	In knee.
Night cries.	Present.	Absent.	Absent.	Present.	Absent.	Present.
Tendency to abscess.	Yes.	No.	No.	Yes.	No.	Yes.
X-ray.	Diseased focus in hip.	Atrophy.	Alteration in joint.	Normal hip.	Alteration in neck angle.	Normal hip, focus in knee.

The *x*-rays clearly show the deformed bone in either coxa vara or coxa valga.

Treatment.—In coxa vara, as long as bending is progressing, employ rest. When the bone hardens, it may be necessary to perform osteotomy below the trochanters. In coxa valga Galeazzi performs osteotomy through the neck of the femur and allows the trochanter to ascend.

Flail-joints.—After an attack of infantile paralysis involving the entire lower extremity of each side the limbs become limp and swing flail-like when the extremity is made to move, and the joints are much relaxed. In such cases the psoas and iliacus muscles are never completely paralyzed, and the aim of the surgeon is to utilize these muscles in enabling the patient to walk. In many cases the application of apparatus is sufficient. In others ankylosis may be established in the ankles and knees by operation. If ankylosis is established in these joints, the psoas and iliacus muscles become able to move the legs. (For more elaborate discussion, see a work on Orthopedic Surgery, and Tubby and Jones on the "Surgery of Paralysis.")

XXIII. DISEASES AND INJURIES OF NERVES

Diseases of Nerves

Neuritis, or inflammation of a nerve, may be limited or be widely distributed (*multiple neuritis*). The first-mentioned form will here be considered. The causes of neuritis are traumatism, wounds, overaction of muscles, gout, rheumatism, syphilis, fevers, and alcoholism.

The **symptoms** of neuritis are as follows: excessive pain, usually intermittent, in the area of nerve-distribution. The pain is worse at night, is aggravated by motion and pressure, and occasionally diffuses to adjacent nerve-areas or awakens sympathetic pains in the opposite side of the body. The nerve is very tender. The area of nerve-distribution feels numb and is often swollen. Early in the case the skin is hyperesthetic; later it may become anesthetic. The muscles atrophy and present the reactions of degeneration; that is, the muscles first cease to respond to a *rapidly* interrupted faradic current, and next to one with slower interruptions; faradic excitability diminishes, but galvanic excitability increases. When, in neuritis, faradism produces no contraction, a slowly interrupted galvanic current which is so weak that it would produce no movement in the healthy muscle causes marked response in the degenerated muscle. In health the most

vigorous contraction is obtained by closing with the − pole; in degenerated muscles the most vigorous contraction is obtained by closing with the + pole. When voluntary power returns, galvanic excitability declines; but power is often nearly restored before faradic excitability becomes manifest (Buzzard).

The **treatment** of neuritis consists of rest upon splints and the use of an ice-bag early in the case and a hot-water bag later. Blisters over the course of the nerve are of value, especially in traumatic neuritis. Massage and electricity must be used to antagonize degeneration. A descending galvanic current allays pain to some extent. Deep injections of chloroform or cocain may allay pain. Treat the patient's general health, especially any constitutional disease or causative diathesis. The salicylate of ammonium or phenacetin may be given internally. In some cases nerve-stretching is advisable.

Neuralgia is manifested by violent paroxysmal pain in the trajectory of a nerve. This disease, unless it is exceedingly severe and persistent, is treated, as a rule, by the physician. Injections of alcohol or osmic acid into the nerve may secure relief or cure. If neuralgia is due to adhesions about the nerve or to the pressure of scar or callus, these conditions should be amended surgically. There is some evidence that neuralgia arises, at least occasionally, from dilatation of the vessels of the sheath and subsequent edema and exudation. If this be the case cure may follow opening the sheath and separating adhesions between the sheath and nerve (Robert M. Simon, in "Brit. Med. Jour.," April 10, 1909). Neuralgia of stumps and scars is a surgical condition, and is due to neuromata, or entanglement of nerve-filaments in a cicatrix. *Tic douloureux* and other intractable neuralgias require careful removal of any cause of reflex irritation. Causal reflex irritation may arise from disease of the stomach, eyes, teeth, uterus, nose, throat, etc. Tic douloureux has been treated by removal of the Gasserian ganglion; intracranial neurectomy of the second and third divisions; division of the sensory root; removal of Meckel's ganglion; ligation of the common carotid artery; neurectomy of terminal branches of the fifth nerve; division of motor nerves; injections of osmic acid (see page 762); injections of alcohol (see page 763); advancing doses of strychnin (Dana) and purgatives (Esmarch). The distribution of the fifth nerve, the seat of pain in tic douloureux, is shown in Fig. 482.

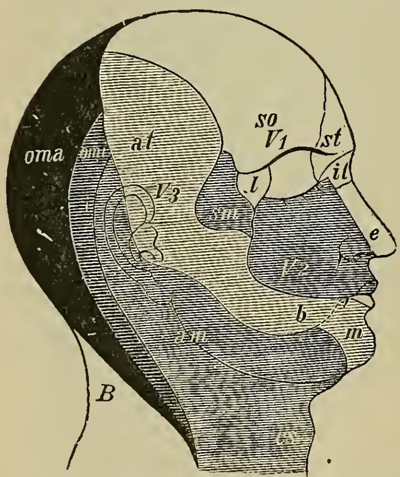

Fig. 482.—Distribution of the cutaneous sensitive nerves upon the head: *oma, omi,* The occipit. maj. and minor (from the N. cervical. II and III); *am,* N. auricular magn. (from N. cervic. III); *cs,* N. cervical. superfic. (from N. cervic. III); V_1, first branch of the fifth (*so,* N. supraorbit.; *st.* N. supratrochl.; N. infratrochl.; *e,* N. ethmoid.; *l,* N. lachrymal.); V_2, second branch of the fifth (*sm,* N. subcutan. malæ seu zygomaticus); V_3, third branch of the fifth (*at,* N. auriculotempor.; *b,* N. buccinator; *m,* N. mental.); *B,* posterior branches of the cervical nerves (Seeligmüller).

Treatment of Neuralgia of Stumps.—Excise the scar; find the bulbous end of the nerve and cut it off. Senn tells us to section the nerve by V-shaped cuts, the apex of the V being toward the body, and to suture the flaps together. Senn's method will prevent recurrence. In some cases reamputation is performed. In entanglement of a nerve in a scar remove a portion of the nerve above the scar and also the neuroma in the scar.

Wounds and Injuries of Nerves

Section of Nerves (as from an incised wound).—After nerve-section sensation and motor power are lost at once. The entire peripheral portion of the nerve degenerates and ceases structurally to be a nerve in a few weeks, but after many months, or even years, the nerve may regenerate. The proximal end degenerates only in the portion immediately adjacent to the section; it rapidly regenerates, and if it does not adhere to the peripheral segment a bulb or enlargement composed of fibrous tissue and small nerve-fibers forms just above the line of section; this bulb adheres to the perineural tissues. The entire distal end degenerates, but new axis-cylinders form in this segment by proliferation of the nuclei on the sheath of Schwann. Union of a divided nerve is brought about by the projection of axis-cylinders from the proximal end or from each end and the fusion of these cylinders. The nearer the two ends are to each other, the better the chance of union. When a nerve has been divided and has not been sutured, abolition of function may be permanent or restoration may occur. Sensation may return in from six weeks to several months. Motor power may never return. If it does return it will do so long after sensory restoration. Restoration of motor power requires from twelve weeks to three and one-half years. It is seldom noted before six months. The return is always slow (John B. Murphy, in "Surg., Gynec., and Obstet.," April, 1907). Failure of return means that the ends are separated by a wide interval or that fascia is interfused between them. In some recorded cases motion and sensation have returned with great rapidity, due, some have said, to anastomoses with adjacent nerves. Murphy shows that when restoration begins, trophic energy returns even before sensation, and when trophic energy returns the blueness and coldness of the limb lessen.

The nerve-fibers which convey impressions of cutaneous pain and of extreme heat and cold regenerate far more rapidly than those which subserve sensations of light touch and slight degrees of heat and cold.

The investigations of Head and others show that restoration of sensation does not begin at the normal area and spread from there over the anesthetic area, but that the reverse is the case. It begins from the confines of the anesthetic area and spreads toward the normal part.

General Symptoms.—Immediately after nerve-section vasomotor paralysis comes on, and for a few days the paralyzed part presents a temperature higher than normal. It then becomes blue and cold. Pronounced changes occur in the trajectory of a divided nerve. The muscles degenerate, atrophy and shorten, and develop the reactions of degeneration. When union of the nerve occurs the muscles are restored to a normal condition. If the nerve contains sensory fibers, complete anesthesia (to touch, pain, and temperature) usually follows its division; but if a part is supplied by another nerve as well as by the divided one, anesthesia will not be complete. Trophic changes arise in the paralyzed parts. Among these changes are muscular atrophy; glossy skin; cutaneous eruptions; ulcers; dry gangrene; painless felons; falling of the hair; brittleness, furrowing, or casting off of the nails; joint inflammations, and anklylosis. The diagnosis as to which nerve is cut depends upon a study of the distribution of motor and sensory paralysis.

A curious fact that was pointed out by Letiévant is that after division of a nerve blunt pressure may be appreciated over the entire analgesic area. This phenomenon was long thought to be due to nerve anastomoses, the sensory areas from different nerves overlapping. The explanation now given is founded on Sherrington's demonstration that the motor branches of a mixed nerve carry sensory fibers through muscles and tendons, and Head's proof that certain afferent fibers convey impressions of deep sensibility as produced by pressure.

The Symptoms of Division of Nerves.—*Brachial Plexus.*—If one or more cords of the brachial plexus are divided, motor paralysis and anesthesia appear in the limb, the extent of the paralysis and the area of the anesthesia depending upon the cord or cords involved. It should be remembered that the inner cord of the brachial plexus gives origin to the ulnar nerve; the inner and outer cords give branches which fuse to form the median nerve. The posterior cord gives origin to the subscapular, the circumflex, and the musculospiral nerves. The outer cord gives origin to the external anterior thoracic and the musculocutaneous, as well as to the outer trunk of origin of the median.

Avulsion or *rupture of the brachial plexus* is sometimes effected by an injury, when the arm is not lost. Most cases are due to indirect violence and are associated with skeletal injury, for instance, dislocation of the shoulder, fracture of the humerus, or fracture of the clavicle (Frazier and Skillern, paper before Section on Surgery, "Amer. Med. Assoc.," 1911). Bristow ("Annals of Surgery," Sept., 1902) reported 3 cases of avulsion of the plexus and collected 24 more. Frazier and Skillern (Loc. cit.) collected 23 cases of avulsion without skeletal injuries and confirmed by operation. In each of these cases the rupture was between the clavicle and the transverse process of the vertebra. In the case of Frazier and Skillern the rupture was within the dura. The patient was seen by them three months after the accident. He suffered from horrible pain in the arm and hand. Sensations to touch and pain were entirely lost in the hand and forearm and in the arm to 2 or 3 inches above the elbow. From this point to about 4 inches below the shoulder they were much impaired. Sensation was impaired in the entire distribution of the intercostohumeral nerve, and of the fifth and sixth cervical roots, as well as in the distribution of the brachial plexus. There was flaccid palsy of the entire extremity, including the deltoid. On the injured side the pupil was contracted and the palpebral fissure narrowed. One of Bristow's cases was operated upon the third day after the accident (Loc. cit.). In this case there was complete paralysis of the upper extremity, with the exception of the sensory area of the intercostohumeral and the circumflex nerves. The accident had been inflicted by the patient's forearm becoming entangled in a rope, which was pulled upon by a steam winch. On reaching the hospital he felt severe pain, referred to the arm. There was much swelling in the inner portion of the subclavian triangle, the left pupil was contracted, and it seemed likely that the nerves had been avulsed close to the intervertebral foramina. From the fact that sensation was preserved in the skin of the convexity of the shoulder down to the insertion of the deltoid, Bristow concluded that some fibers of the posterior cord of the plexus had escaped division; but when the operation was performed this conclusion was found to be erroneous. An incision was made, and it was found that the plexus had given way at the point where the four cervical nerves and the last dorsal unite to form the three trunks. In order to reach the lower ends it was necessary to saw the clavicle and divide the two pectoral muscles; and the torn ends of the nerve-trunks were found underneath the clavicle. Suturing was performed. The ends of the sawn clavicle were sutured together, the wound was closed and dressed, and the arm was put up in Sayre's dressing.

After the performance of this operation sensation over the entire upper arm returned. The author once operated upon a patient that had developed paralysis, motor and sensory, after violent stretching of the arm. In the light of Bristow's case I assumed that avulsion of the plexus had probably taken place. Incision disclosed the fact that the plexus was intact, but was surrounded with dense scar-tissue. The tissue was removed, so as to loosen the nerves, which felt like hard cords; but I have lost track of the patient, and do not know the result. My patient was operated upon many months after the injury.

I operated upon another case and found intravertebral rupture. I anastomosed two divided nerves to a sound one. The operation was done months after the injury and the patient is apparently slightly improved three months after operation. The location of the seat of injury is of great importance. Lesion within the vertebræ is positively indicated by contraction of the pupil, narrowing of the palpebral fissure, and enophthalmos on the affected side (Frazier and Skillern, "Amer. Med. Assoc.," 1911), but there can be intravertebral injury without these phenomena. The ciliospinal fibers on which these phenomena depend usually accompany the eighth cervical and first thoracic nerves.

Injury above the clavicle will involve the circumflex and musculospiral. As the great pectoral is supplied from both the external and internal cords of the plexus, complete paralysis of the great pectoral proves that both cords are involved, and unimpaired movements of the diaphragm on the side of the lesion (observed with the fluoroscope) show that the cords of the plexus are not divided within the foramina, but well outside of them (John B. Murphy, in "Surg., Gynec., and Obstet.," April, 1907). In all cases of rupture prompt operation is indicated. Long delay means a hopeless prognosis.

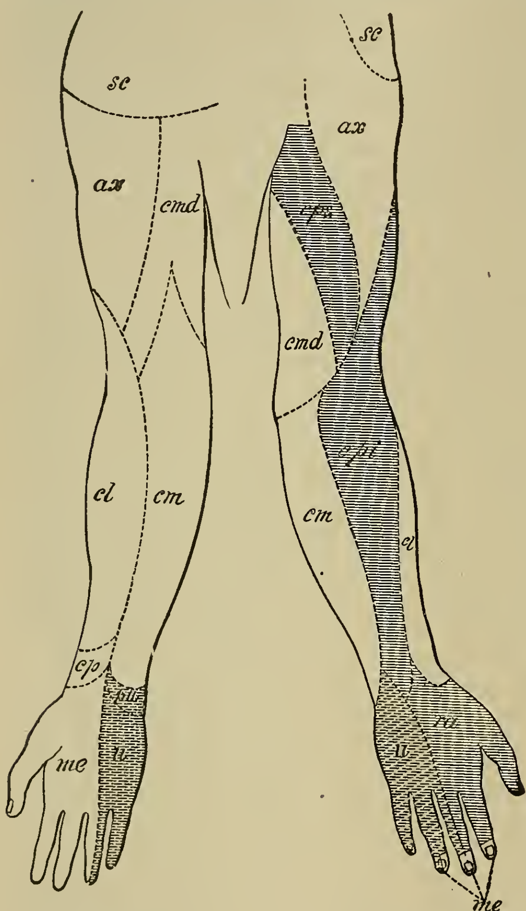
In injury without complete rupture the nerves become fibrous and embedded in scar-tissue. If operation is done before scar-tissue forms follow the advice of Frazier and incise the sheaths of the trunks or cords to liberate inflammatory exudate. If scar-tissue has formed, excise it. It may be necessary to excise portions of nerves or trunks with it. If this is done, suture the divided ends together. It may be necessary to do nerve-lengthening, suture à distance, or grafting in of a nerve from a recently amputated limb (if one can be obtained), or the sciatic of a rabbit. In accessible rupture suture the divided nerves. In some cases a divided cord or trunk may be anastomosed into a sound one. Ruptures near to, in, or within the intervertebral foramina do not admit of suturing. If a sound nerve is left the divided nerve or nerves should be anastomosed to it. If the entire plexus is ruptured we should consider the plan of Alexinsky (quoted by Frazier and Skillern, Loc. cit.): effect anastomosis between nerves of the injured side and nerves of the sound side. When intractable neuralgia follows rupture the posterior roots may be divided.

Brachial Birth Palsy.—It has been pointed out by Clark, Taylor, and Prout ("Am. Jour. Med. Sciences," Oct., 1905) that brachial birth palsy results from tension on the nerve-trunks by overstretching during delivery, the nerve-sheath first rupturing and then the nerve-fibers.. When the sheath ruptures hemorrhage occurs, fibrous tissue forms, and the scar presses on the intact, slightly stretched, or actually lacerated nerve, and prevents repair. The authors tell us that the fifth cervical root first gives way, then the sixth, and so on down the plexus if there is sufficient force. In the milder cases the fifth root alone suffers. They call it brachial birth palsy, or *laceration palsy*, and sum up the symptoms in a severe case as follows: The arm hangs powerless; abduction at the shoulder is impossible because of deltoid and supraspinatus palsy; the forearm is extended and flexion is impossible because of biceps, brachialis anticus, and supinator longus palsy; palsy of supinator brevis and biceps causes pronation of hand; there is inward rotation of the humerus because of palsy of the supraspinatus, infraspinatus, and teres minor.

Brachial birth palsy is manifest soon after its infliction by evidences of pain on handling the extremity, the pain being due to neuritis (authors above quoted). Medical treatment is relied on for one year, and then, if improvement is not manifest, operation is indicated (see page 769).

Posterior (Long) Thoracic Nerve.—Division of this nerve causes paralysis of the serratus magnus muscle, which is made evident by eversion from the thorax and rotation of the scapula when the arm is taken forward (*wing-like scapula*). In paralysis of this muscle the arm cannot be raised above the horizontal.

Suprascapular Nerve.—Division of this nerve produces some anesthesia over the scapula and paralysis of the supraspinatus and the infraspinatus muscles. The supraspinatus is but an adjuvant to the deltoid and palsy of it is not manifestly disabling. Palsy of the infraspinatus renders external rotation of the humerus impossible, and writing becomes most difficult because the pen cannot be moved along the paper. Sewing, too, is greatly interfered with.



Anterior surface. Posterior surface.

Fig. 483.—Distribution of the cutaneous nerves to the shoulder, arm, and hand. The region of the N. radialis is represented by the unbroken hatched line, that of the N. ulnaris by the broken hatched lines. *a*, Anterior, *b*, posterior surface; *sc*, Nn. suprascapular (plexus cervicalis); *ax*, chief branch of N. axillar.; *cps*, *cpi*, Nn. cutanei post. sup. and inf. (from N. radialis); *ra*, terminal branches of N. radialis; *cm*, *cl*, Nn. cutanei medius (also to the plexus) and lateralis (chiefly to the N. medianus); *cp*, N. cutan. palmar., N. rad.; *cmd*, N. cutan. medialis; *me*, N. medianus; *u*, N. ulnaris; *cpu*, N. cutan. palm. ulnaris (Henle).

Circumflex Nerve.—Division of the circumflex nerve produces paralysis of the deltoid muscle, so that it becomes impossible to lift the arm to a right angle with the body. There is some slight retention of power in the anterior fibers, which are supplied by the anterior thoracic nerve. The skin over the lower part of the muscle is usually anesthetic.

Musculocutaneous Nerve.—Division of this nerve produces paralysis of the biceps and of the brachialis anticus muscles (paralysis of the forearm flexors). This palsy becomes especially evident when the forearm is supinated, because in this position the supinator longus can no longer act as a flexor of the elbow. There is anesthesia of the radial side of the forearm anteriorly and posteriorly.

The Musculospiral or Radial Nerve.—Division of this nerve high up near the plexus causes paralysis of the extensor muscles of the elbow and the wrist, of the supinators, and of the long extensors of the thumb and fingers. When divided near the middle of the humerus, the triceps usually, but not invariably, escapes. If the injury is below the branch going to the supinator longus, that muscle will escape; otherwise it will become paralyzed. The extensor palsy causes wrist-drop and loss of the power of extending the first phalanges of the fingers and thumb; and, as Gowers has pointed out, flexion is reduced to one-third of the normal, the flexors having lost power "from the loss of antergic support." As a rule, in musculospiral palsy there is loss

of supination. Sensibility is sometimes greatly affected, and sometimes very slightly. If the injury is above the level of the musculospiral groove there will be anesthesia in the area supplied by the sensory fibers of the nerve (Fig. 483). If the nerve is injured in the musculospiral groove there are seldom sensory disturbances. Anesthesia rarely occurs in the upper arm in any case, and even after an injury in the groove sensation in the hand may be normal or nearly so. Fig. 484 shows the position of the parts in musculospiral palsy and Figs. 483 and 485 the sensory distribution of the nerve. Fracture of the humerus may cause division of the musculospiral nerve.

The Median Nerve.—After division of this nerve there is paralysis of the pronators; the flexor carpi radialis; the finger flexors, except the ulnar portion of the deep flexor; the abductors, and the flexors of the thumb; and the two radial lumbricales. The forearm can be placed in a position midway between pronation and supination; but further pronation cannot be voluntarily effected. In executing flexion of the wrist a strong deviation toward the ulnar side takes place. The thumb is in a position of extension and abduction, and cannot be brought into apposition with the finger-tips. The second phalanges of the fingers cannot be flexed on the first, and the distal phalanges

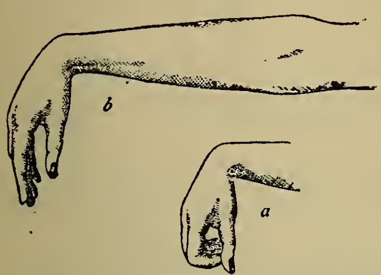


Fig. 484.—Paralysis of musculospiral nerve after fracture of the humerus ("wrist-drop"); but when fingers have been flexed into palm, *a*, they can be extended, *b*, at first interphalangeal joints by lumbricals and interossei, which are supplied by the ulnar and median nerves (Erichsen).

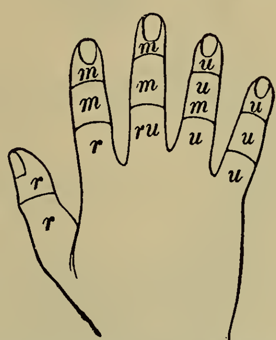

Fig. 485.—Distribution of sensory nerves on the backs of the fingers: *r*, Musculospiral or radial nerve; *u*, ulnar nerve; *m*, median nerve (Krause).

of the first and second fingers cannot be voluntarily flexed. The corresponding phalanges of the third and fourth fingers can be flexed, this being accomplished by the unparalyzed ulnar half of the deep flexor. Flexion of the first phalanges is still possible, as it is accomplished by means of the interossei. The extensor action of the interossei muscles upon the middle and distal phalanges, being unopposed, may eventually cause subluxation. The sensory distribution of the median nerve is shown in Figs. 483 and 485–487. It is the sensory nerve of the radial side of the palm, the front of the thumb, the first and second fingers and half of the third finger, and the back of the last phalanx of the index and the middle finger (Gowers). The sensory changes after median paralysis are quite variable—sometimes widespread and complete, at other times trivial, and occasionally absent. Gowers says that if there is anesthesia it is usually of the palmar surface, but it may also occur on the dorsal aspect of the ends of the first two fingers.

The Ulnar Nerve.—When this nerve is divided there is paralysis of the flexor carpi ulnaris, of the ulnar portion of the deep flexor, of the muscles of the little finger, of the abductor pollicis, and of the inner end of the flexor brevis pollicis (Gowers). It becomes impossible to adduct the thumb, and the majority of the movements of the little finger are abolished. Flexion of

the fingers is impossible at the first joints, and extension is impossible at the other joints; but, as Gowers points out, the loss is slighter in the first two

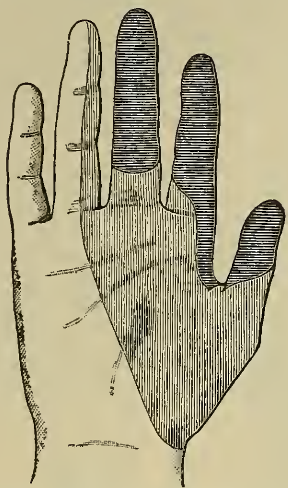

Fig. 486.—Section of median nerve; areas of anesthesia (heavy shading) and of dysesthesia (light shading) on palmar surface of hand (Bowlby).

fingers than in the others because the lumbricales of the first two fingers are supplied by the median nerve. Interosseal flexion is impossible, and the op-

ponents of the interossei, acting without normal antagonism, contract and produce what is known as *claw-hand* (Figs. 488, 489), a condition in which the

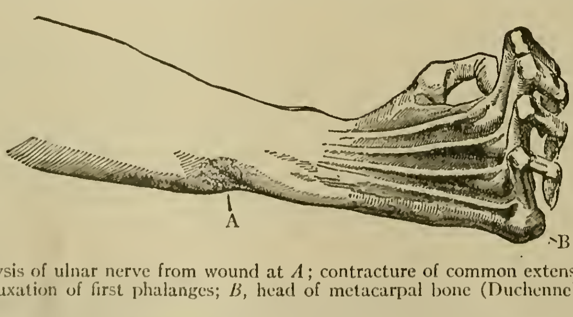

Fig. 489.—Paralysis of ulnar nerve from wound at *A*; contracture of common extensor with posterior luxation of first phalanges; *B*, head of metacarpal bone (Duchenne).

first phalanges are overextended and the others are flexed. The sensory loss in ulnar paralysis is extremely variable. The sensory distribution is

to the ulnar side of the hand, both back and front, involving the little finger, the ring-finger, and the ulnar half of the middle finger (Figs. 483, 485, 490, and 491).

The *lumbar plexus* supplies the cutaneous surface of the lower portion of the abdomen, of the front and the sides of the thigh, and of the inner portion of the leg and foot (Fig. 492). It innervates the flexors and adductors of the hip-joint, the extensors of the knee, and the cremaster muscle. The branches sent to the leg are the obturator and the anterior crural nerves.

The *sacral plexus* supplies the extensors and rotators of the hip, the knee-flexors, and all the muscles of the foot; also the skin of the gluteal region, the back of the thigh, the outer portion and the posterior part of the lower leg, and most of the foot (Gowers) (Fig. 492). Its chief branches are those to the external rotators of the hip—the gluteal nerve, the small sciatic, and the great sciatic.

The Anterior Crural Nerve.—When this nerve is divided the extensor muscles of the knee are paralyzed. The psoas muscle is not affected, even if

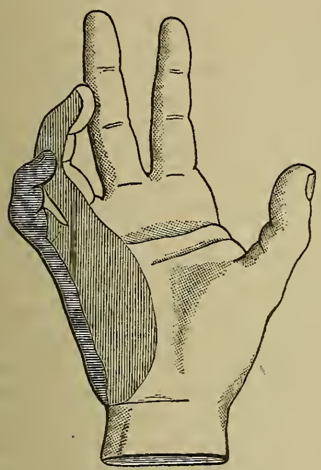

Fig. 490.

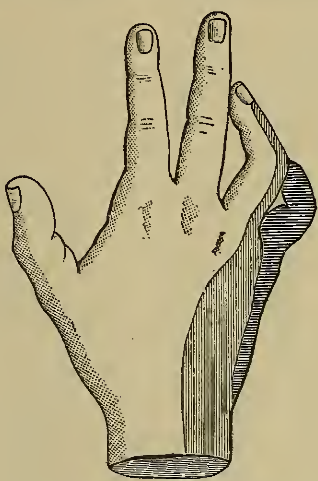

Fig. 491.

Figs. 490, 491.—Showing sensory loss and ordinary position in injuries of the ulnar nerve (Bowlby).

the nerve is divided within the abdomen; but high division may produce paralysis of the iliacus muscle. In anterior crural palsy the skin is anesthetic over almost the entire thigh, the inner surface of the leg and foot, and the inner sides of the first and second toes (Fig. 492).

The Obturator Nerve.—In obturator palsy the adductor muscles of the thigh are paralyzed, and, in consequence, the patient is unable to cross one leg over the other. Gowers points out that external rotation of the thigh is also interfered with.

The Superior Gluteal Nerve.—The division of this nerve paralyzes the gluteus medius and the gluteus minimus muscles, and there is "loss of abduction and circumduction of the thigh" (Gowers).

The Small Sciatic Nerve.—Division of this nerve paralyzes the gluteus maximus muscle and produces anesthesia of the upper half of the calf of the leg and of the middle third of the back of the thigh (Gowers) (Fig. 492).

The Great Sciatic Nerve.—If this nerve is divided near the sciatic notch there is a paralysis of the flexor muscles of the leg. These muscles, as Gowers points out, are also extensors of the hip. There is likewise paralysis of all the

muscles below the knee. If, however, the injury is below the upper third of the thigh, there is no paralysis of the flexors of the leg. If the nerve is damaged on a level below the small sciatic, there is anesthesia of the outer portion of the leg, of the sole of the foot, and of most of the dorsum of the foot (Fig. 492).

The External Popliteal Nerve.—When this nerve is divided, there is paralysis of the tibialis anticus muscle, the extensor longus digitorum, the extensor brevis digitorum, and the peronei; and the patient is unable to flex the ankle and extend the first phalanges of the toes. When he tries to walk he cannot lift the foot from the ground; and eventually there is the development of talipes equinus (Gowers). The anesthesia is manifest on the outer portion of the anterior surface of the leg, and also on the dorsum of the foot (Fig. 492).

The Internal Popliteal Nerve.—Damage to this nerve paralyzes the posterior tibial muscle, the flexor longus digitorum, the muscles of the calf, the popliteus muscle, and the muscles of the plantar surface of the foot. The toes become flexed at the two distal joints, and extend at the proximal joints. Walking is greatly interfered with. There is loss of the power of rotating the flexed leg inward, if the damage is above the branch to the popliteus muscle; and extension of the ankle-joint is lost. As the consequence, talipes calcaneus develops (Gowers). The anesthesia is variable, but usually involves the sole of the foot and the outer surface and lower portion of the back of the leg (Fig. 492).

The Plantar Nerves.—Division of the internal plantar nerve paralyzes the short-toe flexor, the two inner lumbricales, and the plantar muscles of the great toe, except the adductor (Gowers). There is anesthesia of the inner portion of the sole of the foot and of the plantar surface of the three inner toes and of half of the fourth toe (Fig. 492).

Division of the external plantar nerve causes paralysis of the muscles of the little toe, of the adductor of the great toe, of all the interossei, of the two outer lumbricales, and of the flexor accessorius (Gowers). There is

anesthesia of the skin of the outer half of the sole of the foot, of the little toe, and of half of the fourth toe (Fig. 492).

The Facial Nerve.—This nerve may be divided during the mastoid operation or may be lacerated by a fracture of the petrous portion of the temporal bone, and a peripheral palsy results. The face is asymmetrical and is drawn to the sound side. Asymmetry becomes more marked on attempting to smile or to show the teeth. Whistling and frowning are impossible. The sense of taste may be less acute or lost on the anterior two-thirds of the tongue. There is relaxation of the palate and deviation of the uvula. Reactions of degeneration can be demonstrated in the palsied muscles. In some cases there are sensory disturbances (hyperesthesia or anesthesia) and in some there are vasomotor perturbations on the palsied side. On the paralyzed side the muscles are relaxed, the nasolabial fold is to a great extent gone, the nostril cannot be dilated. The brow wrinkles have been smoothed out, the eyelids cannot be closed; on attempting to close the eye the globe tilts upward and outward. The cornea and conjuntiva inflame, the lower lid droops, and tears run down the cheek.

Treatment.—In every wound in which a nerve or nerves might be damaged make careful search and examination to determine the matter. Always suspect nerve injury in wounds of the wrist. In all recent cases of nerve-section try, if possible, to suture the ends of the divided nerve. The earlier suture is done the better the chance for restoration of function. For instance, in fracture of the humerus, with division of the musculospiral, operate at once. After-care is of the greatest importance in all cases of nerve suture. Primary suture means suture within twenty-four hours of the accident. Suture may fail. There may be partial or complete restoration of function. In 123 reported cases of *primary suture*, 119 were cured in from one day to one year (Willard). The return of sensation may be rapid or may be slow; muscular power returns more slowly than sensation. If the patient is not seen until long after the accident, incise and apply sutures (*secondary sutures*); if the nerve cannot be found, extend the incision, find the trunk above and trace it down, and find the trunk below and follow it up. The results are not nearly so good as are those of primary suture. After-care for months is highly important. In 130 reported cases of secondary suture 80 per cent. were more or less improved (Willard). Even after primary suture loss of function is bound to occur for a time. After secondary suture sensation may return in a few days, but it may not return until after a much longer period; in any case muscular function is not restored for months. After partial section of a nerve the ends should be sutured. In performing secondary suture it may be necessary to effect *lengthening* in order to approximate the ends (see page 759). *Transplantation* of a portion of nerve is sometimes practised (*implantation* or *anastomosis*). *Nerve-grafting* is bridging the gap by means of a portion of nerve from one of the lower animals or from a recently amputated human limb. Nerve-transplantation may fail utterly; it may be followed by great improvement, but absolute and perfect restoration of function cannot be obtained. R. Peterson[1] has made a study of the 20 recorded cases of nerve-grafting; 8 of the operations were primary and 12 were secondary. The periods after the injury at which operation was performed varied from forty-eight hours to a year and a quarter; 4 of the 8 primary cases improved; 8 of the 12 cases of secondary operation showed improvement in motion or sensation. The distance between the nerves did not seem to affect the results. No case recovered completely, but in 1 case sensation returned completely and only the abductors of the thumb remained weak. In most of the cases that were benefited sensation returned by the tenth day and motion within two and a half months. In one of the successful cases, that of A. W.

[1] "Amer. Jour. Med. Sciences," April, 1899.

Mayo Robson,[1] the spinal cord of a rabbit was used. A facial nerve divided in the aqueduct of Fallopius may perhaps be sutured at the site of the injury. This should be attempted as soon as the palsy is observed, as was suggested, I believe, by Frederick Sydenham ("Brit. Med. Jour.," May 8, 1909). If the ends of the divided nerve cannot be approximated, *suture à distance* may be practised, as was done successfully by Sydenham (Ibid.). If suture at the site of injury is impossible the end of the peripheral segment of the divided nerve may be anastomosed to the hypoglossal, glossopharyngeal, or spinal accessory nerve (see page 760).

Pressure upon nerves may arise from callus, scars, a dislocated bone, a tumor, or an external body.

The **symptoms** may be anesthetic, paralytic, or trophic.

The **treatment** is as follows: Remove the cause (reduce a dislocated bone, chisel away callus, excise a scar, etc.); then employ massage, douches, exercise, and electricity.

Dislocation of the Ulnar Nerve at the Elbow.—This condition is very rare. It may occur as a complication of a fracture or a dislocation, or as an uncomplicated condition. It may be produced by violence or by muscular effort, which ruptures the fascia, the function of which is to retain the nerve back of the inner condyle of the humerus. In some cases the symptoms are slight and transitory, the nerve functionating well in its new situation. As a rule, there are pain, numbness, or anesthesia of the ulnar trajectory, some stiffness of the elbow, and stiffness of the little finger and ring-finger. The nerve can be felt in front of the inner condyle of the humerus. In some cases neuritis follows, with trophic changes.

Treatment.—Expose the nerve by an incision, incise the fibrous tissue back of the inner condyle, and press the nerve into the bed prepared for it and hold it in place by sutures of chromic catgut passing through the triceps tendon. Wharton advises suturing also "the margin of the fascial expansion of the triceps tendon superficial to the nerve."[2]

Contusion of Nerves.—The **symptoms** of contusion of nerves may be identical with those of section. Sensation or motion, or both, may be lost. The case may recover in a short time, or the nerve may degenerate as after section.

The **treatment** at first is rest, and later electricity, massage, friction, and douches.

Punctured Wounds of Nerves.—The **symptoms** of punctured wounds of nerves may be partly irritative (hyperesthesia, acute pain, and muscular spasm) and partly paralytic (anesthesia, muscular wasting, and paralysis).

The **treatment** after the puncture has healed is the same as that for contusion.

Operations Upon Nerves

Neurorrhaphy, or Nerve-suture.—When a nerve is completely or partially divided by accident it should be sutured at the first possible moment. If there is no tension the best suture material is fine plain catgut; if there is any tension, lightly chromicized catgut (Sherren, in "Brit. Med. Jour.," Jan. 15, 1910). Sherren points out that if silk or linen is used it interferes with complete recovery and may cause symptoms months after the operation. In primary suture render the part bloodless and aseptic. Enlarge the incision if necessary. If the ends can readily be approximated, pass two or three sutures through the sheath and connective tissue outside, and tie them (Figs. 493, 494). If the ends

[1] "Amer. Jour. Med. Sciences," April, 1899.

[2] A report of 14 cases of dislocation of the ulnar nerve at the elbow, by H. R. Wharton, "Amer. Jour. Med. Sciences," Oct., 1895.

cannot be approximated, stretch each end and then suture. The sutures do not traverse the nerve, but go through the perineurium and adjacent connective tissue. After suturing, wrap the suture line in Cargile membrane to prevent adhesions to adjacent structures (Sherren, "Brit. Med. Jour.," Jan. 15, 1910). Suture the deep fascia. Remove the Esmarch band, arrest bleeding, suture the skin, dress antiseptically, and put the part in a relaxed position on a splint. After union of the wound continue the use of the splint to maintain muscular relaxation as long as the muscles are paralyzed (Ibid.), and use massage, friction, electricity, and the douche. When voluntary power returns remove the splint and insist on active exercise. The operation in some instances fails, but in many cases succeeds. In some few cases sensation returns in a few days, but in most cases does not return for many weeks or months. Sensation is restored before motor power. After successful suturing of a divided median nerve sensations of skin pain and of extreme heat and cold appeared in fifty-six days and were restored in two hundred and seven days. Sensations of light touch and slight degrees of heat and cold appeared in two hundred and sixty days and were not completely restored for one year (Kenneth A. J. Mackenzie, in "Annals of Surg.," July, 1909). *Secondary suture* is performed upon cases long after division of a nerve. If operation is not done for three years or more after division it is very improbable that complete regeneration will ever occur, and yet it is always worth trying, for muscular control has been regained after suturing in 1 case twenty-nine years subsequent to nerve division (Alfred S. Taylor, in "Jour. of Orthopedic Surg.," Nov., 1908). The part is rendered aseptic and bloodless; an incision is made; the bulbous proximal end is easily found and loosened from

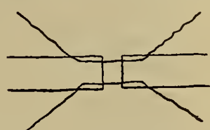

Fig. 493.—Nerve-suture.

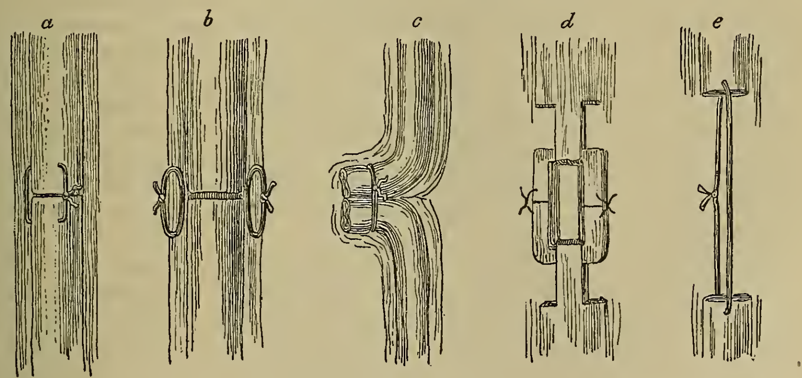

Fig. 494.—Nerve-suture: *a*, Direct; *b*, perineurotic; *c*, paraneurotic; *d*, *e*, neuroplasty (Senn).

its adhesions; the shrunken distal end is sought for and loosened (it may be necessary to expose the nerve below the wound and trace its trunk upward); the entire bulb of the proximal end is cut off; about $\frac{1}{4}$ inch of the distal end is removed. All scar-tissue between the ends is most carefully removed. If the gap between the ends is not wide, each end is gently stretched, and the ends are approximated and sutured together, and the suture line is covered by Cargile membrane. If stretching does not permit of approximation, adopt the expedient shown in Fig. 494, *d*, or in Fig. 495. This operation is *neuroplasty* by the *flap method*. Another method is to make a bridge of strands of catgut running from one divided end to the other. We speak of this plan as *suture à distance* (Fig. 494, *e*). The catgut bridge supports the growing reparative material.

Allis suggested shortening the limb by resecting a piece of bone. This has been done successfully by Keen, Rose, and others.

Letiévant attaches the peripheral portion of a divided nerve into a longitudinal slit in a sound nerve (end to side).

Guelliot suggested *tubulization*, that is, erecting barriers along the path of reparative material to save the ends of the nerve from cellular invasion from the perineural structures (which would block repair) and to guide the new growth. Vanlair uses a piece of artery which has just been removed or surrounds the ends with decalcified bone. Payr uses a tube of absorbable magnesium. Hashimoto and Toknoka use a vein or artery from a recently slaughtered calf, hardened in formalin. *Implantation* or *anastomosis* is advisable in some cases.

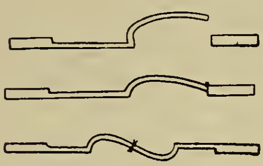

Fig. 495.—Suture of a nerve by splitting the ends (Beach).

Gelatin tubes have been used, silver-foil has been tried, and Cargile membrane has been employed. None of these plans is entirely satisfactory. Murphy covers the line of nerve-suture with fascia, muscle, or fat. In regions where he cannot obtain suitable covering tissue he wraps about the suture line a material composed of equal parts of paraffin and oil of sesame. This mixture can be flattened out very thin ("Surg., Gynec., and Obstet.," April, 1907).

The operation of anastomosis is employed after an exsection which leaves a very large gap, for facial palsy, for infantile palsy, for avulsion of the brachial plexus, and for brachial birth palsy.

Nerve-grafting is practised by some. A. W. Mayo Robson used the spinal cord of a rabbit to fill a gap between the ends of the divided median nerve of a man. The restoration of function was almost complete. Some surgeons have grafted in bits of nerve obtained from a recently amputated limb. It makes no difference whether the grafted nerve is motor, sensory, or mixed. The results of grafting are seldom good. Chas. A. Powers ("Transactions of the American Surgical Assoc.," 1904) collected 22 cases from literature, 20 from Peterson's paper, 1 case of Durante's, and 1 of his own. In this series there were 3 good results and 3 "fair" results. The bit of nerve grafted does not participate in repair—it is a mere bridge, and acts as does the suture à distance.

Neurectasy, Neurotomy, and Neurectomy.—*Neurectasy*, or nerve-stretching, may be applied to motor, sensory, or mixed nerves. A nerve can be stretched about one-twentieth of its length. Nuerectasy has been employed for neuralgia, neuritis, muscular spasm, hyperesthesia, anesthesia, painful ulcer, perforating ulcer, the pains of locomotor ataxia, and many other conditions. The operation, which was once the fashion, seems to benefit some cases, but it is not now thought so highly of as formerly. The incision for neurectasy is identical with the incision for neurectomy or neurotomy of the same nerve. *Neurotomy*, or section of a nerve, is performed only upon small and purely sensory nerves (in spasmodic wry-neck a motor nerve is cut). It is performed chiefly for peripheral neuralgia or for some other painful malady. It is almost useless in painful conditions, because sensation, as a rule, soon returns. Paget saw complete return of sensation in four weeks after division of the median nerve. Corning endeavors to prevent this regeneration by inserting oil between the ends. He uses oil of theobroma containing enough paraffin to make the melting-point 105° F. The oil is melted, is injected around the nerve, and cold is applied. The nerve is now sectioned with a canaliculated knife, the ends are separated widely, more oil is injected, and cold is again applied. The theory is that this oil, which is solid at the

temperature of the body, devitalizes the nerve at the point of section and acts as a barrier to the passage of regenerating fibers. This method has been applied especially in cervicobrachial neuralgia.[1] *Neurectomy*, or excision of a portion of a nerve-trunk, is applicable to sensory nerves and to painful affections.

Sympathectomy.—*Jonnesco's Operation.*—It has long been known that division of the sympathetic nerve in the neck may produce important changes in the eye and in the cerebral circulation. In 1893 Jaboulay divided the sympathetic on each side for the purpose of treating epilepsy. The removal of the ganglia of the sympathetic was proposed by Baracz; and the operation was first performed by Jonnesco, in 1896, for epilepsy. The operation is performed by some surgeons for epilepsy, for exophthalmic goiter, for glaucoma, and for trifacial neuralgia. In operating for glaucoma the superior cervical ganglion on each side is removed, as it is from this that the sympathetic fibers that pass to the eye are derived. If the operation is done at all, it should be a bilateral one.

This operation is used in epilepsy on the theory that there is an anemic condition of the brain in this disease which is corrected by producing a hyperemia, and that the hyperemia improves cerebral nutrition. The operation in epilepsy is largely theoretical, although Jonnesco claims 12 per cent. of cures in a large number of operations. In exophthalmic goiter there seems to be some distinct evidence that the operation may be beneficial, but Curtis shows that the mortality is high. Personally, I have not employed it in epilepsy, and at the present time I should not be inclined to do so. In exophthalmic goiter, if any operation is necessary, I perform partial thyroidectomy or ligation of the thyroid arteries; but in progressive glaucoma, which is always so absolutely hopeless, the operation is a justifiable procedure and occasionally seems to have a distinct influence in retarding the development of the disease.

The incision should be made along the posterior margin of the sternocleidomastoid muscle. I have become convinced, in performing two operations of this kind and through studies made upon the dead body, that the ganglion may be more easily reached from behind the sternocleidomastoid than from in front of it. The internal jugular vein and the carotid artery are lifted upward and forward; and the superior ganglion will usually adhere to the under portion of the carotid sheath and be lifted up with it. Theoretically, it is not necessary to open the carotid sheath in this operation, but, practically, this had better be done, so that one may, without any possibility of doubt, distinguish between the pneumogastric and the sympathetic nerve. The moment the nerve is cut the pupil on that side will contract.

Stretching of the Sciatic Nerve.—Some surgeons stretch the sciatic nerve by anesthetizing the patient and holding the leg and thigh in line, strong flexion being made upon the hip, the entire lower extremity being used as a lever. This method, which has caused death, inflicts needless damage, and stretching after an incision has been made is safer and better. The patient lies prone, the thigh and legs being extended. An incision 4 inches in length is made a little external to the middle of the thigh, and going at once through the deep fascia; the biceps muscle is found and is drawn outward; the nerve is discovered between the retracted biceps on the outside and the semitendinosus on the inside, resting upon the adductor magnus muscle. The nerve, which is caught up by the finger, is first pulled down from the spine and then up from the periphery, and finally the hook of a scale is inserted beneath the trunk and the nerve is stretched to the extent of 40 pounds.

[1] "Medical Record," Dec. 5, 1896.

Very rarely is even a single ligature needed. The wound is sutured and dressed. If the incision is made at a higher level, just below the gluteo-femoral crease, the sciatic nerve will be found just by the outer border of the biceps.

Neurectomy of the Infra-orbital Nerve.—This operation was first performed by Abernethy in 1793. The patient lies upon his back, the head being raised a little by pillows. The surgeon stands to the outside of and faces the patient. A curved incision $1\frac{1}{2}$ inches long is made below the lower border of the orbit. The nerve lies in a line dropped from the supra-orbital notch to between the two lower bicuspid teeth and is found upon the levator labii superioris muscle. A piece of silk is passed under the nerve by an aneurysm needle and firmly fastened. The upper border of the incision is drawn upward; the periosteum of the floor of the orbit is elevated and held by a retractor; the roof of the infra-orbital canal is broken through; the nerve is picked up far back by the blunt hook and is divided by scissors, and the entire nerve in front of the section is drawn out by making traction upon the silk. The bleeding in the orbit is checked by pressure. The wound is stitched without drainage.

Neurectomy of the Supra-orbital Nerve.—Before sterilizing the parts shave off the eyebrow. A curved incision 1 inch long discloses the nerve as it emerges from the supra-orbital notch or foramen at the junction of the inner and middle thirds of the eyebrow. The nerve is pulled forward and cut off above and below.

Neurectomy of the Inferior Dental Nerve.—Make a curved incision around the angle of the jaw. Lift the supramaxillary branch of the facial nerve downward (Kocher). Separate the masseter muscle by a periosteum elevator and slight touches of the knife. Chisel an opening in the center of the ascending ramus (Velpeau's rule). This opening exposes the beginning of the dental canal. If necessary, the opening may be enlarged by a rongeur. Pull the nerve out by a hook and remove a piece from it.

Extracranial Operation for Neuralgia of the Fifth Nerve.—The operation for removal of the Gasserian ganglion is difficult, bloody, and dangerous. Removal of portions of the pain-haunted nerve-trunks sometimes cures the condition and often ameliorates it for a considerable time. The injection of osmic acid into the peripheral nerves, or of alcohol into the nerves as they emerge from the cranium, may actually cure or secure prolonged relief. The serious operation of removing the ganglion may be performed if peripheral operations and injections fail, or in violent and intractable cases of long standing in which pain is felt in more than one branch. Removal of nerves by ordinary neurectomy often gives comfort for a few months, but rarely gives prolonged relief. If we seek striking benefit by an extracranial operation, it must be thoroughly done.

Injection of Osmic Acid.—This method was suggested by Bennett, of London, in 1897. Osmic acid had been used for many years in a sort of haphazard way, being thrown into tissues about the nerves by means of a hypodermatic syringe. Bennett suggested exposure of the nerve and the injection of 5 to 10 min. of a 1 per cent. solution. Acid when so used actually destroys nerve-fibers, and a considerable amount of fibrous tissue forms which intercepts regenerating fibers. It is probable that secondary degenerative changes occur in the nerve-trunks, but they do not ascend and reach the ganglion. Murphy warmly advocates the method. It certainly produces immediate relief by causing anesthesia, but such relief is very seldom, if ever, permanent. I have used it in several cases with satisfaction. In 1 case in which I exposed the ganglion I injected that structure, and the result seemed to be the same as if I had removed the ganglion. In neuralgia of

the fifth nerve the painful nerve or nerves should be exposed, and from 5 to 10 min. of a 2 per cent. solution of osmic acid injected into several different parts of the nerve and also between the nerve-sheath and the bony canal (Murphy). The osmic acid method does not seem to grow in favor.

Injections of Alcohol Into the Second and Third Divisions.—This method was devised by Schlösser in 1903. The injections are made into peripheral branches or divisions of the ganglion, and have even been made into the ganglion. Siccard and others have warmly praised the method. It acts similarly to osmic acid. It produces local necrosis of the nerve and fibrosis about it. The necrosis does not tend to ascend (May, "Brit. Med. Jour.," Aug. 31, 1912). It gives relief sometimes after one injection, sometimes after two or more. The permanence of the relief is uncertain. Usually it is complete for six months and then recurrent pain may require renewed injection. Recurrences are milder than the previous condition. Apparent cure may last for three or four years.

I have used the method many times and am satisfied as to its value in proper cases. It is superior to peripheral operations. It is used in very old subjects, feeble subjects the victims of grave organic disease, and in those who refuse radical operation. In strong young persons removal of the ganglion may still be preferred. In some cases it is used before a ganglion extirpation in order to remove pain and permit of such improvement in health and strength as to make the radical operation safer. Never attempt to make a deep injection about the ophthalmic branch. To do so may damage a great vessel, the optic nerve, the third, fourth, or sixth nerve, or the alcohol may enter the orbit and destroy the eye. If there is pain in the supra-orbital and supratrochlear branches, inject them where they are superficial.

Injection of the Supra-orbital Branch.—Use an ordinary hypodermatic needle and inject 10 to 20 min. of the fluid recommended below. Throw the fluid about the nerve at the foramen. After withdrawing the needle make pressure at the puncture. Such pressure is advised by Patrick to stop bleeding, prevent a black eye, keep the tissues exsanguine, and add to the effect ("Jour. Am. Med. Assoc.," Jan. 20, 1912). The lids always swell.

I used for a time 80 per cent. alcohol, each dram of which contained $\frac{1}{6}$ gr. of stovain, but this hardens the tissues so much that they become resistant to reinjection. I now use Patrick's formula, viz.: 2 gr. of muriate of cocain, $2\frac{1}{2}$ drams of alcohol, and distilled water sufficient to make $\frac{1}{2}$ oz. The usual dose is 2 c.c. A special needle is used. It is straight, is graduated in centimeters, and carries a stylet which is flush with the point. The stylet is pulled back slightly while the needle is being driven through the skin and fascia; it is then pushed all the way in. I follow the method of Lévy and Baudoin ("Presse Méd.," April 17, 1906), which is as follows:

Superior Maxillary Division.—Drop a perpendicular from the posterior border of the orbital process of the malar bone (the beginning of the zygoma) to the inferior edge of the zygoma; $\frac{5}{10}$ c.c. back of this point is where the needle should be introduced. It is carried in and very slightly upward. At a depth of 2 cm. the coronoid process may obstruct; at a greater depth, the external pterygoid plate. Either obstruction may be avoided by inclining the needle very slightly forward (never much or alcohol might enter the orbit). At a depth of 5 cm. the needle encounters the nerve as it emerges from the foramen rotundum. The injection usually causes decided but brief pain. If the injection reaches the nerve there will be immediate analgesia throughout its trajectory. This should last two or three days.

Inferior Maxillary Division.—The point for entrance of the needle is at the lower border of the zygoma, 2.5 cm. in front of the anterior root of the zygoma. The needle is carried inward, somewhat backward, and slightly upward. At a

depth of 4 cm. the nerve is reached. Be sure the nerve has been reached by finding analgesia throughout its trajectory after injection.

Rose's Method of Neurectomy.[1]—This operation is a modification of the Braun-Lossen method, and is employed when the second division of the fifth nerve is the seat of pain. The infra-orbital nerve is exposed by an incision, a ligature is tied around it, the roof of the infra-orbital canal is opened by a chisel, and the nerve is traced back as far as possible. The wound is then packed temporarily with gauze. The next step in this operation is to open a way into the sphenomaxillary fossa (Fig. 496). The knife is inserted slightly below the external angular process of the frontal bone, is carried back along the zygoma, down in front of the ear to just above the angle of the jaw, and then forward for 2 inches. This flap, which is composed of skin and subcutaneous fat only, is dissected forward, and Steno's duct and branches of the facial nerve are not damaged. The flap is wrapped in gauze and temporarily stitched to the side of the nose. The zygoma is exposed by a transverse incision. At the root of the zygoma two holes are drilled ¼ inch apart, and two more holes ¼ inch apart are drilled through the zygomatic process of the malar bone. The zygoma is then divided by a saw (Fig. 497). The posterior saw line runs between the two drill-holes at the root of the zygoma. The anterior cut passes between the two anterior drill-holes. The direction of the first cut is directly downward. The direction of the second cut is downward and forward from above. The arch is freed and detached downward and backward. The exposed tendon of the temporal muscle is retracted backward. The removal of a little fat exposes the pterygomaxillary fossa. The internal maxillary artery is exposed, two ligatures are applied, and the vessel is divided between them. The finger feels for the sphenomaxillary and pterygomaxillary fissures. The external pterygoid muscle is separated from the greater wing of the sphenoid and from the root of the external pterygoid process. On the edge of the greater wing of the sphenoid a long prominence is usually detectable. It overhangs the sphenomaxillary fossa and should be cut away by the use of a chisel. The superior maxillary nerve is lifted on a blunt hook, is grasped by forceps, and is twisted off as near the ganglion as possible (Fig. 498). The

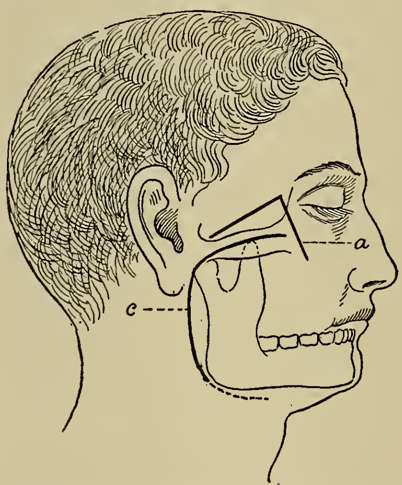

Fig. 496.—*a*, The Braun-Lossen incision; *c*, Rose's incision for reaching the sphenomaxillary fossa (Rose).

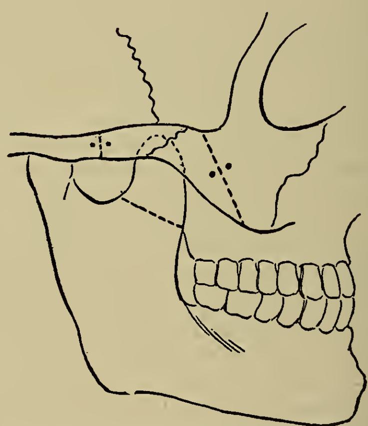

Fig. 497.—Lower jaw and zygoma. Drill-holes and saw-cuts are shown (Rose).

[1] See article by Wm. Rose, "Practitioner," March, 1900.

distal end is drawn upon, and the nerve, having been previously loosened, is drawn back through the infra-orbital canal. The zygomatic arch is wired in place, the temporal fascia is sutured with buried sutures, and the skin-wound is closed. If the pain involved not only the second division, but also the third division, the operation previously described should be performed first, and the third division should be attacked a few weeks later. The third division is reached by removing the coronoid process. The inferior dental and lingual nerves are found, and are traced up to the foramen ovale, and are twisted off close to the ganglion, and the distal portions are removed.

Removal of the Gasserian Ganglion.—This formidable procedure was first suggested by J. Ewing Mears in 1884, and was first performed by Wm. Rose in 1890. The operation is often bloody and difficult, and is only undertaken in very severe cases of tic douloureux in which the first division is involved, or in cases upon which less grave procedures have failed. Jaboulay and Cavaillin ("Lyon. Med.," May 17, 1908) speak of it as a grave operation of difficult technic which should be left as a final resort. Many operators deny that there is a large mortality after gasserectomy and claim that it is only about 5 per cent. Some operators report a mortality of from 10 to 17 per cent. The greater the experience of the surgeon in this operation, the smaller will be the mortality. Knowledge of the region and parts, dexterity from frequent repetition, and special training count for much. The operation usually cures the pain if the patient recovers from the actual procedure. It is claimed that the pain may recur even after complete removal of the ganglion. I have never seen this occur and am disposed to think that recurring pain is apt to mean that there was a partial removal. Carson collected 100 cases; Murphy and Neff, 42 cases. The mortality in this group of 142 cases was 15 per cent. Most of the cases reported by Murphy and Neff were operated upon during or after 1899, and in this group the mortality was 10 per cent. ("Progressive Medicine," March, 1903). In Lexer's series of 201 cases, referred to below, the mortality was 17 per cent. In many cases a perfect cure is obtained. In some few the pain returns upon the side operated upon. Occasionally it arises on the side not operated upon. In some cases ulceration of the cornea follows operation. Such ulceration may be trivial, may result in opacity, or may destroy the eye. Paralysis of the abducens occurs in some cases. The hemorrhage may be so profuse as to require packing of the wound and suspension of the operation for a few days. The bleeding may come from the meningeal artery, from the sinus, or from the veins of Santorini. Lexer ("Arch. f. klin. Chir.," Bd. lxv, H. 4) gives a table of 201 cases. Of the survivors, 93.4 per cent. were apparently cured. In two-thirds of the cases the trouble was right sided. In 10 the operation was temporarily abandoned because of hemorrhage. The experience of surgeons in general is that after the removal of the ganglion there is apt to be some atrophy of the tongue and the eye usually becomes insensitive and watery. The masseter muscle will be paralyzed.

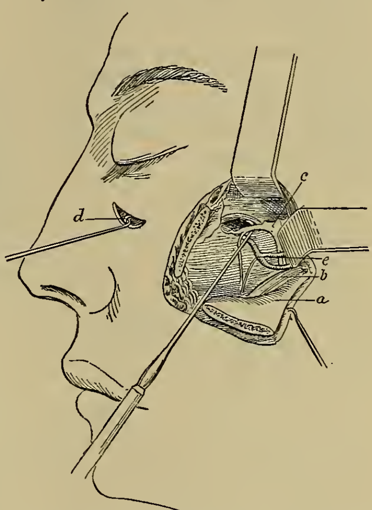

Fig. 498.—*a*, The zygomatic arch, turned down after sawing; *b*, tendon of the temporal muscle retracted; *c*, superior maxillary nerve and Meckel's ganglion; *d*, infra-orbital nerve emerging from canal; *e*, internal maxillary artery.

The Hartley Operation for Removal of the Gasserian Ganglion.—This operation was first performed by Hartley in 1891, five months before Krause performed it. An electric forehead-light is required. Long strips of gauze must be ready for packing in case of hemorrhage. The patient is placed recumbent, with head turned to the opposite side. The application of a provisional ligature or clamp to the external carotid artery is advocated by some, but this step will not control the venous bleeding, which is the most harassing hemorrhage encountered. Many operators form a large osteoplastic flap in front of the ear (Fig. 499) and break it out. I do not believe that an osteoplastic flap is necessary. The temporal fascia is so thick and tense that when the wound in it is carefully sutured protection is perfect and safety is secured. Hemorrhage is to be carefully arrested. It may be found that the meningeal artery has been ruptured. If this accident has happened and the vessel lies in a bony canal, plug with Horsley's wax. If the vessel is bleeding upon the dura, ligate by passing suture-ligaments around it. If it is torn off at the foramen spinosum, pack the foramen with iodoform gauze, and postpone the conclusion of the operation for forty-eight hours. It may be necessary at any stage of this operation to pack the wound and postpone completion for two days. Some surgeons (Krause, Bergmann) ligate the meningeal artery as a routine procedure, but this operation may be difficult and require much time. If the unligated vessel is divided, the hemorrhage can be arrested by gauze packing or by plugging the foramen spinosum with a bit of sterile wood, but it is best to ligate the vessel. The head and body of the patient should now be elevated. This allows the brain to drop posteriorly and renders forcible retraction unnecessary, and, further, it lessens venous bleeding (Lexer). The next step is to lift up the dura and with it the brain (Fig. 500). Find the inferior maxillary nerve and clamp it with hemostatic forceps. Find the superior maxillary nerve and clamp it. Uncover the ganglion. Loosen the nerves from their beds by a dry dissector and divide each one at its foramen of exit. Twist the clamp forceps so as to reel up the nerves. This pulls out the ganglion intact with the motor root and the root of origin, as far back as the pons (Krause's method). Arrest bleeding; close the flap;

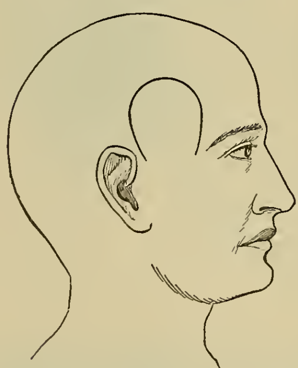

Fig. 499.—Hartley's osteoplastic flap in removal of Gasserian ganglion (Tiffany).

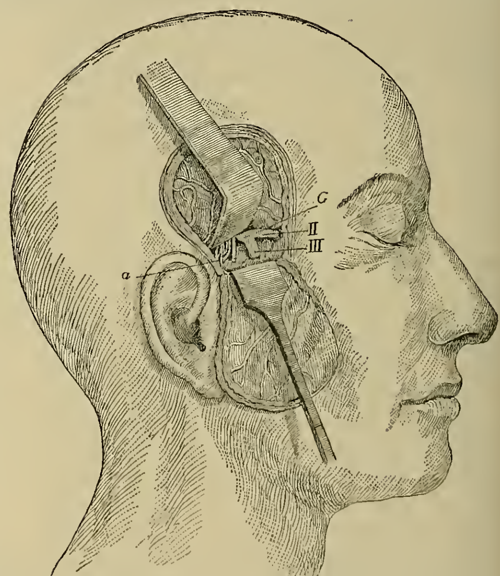

Fig. 500.—Removal of Gasserian ganglion: *a*, Middle meningeal artery; *II*, ophthalmic division; *III*, submaxillary division; *G*, ganglion (Krause).

sew together by a couple of stitches the lids of the affected side in order to keep them temporarily closed, and cover the eye with a watch-crystal. The eye is to be frequently washed out. Thus irritants are excluded.

Cushing has modified the Hartley operation so as to permit of extradural manipulation below the arch made by the middle meningeal artery and thus lessen the danger of laceration of the artery ("Jour. Amer. Med. Assoc.," April 28, 1900). The anterior arm of the incision of the soft parts is so placed that it does not cut the nerve to the occipitofrontalis muscle. Thus drooping of the lid and oblation of brow wrinkles on that side are avoided. He trephines the wall of the temporal fossa very low down, opens into the skull below the arch of the meningeal vessels, and thus avoids the meningeal at the foramen spinosum of the sphenoid bone and the sulcus arteriosus of the parietal bone.

Horsley's Intradural Method.—An opening is made into the middle fossa of the skull, the dura is opened, and the ganglion is found and removed. This operation is easier than the extradural method, but is believed to be more dangerous.

The Frazier-Spiller Operation of Intracranial Neurotomy of the Sensory Root of the Trigeminus.—If experience shows that after division of the sensory root the nerve does not regenerate, and it seems probable that it does not, the operation must be regarded as a valuable addition to our resources. This operation is by many surgeons preferred to removal of the ganglion. In this operation the zygoma is temporarily resected. The temporal fossa is exposed, the bony wall is trephined, and the trephine opening is enlarged by the use of a rongeur. The dura is separated and the ganglion is reached. The dural envelope of the ganglion is opened, separated, and the sensory root exposed. The sensory root is then picked up on a blunt hook and divided. It is frequently possible, Frazier tells us, to separate the sensory root from the motor root. In this operation we avoid the venous hemorrhage from the foramen ovale and foramen rotundum which is apt to be encountered when removing the ganglion.

Abbe's Operation of Intracranial Neurectomy of the Second and Third Divisions.—This operation is preferred by Charles A. Ballance, who opposes exposure of the ganglion or division of the sensory root unless the first division of the nerve is the seat of pain. He advocates this in spite of knowing full well that the pain may return in a few years. He advocates it because of its safety, its simplicity, its freedom from serious hemorrhage, its avoidance of opening the intradural space and of all danger of corneal anesthesia, and also because if pain returns the operation can be repeated. The operation is performed as follows: Ligate the external carotid artery of the diseased side, make a vertical incision over the middle of the zygoma down to the bone. An opening into the skull is made by a mallet and gouge, and this opening is enlarged by a rongeur until it is 1½ inches in diameter. The dura is lifted from the middle fossa and the nerves are exposed. Each nerve-trunk is clamped, is divided near its foramen of exit, and is separated from the ganglion by cutting or twisting by the forceps. A strip of sterile rubber tissue, 1½ inches in length and ¾ inch in width, is laid over the round foramen and the oval foramen and is pressed into place by gauze. In a few moments the gauze is withdrawn and the ganglion is allowed to descend upon the rubber tissue. The wound is then closed. (See Robert Abbe, in "Annals of Surgery," Jan., 1903.) The rubber tissue is used to block the foramina of exit and prevent future emergence of regenerating nerves. Mayo Robson blocks the foramina by a thin plate of lead or silver, a knob of the plate entering the oval foramen to prevent displacement.

Division of the Auditory Nerve for Tinnitus Aurium and for Aural Vertigo.—This operation was proposed for tinnitus by Krause in

1902. Ballance did it on the right side with success in a most distressing case of painful tinnitus. When the cerebellar hemispheres were displaced by sponges the nerves of the posterior fossa were brought into view. He divided the eighth nerve, but made no attempt to preserve the nerve of Wrisberg. Five months after operation the patient was well except for deafness and deviation of the tongue to the left. (See Ballance, in "Lancet," 1908, vol. ii.) Frazier has divided the auditory nerve for aural vertigo, with partial relief.

Operation for Facial Paralysis of Extracerebral Origin (Facio-accessory Anastomosis and Faciohypoglossal Anastomosis).—(See "Remarks on the Operative Treatment of Facial Palsy of Peripheral Origin," by Chas. A. Ballance, Hamilton A. Ballance, and Purves Stewart, "Brit. Med. Jour.," May 2, 1903; and also the "Surgical Treatment of Facial Paralysis by Nerve Anastomosis," by Harvey Cushing, "Annals of Surgery," May, 1903.) In 1898 Furet suggested to Faure that he should anastomose the peripheral end of a divided facial nerve to that portion of the spinal accessory nerve which goes to the trapezius muscle. Faure did this, but the operation failed. Robert Kennedy, of Glasgow, did the first successful operation. He divided the facial for the relief of spasm and at once anastomosed to a partly divided spinal accessory. The procedure first employed by Ballance was, after noting by galvanism that muscular fiber still remained, to expose the facial nerve at its point of exit from the stylomastoid foramen, to cut the nerve-trunk across as high up as possible, to expose the spinal accessory, and to suture the distal end of the facial into the trunk of the spinal accessory. The spinal accessory was cut half through to make a bed for the end of the facial. The paper of the Ballances and Stewart above referred to recommends end-to-side anastomosis between the divided facial and the hypoglossal. The authors have operated five times for facial palsy. Cushing, Keen, Hackenbruch, Körte, Currie, Beck, Vidal, Girard, Lund, Alt, Frazier, and others have done similar operations. Marked improvement may follow operation even if palsy has lasted for a considerable time. Improvement followed operation in Currie's case, although the palsy was nearly a year old. The period when improvement should be expected is uncertain. Signs of improvement may not be evident for six months or longer. In Cushing's case they began in thirteen days; in Kennedy's case, in seven days. In most cases operation restores facial symmetry when at rest and in many cases during volitional movements. The patient will often become able to close the eye and raise the angle of the mouth. Curious associated movements may occur. In Currie's case when the patient lifted his shoulder there was contraction of the occipitofrontalis muscle ("South African Med. Record," 1907). Grant operated upon a case of traumatic facial paralysis over four months after the injury. He anastomosed the facial to the spinal accessory and the peripheral end of the accessory to the descendens hypoglossi. At the end of fifteen weeks there were feeble association movements of the face and shoulder, which later disappeared. At the end of a year the result was most gratifying ("Jour. Am. Med. Assoc.," Oct. 22, 1910).

Facio-accessory anastomosis does not restore emotional movements, but faciohypoglossal anastomosis may restore them. Küster reports a case which confirms this.

Operation is indicated when a complete facial palsy is of such duration that recovery is not to be hoped for by longer delay. The Ballances and Stewart believe that when palsy has lasted six months without sign of recovery, operation is indicated. A paralysis due to traumatism gives a much better prognosis after operation than does a paralysis due to a septic process (Chas. A. Ballance, Hamilton Ballance, and Purves Stewart, in "Brit. Med. Jour.," May 2, 1903). Murphy has collected 33 cases of anastomosis of the facial

nerve with the spinal accessory, hypoglossal, or glossopharyngeal, and Joseph Beck has added 5 cases of his own in which he performed faciohypoglossal anastomosis.

The hypoglossal is preferred to the accessory. Its trunk is larger and its cortical center is adjacent to the facial cortical area. After such an operation associated movements are not observed when the mouth is kept closed, and, if Gowers is correct, the fibers of the facial, which supply the muscles closing the mouth, may take origin from the hypoglossal nucleus (John B. Murphy, in "Surg., Gynec., and Obstet.," April, 1907). Murphy points out that an anastomosis may be end to end, implantation of the facial into a slit in the other nerve, implantation of the facial into a partial transverse division of the other nerve, or end to side (Ibid.).

Operation for Brachial Birth Palsy.—(See article by L. P. Clark, A. S. Taylor, and T. P. Prout, in "Am. Jour. Med. Sciences," Oct., 1905.) These authors report 8 cases of operation with some notable improvements and with 2 deaths. In these cases they found great thickening of the fascia and in some cases fibrous tissue almost completely obscured the remains of lacerated trunks or roots. They advise that the patient be placed recumbent, with a sand-pillow beneath the shoulders and with the head extended and bent toward the opposite shoulder. An incision is made at the posterior border of the sternocleidomastoid and the plexus is exposed and explored. If the lesion is above the clavicle, it is at once attacked; if below that bone, the incision is carried down and the bone is sawed in two. The scar tissue with the lacerated nerves is removed and the nerves or nerve-roots are sutured. The wound is closed, the clavicle being wired if it was divided. After dressings are applied the head is bent toward the shoulder of the damaged side and fixed with plaster of Paris.

I operated on a case of Dr. Charles S. Potts's in the Philadelphia Hospital. The roots were not torn, but were found embedded in a thin layer of scar which it was possible to remove. The result was good. Nerve anastomosis may be necessary if exsection of scar leaves an unbridgable gap or if nerve-roots were divided within the foramina.

Operation for Avulsion of the Brachial Plexus.—(See page 750.)

XXIV. DISEASES AND INJURIES OF THE HEAD

Diseases of the Head

In approaching a case of brain disorder, first endeavor to locate the seat of the trouble; next, ascertain the nature of the lesion; and, finally, determine the best plan of treatment, operative or otherwise. In all operations upon the brain the surgeon must be able to determine accurately the situations of certain fissures and convolutions, the finding of the situations of these convolutions and fissures comprising the science of *craniocerebral topography*.

The *regional terms* used in craniocerebral topography are derived from Broca (Fig. 501). The middle meningeal artery is found at the *pterion*, $1\frac{1}{4}$ inches posterior to the external angular process, on a level with the roof of the orbit (Fig. 502). The fissures and convolutions of the brain are shown in Figs. 503–505. The *fissure of Bichat* is marked by a line on each side drawn from the *inion* to the external auditory process. A line from the *glabella* to the inion overlies the median fissure and the superior longitudinal sinus. The *fissure of Rolando* is very important, as marking the posterior limit of the motor region of the brain. It begins near the median line, $\frac{1}{2}$ inch posterior to the middle of the distance between the inion and glabella (Thane). This fissure runs downward and forward at an angle of 67.5° for a distance of $3\frac{3}{8}$ inches.

Chiene finds the fissure of Rolando by the following method: He takes a square piece of paper and folds it into a triangle (Fig. 506, 1); the angle B–A–C of this triangle is 45°; the edge D–A is folded back on the dotted line A–E; the angle

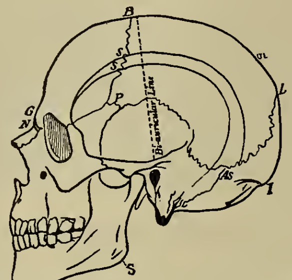

Fig. 501.—Skull, showing the points named by Broca: *As*, Asterion (junction of the occipital, parietal, and temporal bones); basion, middle of anterior wall of foramen magnum; *B*, bregma (junction of the sagittal and coronal sutures); *G*, ophryon (on a level with the superior border of the eyebrows, and corresponding nearly to the glabella, the smooth swelling between the eyebrows); *g*, gonion (angle of the lower jaw); *I*, inion (external occipital protuberance); *L*, lambda (junction of sagittal and lambdoidal sutures); *N*, nasion (junction of the nasal and frontal); *Ob*, obelion (the sagittal between the parietal foramina); *P*, pterion (point of junction of great wing of sphenoid and the frontal, parietal, and squamous bones—this may be H-shaped or K-shaped or "retourné," in which the frontal and temporal just touch); *S*, stephanion (or, better, the superior stephanion, intersection of ridge for temporal fascia and coronal suture); *S′*, inferior stephanion (intersection of ridge for temporal muscle and coronal suture).

D–A–E equals half of 45°, or 22.5°, and the angle C–A–E equals the same (Fig. 506, 2); the paper is unfolded in the line C–A; in the figure thus formed B–A–C = 45° and E–A–C = 22.5°; E–A–B = 67.5°, which is the angle desired. Place the point A in the midline of the head, over the point of origin of the Rolandic fissure; the side A–B is laid along the middle line of the head, and the line A–E corresponds to the fissure of Rolando.[1] Horsley determines the situation of the Rolandic fissure by the use of his metal cyrtometer (Fig. 507). He places the point marked zero over the inioglabellar line and midway between the inion

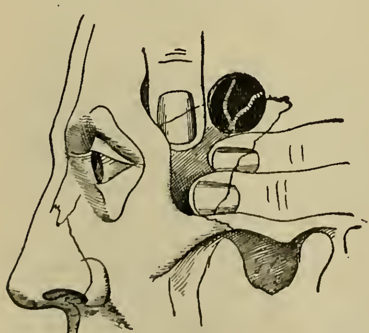

Fig. 502.—The meningeal artery exposed by trephining (after Esmarch).

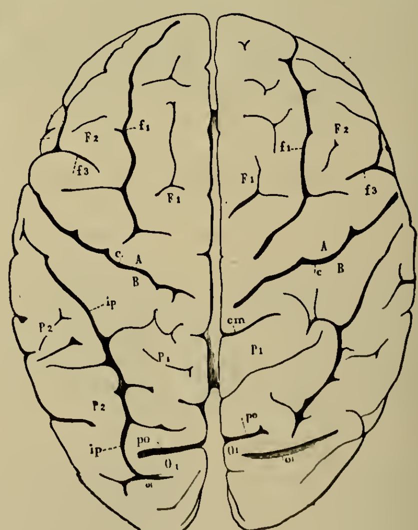

Fig. 503.—View of the brain from above (Ecker).

and the glabella. To find the *fissure of Sylvius* (Fig. 504, *S*, *S′*, *S″*), draw a line from the external angular process to the occipital protuberance. The fissure of Sylvius begins on this line $1\frac{1}{8}$ inches behind the external angular process;

[1] "American Text-Book of Surgery."

the main branch of the fissure runs toward the parietal eminence; the ascending branch of the fissure corresponds to the squamosphenoidal suture, and continues upward in the same line $\frac{1}{2}$ inch above the suture. The *precentral sulcus* (Fig. 504, F) limits anteriorly the ascending frontal convolution; it runs parallel with and just behind the coronal suture, and a finger's breadth in front of the fissure of Rolando. The *intraparietal fissure* (Figs. 503, 504, *ip*) limits the ascending parietal convolution posteriorly. It begins opposite the junction of the lower and middle thirds of the fissure of Rolando, passes upward in a line parallel with the longitudinal fissure and midway between the Rolandic fissure and the parietal eminence, passes by the parieto-occipital fissure, and downward and backward into the occipital lobe. The motor areas, which on the outer surface are adjacent to the fissure of Rolando, are shown in Figs. 503

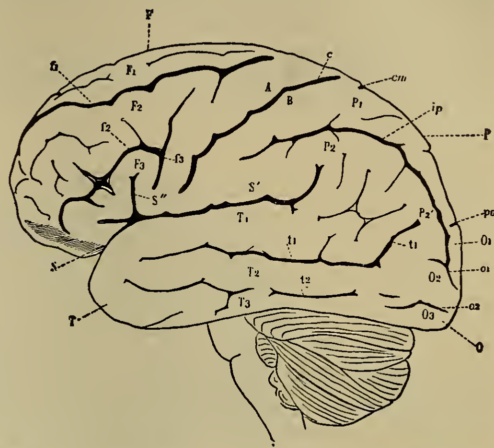

Fig. 504.—Outer surface of the left hemisphere of the brain (Ecker).

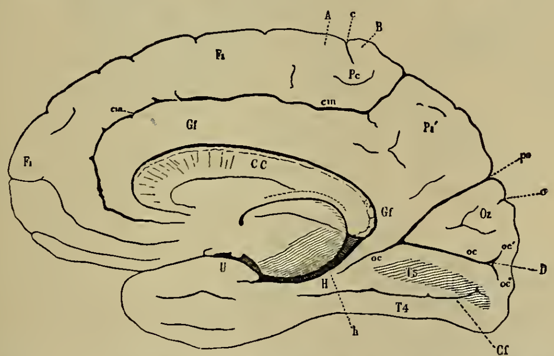

Fig. 505.—Inner surface of the right hemisphere of the brain (Ecker).

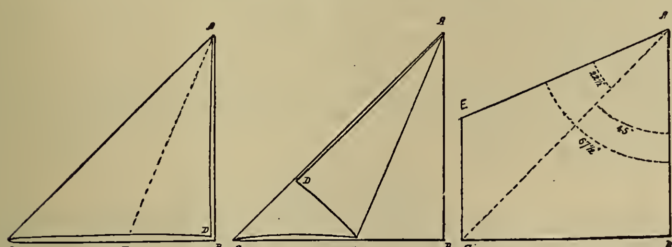

Fig. 506.—Chiene's method of fixing position of Rolandic fissure ("American Text-Book of Surgery").

and 504.[1] The superior longitudinal sinus is overlaid by a line from the inion to the glabella. The lateral sinus is indicated by a line running from the occipital

[1] Recent studies indicate that the motor region is entirely in front of the Rolandic fissure.

protuberance horizontally outward to a point 1 inch posteriorly to the external auditory meatus, and from this point by a second line dropped to the mastoid process. The *suprameatal triangle* of Macewen is bounded by the posterior root of the zygoma, the posterior bony wall of the auditory meatus, and a line join-

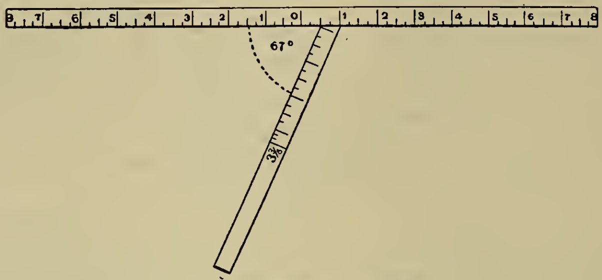

Fig. 507.—Horsley's cyrtometer.

ing the two. The mastoid antrum is opened through *Macewen's triangle* to avoid injury to the lateral sinus. *Barker's point*, the proper spot to apply the trephine for abscess of the temporosphenoidal lobe, is $1\frac{1}{4}$ inches above and $1\frac{1}{4}$ inches behind the middle of the external auditory meatus. Fig. 508 shows clearly the main points of craniocerebral topography, obtained by methods approved by many scientists.

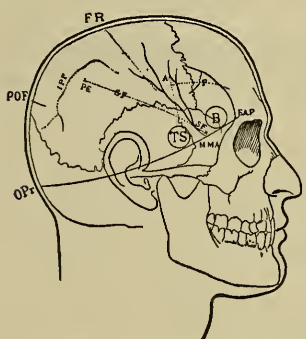

Fig. 508.—Head, skull, and cerebral fissures: B corresponds to Broca's convolution; EAP, external angular process; FR, fissure of Rolando; IF, inferior frontal sulcus; IPF, intraparietal sulcus; MMA, middle meningeal artery; OPr, occipital protuberance; PE, parietal eminence; POF, parieto-occipital fissure; SF, Sylvian fissure; A, its ascending limb; TS, tip of temporosphenoidal lobe. The pterion (to the left of B) is the region where three sutures meet, viz., those bounding the great wing of the sphenoid where it joins the frontal, parietal, and temporal bones (adapted from Marshall by Hare).

Krönlein's method for localizing certain areas is the most generally serviceable (Figs. 509, 510). A line, known as the base line, Z–M, is carried horizontally backward from the lower border of the orbit through the upper border of the external auditory meatus. Another horizontal line, K–K′, is drawn parallel with this, on a level with the supra-orbital ridge. A line Z–K is erected from the middle of the zygoma to the supra-orbital line. A vertical line is drawn from the articulation of the lower jaw, A, and is prolonged to R. A vertical line is drawn from the posterior border of the mastoid base (M–K′) and is taken to P, the middle line of the skull. A line is drawn from K to P, and between the points R and P′ it overlies the fissure of Rolando. The angle P–K–K′ is bisected by the line K–S, which corresponds to the fissure of Sylvius from its point of bifurcation to its posterior termination; K marks the bifurcation of the fissure of Sylvius. To reach the anterior branch of the middle meningeal artery trephine at K; to reach the posterior branch, trephine at K′.

Head Injuries During Labor.—Caput Succedaneum.—This condition is edema of the scalp due to prolonged pressure. The edema is circular and circumscribed and occupies the part not subjected to continued pressure during the uterine contractions of labor. The ring of tissues which are impressed around project like a cup into the birth canal. The veins become congested and edema results. The parts subjected to pressure may appear normal or may exhibit ecchymoses or even excoriations. The pressure is

usually made by the os, and its situation varies with the presentation, but because the most frequent presentation is left occipito-anterior, the common position of the caput is over the superior and posterior portion of the right parietal bone. In a face presentation great disfigurement may occur. It is seldom that a double caput is encountered. It always means that the presentation has shifted. The worst cases of caput follow prolonged labor. The edematous swelling contains bloody serum, pits on pressure, does not fluctuate, is not limited to the outline of one bone, and the skin above it is usually

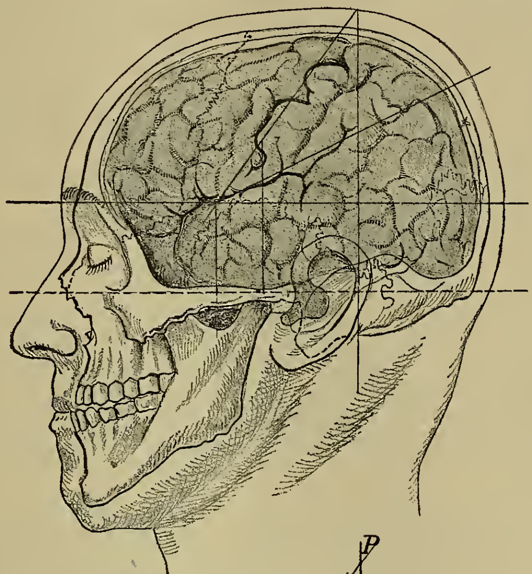

Fig. 509.

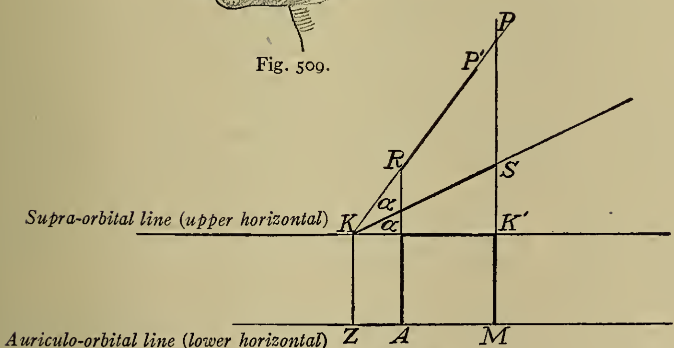

Fig. 510.

Figs. 509, 510.—Krönlein's method of locating the fissure of Rolando (*R–P′*) and Sylvius (*K–S*); Krönlein's point of trephining for hemorrhage from the middle meningeal (*K–K′*); and von Bergmann's region for trephining for abscess of the temporosphenoidal lobes (*A–a–K′–M*) ("American Text-Book of Surgery").

discolored by ecchymoses. No treatment is necessary, as the condition will disappear in from a few hours to three days.

Cephalhematomata.—By this term we mean extravasations of blood beneath the untorn pericranium. It is supposed by many to be always due to pressure and venous congestion, as is a caput succedaneum. As Cushing points out, the condition cannot result from the venous stasis of prolonged pressure alone. If it did it would always exhibit above it a caput succedaneum, "and this is far from our actual experience" (Harvey Cushing, in "Keen's

Surgery," vol. iii). It is certainly due in some cases to bending or breaking of a cranial bone. The condition is said to occur in 1 labor out of 200. In most cases there is but one cephalhematoma, but there may be two, three, or even four. The commonest situation is over the right parietal bone (the common seat of caput succedaneum), and caput succedaneum may be associated with a cephalhematoma. The blood begins to flow beneath the pericranium during labor and the swelling increases during the first few days after birth; in fact, it is frequently not noticed for a day or two. The swelling is tense and smooth, with a convex outline. It may cover but a small portion of a bone or an entire bone, but never extends beyond the bounding sutures. This limitation is due to the fact that the pericranium is adherent to the sutures. In the course of a couple of weeks the tumor may become surrounded by a hard ring due to the formation of new bone, and a shell of bone may eventually surround and cover over the clot, an area of permanent bony thickening remaining. In other cases no bone forms, but the clot gradually disappears. Extradural and even subdural hemorrhage may be associated with a subpericranial cephalhematoma.

Cephalhematomata unassociated with cerebral symptoms usually disappear without operation. If there is no sign of subsidence after two weeks, follow Cushing's rule, evacuate by a puncture-like incision and apply pressure. If suppuration occurs, incision is necessary. Suppuration may occur if the scalp was excoriated. In cephalhematoma with cerebral symptoms operation is indicated (incision of the scalp and removal of a piece of bone).

Diseases of the Scalp.—The scalp is composed of skin, subcutaneous fat, the occipitofrontalis muscle and aponeurosis, the subaponeurotic cellular tissue, and the pericranium. The scalp is liable to inflammation from various causes, and also to certain diseases—namely, tumors, cysts, warts, moles (local cutaneous hypertrophies), cirsoid aneurysm (see page 434), nevi, and lupus. *Abscesses of the scalp* are common. If an abscess forms beneath the pericranium, the pus diffuses over the area of one bone, being limited by the attachment of the pericranium in the sutures. In cranial osteomyelitis pus may gather between the dura and bone and between the bone and pericranium. The condition is known as *Pott's puffy tumor*. If an abscess forms in the tissue between the occipitofrontalis and the pericranium, it is widely diffused. Treves calls this subaponeurotic connective tissue "the *dangerous area*." Abscess of the subcutaneous tissue is apt to be limited because of the great amount of fibrous tissue. Abscess beneath the pericranium does not spread beyond the suture lines. It is limited by the sutural membrane which runs from pericranium to dura. Abscess is treated by instant incision at the most dependent part and drainage. In abscess beneath the occipitofrontalis aponeurosis it is necessary to open and drain above the eyebrows, above the superior curved line of the occipital bone, and at each side above the line of origin of the temporal fascia.

Diseases and Malformations of the Bones of the Skull.—The bones of the skull are liable to caries, necrosis, osteitis, periostitis, osteomyelitis, atrophy, hypertrophy, tumors, etc. (See Diseases of Bones.)

Cranial Pneumatocele.—This rare condition is a result of perforation of a bone which permits air to collect beneath the periosteum. It may occur in the mastoid or occipital region or over the frontal region. These protrusions vary greatly in size; and as their shape depends upon the periosteal attachment to sutures in the neighborhood, they vary in shape. The overlying tissues are natural in appearance. The protrusion is tense, but may lessen or disappear on pressure. McArthur ("Jour. Am. Med. Assoc.," May 6, 1905) points out that if diminished by pressure, the patient may hear a sound like rushing air or water in the ear if the protrusion is occipital or

mastoid; and in the nose, if it is frontal. An elevated ridge of bone surrounds a pneumatocele. The protrusion is tympanitic on percussion. The condition is due to perforation of the bony wall of an air sinus by disease, injury, or rupture. McArthur points out that in half of the reported cases the rupture was not preceded by any history of inflammation or injury. The condition is not dangerous.

Treatment.—Incision, finding the opening in the bone, enlarging it, removing osteophytes; bringing the walls of the cavity together and applying pressure.

Microcephalus.—By "microcephalus" is meant unnatural smallness of the head due to imperfect development. Marked microcephalus is not a common condition, but it is an occasional cause or associate of idiocy. A child may be born with a skull completely ossified even at the fontanels, or the ossification may become complete soon after birth, but in many cases of microcephalus ossification takes place late or not at all. In microcephalus the face is usually fairly well developed; the jaws are prominent; the forehead is flat; the cranium and brain are small; the convolutions of the brain are simpler than is natural; there is apt to be marked asymmetry of the two sides of the brain; internal hydrocephalus may exist; areas of sclerosis and atrophy are common; porencephaly is not unusual. Some patients have perfect motor power; others are slow and incoördinate. Epilepsy, chorea, and athetosis frequently complicate the case. Idiots of this type often present deformities such as cleft palate, strabismus, distorted ears, hypertrophied tongue, deformed genitals or extremities, ill-shaped and irregularly developed teeth. They exhibit irregular muscular movements, are frequently paralyzed in childhood (infantile paraplegia or hemiplegia), and suffer from subsequent contractures. They are active, destructive, excitable, and are liable to be violent and almost demoniacal. As Clouston says, they look impish and unearthly.

Treatment.—Skilled training in a school for the feeble minded or in an institution for idiots is necessary in treating microcephalic idiocy. Idiots have but little power of attention, and sensory impressions give rise to but few concepts, and these are feeble and fleeting. In order to educate the idiot it is highly desirable that speech be acquired, and "the more strongly the attention can be aroused, the more perfect does speech become" (Kirchhoff). The principle of the education of idiots is to stimulate, coördinate, and guide sight, hearing, feeling, taste, and smell.

Lannelongue, of Paris, suggested an operation for idiocy with premature ossification (see Linear Craniotomy, page 831). In this procedure the author has no confidence. Idiocy is a general disorder and not a local brain disease. Soft parts mold bone, and bone does not control soft parts. There is no evidence that the brain is being compressed; in fact, the simplicity of the convolutions suggests the contrary. In many typical cases of microcephalic idiocy there is no synostosis even years after birth. The operation has been much abused. It is sometimes fatal, and, although a fatality may gratify the family, a surgeon is not a legal executioner. The remarkable improvement which has been reported in some cases is wrongly supposed to be due to the operation. As a matter of fact, the new surroundings, the strange faces, the firm discipline, the effect of the anesthetic, and the shock of the operation attract the feeble attention and rouse the sluggish senses. Many cases are brought for operation because they are for the time being unusually intractable and excitable, and the return to the usual level of conduct after operation is regarded as a permanent gain, when it is often but a temporary alleviation. We believe that scientific training is the proper treatment, and that the efficiency of training is not increased by the previous performance of craniotomy, and we follow the precept of Agnew, that a

surgeon might as well cut a piece out of a turtle's back to make a turtle grow as to cut a piece out of the skull to make the brain grow. It would be as wise to take a piece out of the dome of a cathedral to increase the stature of the dean and chapter.

Diseases and Malformations Involving the Brain.—Cephaloceles.—A cephalocele is a congenital protrusion of intracerebral contents through a defect in the skull. These protrusions are covered with skin. The defect through which the protrusion occurs is always in the median line, although in some cases (as at inner angle of the orbit) the visible protrusion may be at the side. Nearly all such protrusions are either frontal or occipital, although now and then one presents in the pharynx, having emerged from the skull between the body of the sphenoid and the ethmoid.

Frontal cephaloceles are divided into:

1. Nasofrontal—those which are in the region of the glabella.
2. Naso-orbital—those at the inner angle of the orbit.
3. Naso-ethmoidal—those below the nasal bone.

Each one of the above forms passes through the horizontal plate of the ethmoid.

Occipital cephaloceles are divided into:

1. Superior—those above the external occipital protuberance. In these the bony gap may join the posterior fontanel.
2. Inferior—those below the external occipital protuberance. In these the bony gap may join the foramen magnum.

The above regional classification is that advocated in von Bergmann's "System of Practical Surgery" (translated and edited by Wm. T. Bull and Walton Martin).

The commonest form is hydrencephalocele, and all other forms result from retrograde changes in this.

Hydrencephalocele.—This is by far the commonest and is also the most dangerous form encountered. The protrusion consists of arachnoid, a layer of brain tissue, and a cavity containing ventricular cerebrospinal fluid and connected with the lateral ventricle. It is, in reality, a protrusion of the lateral ventricle. It is covered with skin—natural skin—unless the protrusion is very large, in which case the skin is more or less atrophied. Beneath the skin is fascia, and beneath this, arachnoid. The pericranium and dura do not cover it, but each has a gap in it and these two tissues join each other around the bone margins.

Encephalocele results from retrograde changes in a hydrencephalocele. The protrusion of the ventricle has become reduced and the hernia consists of a portion of brain covered by arachnoid. Encephalocele is only seen in the nasofrontal region. If there is any fluid in this protrusion it is not in its interior, but on its surface, and results from a cyst of the arachnoid.

Meningocele.—We formerly understood by a meningocele a protrusion of the membranes alone; we now regard it as a condition resulting from retrograde changes in a hydrencephalocele. The brain tissue of the latter disappears; beneath the arachnoid is a layer of cells identical with those which line the ventricles; the connection with the ventricle is entirely or almost completely cut off; a cyst forms in the subarachnoid tissue, and thickened pia surrounds the cyst. (See "System of Practical Surgery," by E. von Bergmann, vol. i, translated and edited by Wm. T. Bull and Walton Martin.) The above condition is called by von Bergmann encephalocysto-meningocele.

Diagnosis.—The congenital origin and situation make certain that the condition is cephalocele. The bony gap can usually be felt; whether it can or cannot, an *x*-ray picture should be taken. Such a picture may indicate that the mass contains brain matter. The protrusions vary greatly in size and shape.

Some are rounded, some are flattened, some are stalked. The skin covering them may be natural, atrophied, filled with vessels, scarred, or ulcerated. Sometimes the cephalocele is very tense; sometimes it is loose. In naturally hairy regions the skin over the summit of the protrusion is bald, but that around the base is hairy. If there is connection between the interior of the protrusion and the ventricle, the mass can be diminished in size by compression. If it shrinks rapidly from compression, the opening into the ventricle is large. In such cases compression of the mass quickly causes signs of cerebral pressure. Lumbar puncture may cause the protrusion to diminish in size; crying may cause it to increase in size. Large cephaloceles fluctuate and perhaps pulsate. Meningocele feels and looks like a cyst (is translucent and fluctuates); it does not usually pulsate, it has a small base, it becomes tense on forcible expiration, and some cases can be very slowly diminished by compression.

Encephalocele is small, opaque, does not fluctuate, has a broad base, does pulsate, becomes tense on forced expiration, and attempts at reduction fail and cause pressure symptoms.

Hydrencephalocele is larger than a meningocele, is translucent, fluctuates, rarely pulsates, is pedunculated, is rendered a little tense on forced expiration, and can be lessened in size by compression, but cannot be reduced.

Treatment.—In von Bergmann's "System of Practical Surgery" we find the wise caution to attempt no operation for an occipital protrusion beneath the protuberance when the cleft enters the foramen magnum and is associated with cleft of the cervical vertebræ—for a condition in which the soft parts are defective and the brain is exposed (*cranioschisis*)—on a case complicated by hydrocephalus or on a case complicated by some other condition which is of necessity fatal. We no longer refuse to operate because the mass contains some brain matter or because it communicates with the ventricle, although if it does so, the prognosis is much worse. For a large hydrencephalocele nothing can be done and early death is inevitable. In rare instances an encephalocele is converted into a meningocele, and the bony aperture closes, thus bringing about a cure. Among the expedients for treating meningocele are electrolysis, injection of Morton's fluid (10 gr. of iodin, 30 gr. of iodid of potassium, 1 oz. of glycerin), pressure, and excision. In cases of cephalocele, when portions of the nerve-centers are not contained in the sac, A. W. Mayo Robson advises the performance of a plastic operation. He ligates the neck of the sac, excises the sac, sutures the skin-flaps separately, and leaves the stump outside the line of superficial sutures. It is usually possible to tell by palpation if nerve-centers are in the sac, but if in doubt, make an exploratory incision, and sweep the finger around inside of the sac.[1] Meningoceles should be operated upon by Robson's plan.

Spurious Meningocele.—It occasionally happens, after a fracture of a child's skull, that cerebrospinal fluid gathers beneath the pericranium and bulges the pericranium and scalp. This condition is called spurious meningocele. When a spurious meningocele forms, the bone must have been broken and the dura and arachnoid ruptured. This protrusion fluctuates, pulsates, and is influenced by respiration. In some cases there is communication with the ventricles of the brain. The parietal and frontal regions are the most usual seats of the trouble. The opening in the skull may close; it may remain stationary; it may actually enlarge by bone-absorption. In some cases the spurious meningocele undergoes spontaneous cure; in some cases rupture occurs; in other cases death takes place as a result of the cerebral injury. (See Joseph Sailer on "Spurious Meningocele," "University Med. Magazine," Sept., 1900.)

Treatment.—Close the opening by a plastic operation.

[1] "Amer. Jour. Med. Sciences," Sept., 1895.

Hydrocephalus.—In *external* hydrocephalus the fluid is on the surface of the brain; in *internal* hydrocephalus the fluid is in the ventricles. Hydrocephalus may be *acute* or *chronic*, *congenital* or *acquired*.

Acute hydrocephalus is usually internal, but may be external. It results from meningitis—usually tuberculous meningitis of the base. The symptoms are headache, elevated temperature, delirium, stupor, convulsions, paralysis, and choked disk.

Treatment of acute hydrocephalus by medical means is of no avail. Tapping of the ventricles may be tried. Drainage of the cisterna magna has been suggested.

Chronic internal hydrocephalus is usually congenital, but may arise after birth in children under seven. In congenital hydrocephalus the condition may be due to circulatory disturbances in the brain of the embryo resulting from uterine disease or injury during pregnancy. Syphilis and alcoholism in parents seem sometimes to be responsible. Chronic acquired hydrocephalus results from inflammation, especially tuberculous inflammation. A tumor pressing on the veins of Galen may cause it. In chronic acquired internal hydrocephalus there is overproduction or underabsorption of cerebrospinal fluid and perhaps both conditions may exist. The usually causative condition is an inflammation of the interior of the ventricles, particularly of the choroid plexuses, and as a consequence venous return is obstructed and oversecretion occurs. In very rare cases one or both foramina of Monro may be closed, and if only one is closed, unilateral hydrocephalus may arise (Alfred S. Taylor, in "Am. Jour. Med. Sciences," August, 1904). The aqueduct of Sylvius, the foramen of Magendie, and the central canal of the cord may be, but seldom are, occluded. Guthrie ("Practitioner," July, 1910) studied 182 cases of meningitis at autopsy. In about 40 per cent. of the tuberculous cases and in 56 per cent. of the non-tuberculous cases hydrocephalus existed. A tumor may cause hydrocephalus by directly obstructing the flow of fluid from the ventricles, but a tumor far away from such a position may cause it by so increasing the intracerebral tension that the brain stem is forced down into the foramen magnum. Such a position of the pons and cerebellum cuts off the flow of cerebrospinal fluid between the subarachnoid spaces of the brain and cord. In hydrocephalus the cranium enlarges enormously and the bones of the skull are widely separated. The brain is distended and thinned and the sulci are obliterated. The broad forehead overhangs the eyes; the fontanels are elevated. The fontanels and sutures are open. The child is mentally weak or is an idiot, and very often does not learn to walk or to talk. Convulsions, palsies, and contractures are common, and blindness is frequent. Such children usually die young.

The *treatment* of chronic hydrocephalus is rarely of much avail. Pressure by strapping with adhesive plaster has been tried. Tappings through a fontanel may be performed by means of a trocar (only 2 or 3 oz. of fluid being withdrawn at a time). If much fluid is allowed to flow out, the head must be strapped with adhesive plaster afterward. If the skull ossifies, the lateral ventricles may be tapped after trephining. It has been proposed to drain by tapping the theca of the spinal cord (Quincke). This last operation is called *lumbar puncture* (see pages 861, 862). It will, of course, fail if the foramina in the floor of the fourth ventricle or the aqueduct of Sylvius are blocked. Even if they are open, it is of little service. The operation which promises most was devised by Sutherland and Cheyne, and is known as *intracranial drainage* ("Brit. Med. Jour.," Oct. 15, 1898). Their theory is that in hydrocephalus fluid distends the ventricles because the channels of communication between the ventricles and the subarachnoid spaces are closed. The subarachnoid spaces communicate directly with veins, hence fluid cannot collect under pres-

sure in these spaces. Intracerebral drainage establishes a communication between the subarachnoid space and one ventricle. It is not necessary to operate on both sides in bilateral hydrocephalus, because the lateral ventricles communicate. A small opening is made in the skull. The dura is incised. A number of strands of catgut, which are tied together, are pushed through the brain so that one end of the catgut mass lies in a ventricle and the other end beneath the dura. The dura and scalp are then sutured. Brewer makes an osteoplastic occipital flap, also a dural flap, lifts the cerebral lobe, and pushes a drain of rubber tissue into a lateral ventricle.

The elder Senn passed a rubber tube into the ventricle and put the outer end of the tube beneath the skin of the scalp.

Alfred S. Taylor ("Am. Jour. Med. Sciences," August, 1904) makes an osteoplastic flap with its base over the right mastoid, cuts a dural flap, passes a slender aspirating needle through the second temporosphenoidal convolution into the lateral ventricle, draws off a *little* fluid, and measures the thickness of the brain. He then takes 6 strands of No. 2 forty-day catgut, each strand ½ inch longer than the thickness of the brain. The strands are tied together with a spiral of catgut, 1¼ inches of the loop being left free. Three layers of Cargile membrane are wrapped about the shaft, but the tip remains free. It is carried into the ventricle along the needle track by thumb forceps, and the loops are slipped here and there, but chiefly downward, under the dura. Cargile membrane is placed between the loops and dura and the dura and skin are sutured. Taylor operated on 6 cases and 2 recovered, with relief of all signs of pressure.

The cisterna magna may be drained. Cotterill actually opened the foramen of Majendie, and the patient distinctly improved ("Lancet," Nov. 12, 1910).

Cushing, after determining by lumbar puncture that the ventricles can be emptied, obtains retroperitoneal drainage by a combined laparotomy and laminectomy. Marmion establishes drainage from the ventricles into the highly lymphatic tissues about the parotid gland ("Zentralb. für Chirurgie," August 12, 1911), and Payr, with the internal jugular vein by means of a transplanted artery or vein ("Archiv. für Klin. Chirurgie," August 26, 1911).

Puncture of the corpus callosum has been recommended by Anton and others

Injuries of the Head

Caput Succedaneum.—(See page 772.)

Cephalhematoma.—(See page 773.)

Scalp-wounds bleed profusely because the scalp is very vascular, because many of the blood-vessels are in fibrous tissue and cannot contract and retract, and because even blunt force splits the scalp almost like an incision. Scalp-wounds are treated as are other wounds. Even a large piece of scalp with only a narrow pedicle may not slough; hence try to save any piece that has an attachment. Always shave a wide area and disinfect the shaved area and the wound. Arrest hemorrhage, and exercise great care in cleansing the wound and the parts about it. Stitch the wound with silkworm-gut. Very few sutures are needed if the wound is longitudinal, but many are required if it is transverse. Deep vessels are ligated. The permanent arrest of hemorrhage from the skin and subcutaneous tissue is rarely affected by ligatures, but rather by sutures judiciously placed. If drainage is required, use a few strands of silkworm-gut; but drainage is rarely used unless we know the wound is grossly infected. Wet antiseptic dressings are used for the first few days and moderate pressure is applied by wet gauze bandages. Avulsion of the Scalp is discussed on page 273.

Contusions of the Head.—Scalp swelling from hemorrhage is usually considerable. The patient may be stunned or dazed. The swelling of *hema-*

toma of the scalp must not be mistaken for *fracture* with depression. In hematoma there is a central depression; hard pressure on the center finds bone on a level with the general contour of the bone, and the margin of a hematoma is circular, is not quite hard, and is elevated above the general contour. In depressed fracture the edge is on a level with the central depression, is below the level of the general bony contour, and the margin is sharp and irregular. The **treatment** is by bandage-pressure. If suppuration arises, at once incise.

Concussion, Contusion, and Laceration of the Brain.—For many years it was customary to regard concussion as a condition produced by molecular vibrations in the nervous substance of the brain. Duret's classical observations profoundly modified surgical thought, and led to the opinion that in concussion of the brain there is injury to the brain itself, a rupture of cerebral vessels brought about by the advance and recession of waves of cerebrospinal fluid. This wave, it is thought, first flows in the direction of the force. Keen says that there may be slight brain injuries which can properly be called "concussions," but it is better to consider concussion as synonymous with laceration of the brain. Kocher considers concussion as identical with *contusion of the brain*. It seems, however, highly improbable that slight cases of concussion are accompanied by vascular rupture or organic mischief; the symptoms are too transitory and reaction too rapid and complete to permit of any such view. Experiments on animals show we can develop concussion without laceration or contusion. Autopsies have been carefully made in some cases of death from concussion, and no organic lesion has been discovered. It is quite true that the same force which causes the concussion may cause contusion or multiple lacerations, and a severe force is apt to do so. But we are not then justified in assuming that concussion is contusion or laceration: we should rather conclude that the individual had both concussion and a demonstrable injury. Both conditions arise from violence, but the two conditions are not identical. I believe, with von Bergmann, that there is such a condition as concussion, which may be pure concussion or may be associated with organic damage, and even if a man dies and is found to have an organic injury, the concussion may have caused or, at least, have hastened the fatal result. I believe, with von Bergmann, that it is not repeated waves of force from the blow, but the concussion of the blow itself that does the harm. The brain is momentarily displaced by the blow. The blow acts on the entire brain; the centers are first stimulated and then depressed, and in fatal cases are not only depressed, but are paralyzed. The cause of concussion is violent force, either direct (as a blow upon the head) or indirect (as a fall upon the buttocks). This force momentarily displaces the brain, giving rise to stimulation and then to exhaustion of the nerve-centers, and perhaps to rupture of vascular twigs, large vessels, or even the membranes. In the less severe cases concussion only exists; in the more severe cases there is also contusion or laceration or compression soon arises.

As von Bergmann points out, the entire cortex in concussion is momentarily stimulated and then depressed. The momentary stimulation exists when a man "sees stars" as a result of a blow. The depression or exhaustion is manifested by heaviness, dulness, stupor, perhaps by unconsciousness. The stimulation of the medullary centers, von Bergmann points out, lasts longer, as a rule, than the stimulation of the cortex, and is manifested particularly by a slow pulse. If the pulse grows rapid and weaker, the pneumogastric center is becoming exhausted and the patient is in danger of death. In slight cases of concussion only the cortex may be involved, the medullary center escaping. In rapidly fatal cases of concussion the medullary centers are quickly paralyzed.

Symptoms.—In very trivial cases the patient is slightly and momentarily

dazed and the pulse is temporarily slow and weak, but he is otherwise unaffected. In a rather slight case of brain concussion the patient may or may not fall; his face is pale; he feels weak, giddy, nauseated, and confused, but he soon reacts, and often vomits. The pulse is slow for a time and then becomes normal. In a severe case he lies in a state of complete muscular relaxation. The extremities are cold; the skin is pale and cold; the pulse is small and slow. The slow pulse is due to stimulation of the pneumogastric center; the respiration varies, being sometimes deep, sometimes superficial, sometimes rapid, and sometimes irregular. He seems unconscious, but can usually be roused to monosyllabic response by shouting, pinching, or holding a bright light near his face. Occasionally, however, there is complete unconsciousness. The urine and feces are often passed involuntarily. The pupils may be unaltered, may be dilated or contracted, may be equal or unequal, but in any case they will react to light. Paralysis rarely exists, but if there is paralysis, it is temporary. The temperature at first is subnormal. In a very severe concussion in which there is great danger of death the pulse is very rapid, small, weak, and probably irregular because of exhaustion of the medullary center, and the patient is absolutely unconscious because of depression of the cortex. If there is a severe cortical laceration there will be twitchings or even general convulsions, or the patient will lie curled up with limbs flexed and eyelids shut, and will resist all attempts to open his eyes or mouth or to move his limbs (A. Pearce Gould). Erichsen called this condition "cerebral irritability." If a patient with very severe concussion and very rapid pulse is going to get better, the pulse will become slower. If a patient with severe concussion and a slow pulse is improving, the pulse will become normally rapid; if he is getting worse, it will become abnormally rapid and weaker. How long may concussion last? As von Bergmann well says: Concussion is transient in its manifestations. It is a matter of a few minutes or, at most, a few hours, and any prolongation of severe symptoms beyond this time, especially if they are intensifying as time goes on, indicates an associated injury. When the patient reacts from concussion he will probably vomit. Within twenty-four hours he usually improves, but is feverish and complains of headache and lassitude, sometimes becomes delirious, and in rare cases develops mania. If the patient in concussion recedes from, instead of advances toward, recovery, coma will set in or inflammation will develop. The prognosis is always uncertain. Any concussion producing more than very temporary unconsciousness is almost surely a serious injury, because considerable laceration has probably occurred. Recovery from concussion may be complete and permanent, but, on the contrary, the entire nature may undergo a change. Such a change, which may not be evident for weeks or months, is apt to be manifested by egotism, selfishness, censoriousness, mendacity, great irritability, outbreaks of violent rage about trivial things, and forgetfulness. The forgetfulness is particularly as to recent events. There are headaches, insomnia, attacks of depression, lassitude, and vertigo. Such a patient is very susceptible to alcohol, the heat of the sun, and physical or mental strain. He can do nothing requiring mental effort.

After concussion a patient may develop hysteria, epilepsy, amnesia, or actual insanity. A condition resembling Korsakow's psychosis may develop (a condition of confusion with gaps in memory which are filled up spontaneously by fabrications, the patient also having multiple neuritis), melancholia, confusional insanity, or mania may arise, or a condition like hallucinatory paranoia or mental weakness, which may resemble paresis. Concussion may pervert or wipe out all memory of the causative accident and also, strange to say, of a varying period preceding the accident. The loss of memory of the accident is permanent; the amnesia for a period preceding the accident may

be permanent or may only be temporary. Statements made regarding an accident by one who has had concussion must be received with many grains of salt. A man may tell a story he believes himself, and yet it may be a mass of dream fancies without a word or with scarcely a word of truth.

Treatment.—In treating brain concussion bring about reaction by the administration of aromatic spirits of ammonia (no alcohol, as this agent excites the brain), by pouring a few drops of ammonia on a handkerchief and holding it near the nose, by surrounding the patient (who lies in bed with his head on a pillow) with hot bottles, by hot irrigation of the head, by the application of mustard over the heart, and by the administration of enemata of hot coffee or hot saline fluid. Do not pour fluid into the patient's mouth until be becomes able to swallow easily. If he cannot easily swallow, rely on hot enemata and hypodermatic injections of strychnin. Place the patient in bed in a quiet room and watch him. If reaction is inordinate, apply cold to the head, give arterial sedatives and diuretics, and purge. For some days or for some weeks, according to the case, insist on a very quiet life. For many weeks after a grave concussion a patient must be kept away from business and be watched, because of the possibility of an abscess of the brain arising, and because of the liability of such patients to develop hysteria, neurasthenia, or insanity. Give a plain diet containing a minimum of meat, administer an occasional purgative, and secure sleep. Sleep can often be obtained by some simple expedient, such as the administration of warm milk, placing a hot-water bag to the abdomen or feet, or applying a mustard plaster for a short time to the back of the neck. In cases in which obstinate wakefulness exists, it becomes necessary to give bromid, chloral, sulphonal, trional, or some other hypnotic. Morphin is avoided because it is thought to increase venous congestion of the brain, but the elder Gross often used it, especially in cerebral irritation. If signs of compression arise, it is best to trephine, as the compressing agent may be a clot (see page 786). If inflammation arises, some surgeons will not trephine; but most regard it as wise and proper, especially if the damage seems to be localized, to incise the scalp and inspect the bone. If a fracture is discovered and the symptoms are serious, perform an exploratory trephining, open the dura, and secure drainage for inflammatory products. Personally, I believe that trephining for drainage is indicated in such cases even when there is no fracture.

In any severe concussion of the brain with contusion of the scalp the surgeon should at once incise the scalp and inspect the bone.

Compression of the Brain.—The combination of symptoms indicative of cerebral compression may be present in a number of different conditions. We find these symptoms in abscess of the brain, tumor of the brain, intracranial hemorrhage, foreign bodies, inflammatory exudate, and fracture of the skull with marked depression. The symptoms of compression are expressive of impairment of the functions of the entire brain by insufficient and imperfect circulation of blood, this impairment of circulation being the result of a lessening in capacity of the cavity containing the brain, its membranes, the blood-vessels, and the cerebrospinal fluid (von Bergmann). Duret injected wax within the cranium of an animal and showed that a diminution of 5 per cent. in the intracranial capacity produced somnolence, and a diminution of 8 per cent. caused death. If a brain tumor, abscess, blood-clot, or portion of depressed bone occupies space previously given to brain matter, vessels, etc., there is less room within the skull to contain the special structures. The bones cannot yield, the brain is incompressible, so the cerebrospinal fluid is displaced, the vessels are squeezed, and the circulation is greatly impeded. Pressure upon either arteries or veins causes compression. This condition of cerebral pressure or compression is one of anemia. In reality it is compression of the vessels which feed the brain with blood, and such compression grievously disturbs

the normal relationship between the blood-supply of the brain and the circulation of cerebrospinal fluid. Compression begins in obstruction to the onflow of venous blood. It extends gradually to the arteries. The circulation is slowed, and because of slow circulation the activity of the centers is finally inhibited. It is stated by Cushing that the rise which occurs in the blood-pressure is conservative and is expressive of Nature's effort to maintain the circulation in the compressed medullary centers. Increased vascular tension is made manifest by estimating the blood-pressure and observing venous stasis in the optic disk. Increased tension of cerebrospinal fluid is shown by lumbar puncture. The fluid flows out rapidly or jets out. The cortex is temporarily stimulated and then depressed, because of impairment of nutrition. The medullary centers are first stimulated. The respiratory center is stimulated by retention of CO_2 in the blood, then the vasomotor center is stimulated, then the vagus, and finally, perhaps, the convulsive center (von Bergmann's "System of Practical Surgery"). The stimulation of the cerebral centers is followed after a time by weakening or actual paralysis. The centers are said to suffer in regular order, viz., the cortex, the corona radiata, the gray matter of the cord, and, finally, the medulla (Huguenin). As von Bergmann points out, by the time the convulsive center becomes stimulated the cortex is usually exhausted and the patient is unconscious. In compression the sensitive cortex first feels the effect and feels it most gravely, and the cortical impairment may last long after other trouble has passed. In some cases the cortex alone seems to be distinctly involved. When the vagus center is stimulated the pulse becomes slow; later, as the center becomes exhausted, it becomes rapid and weak, and this change has the same unfavorable significance as in concussion. If death occurs it results from paralysis of respiration and not of circulation. The displaceable cerebrospinal fluid is a great safeguard against compression, but Cushing has shown us that in intracranial obstruction of the venous circulation the flow of cerebrospinal fluid into the space about the cord is prevented because the medulla and cerebellum are jammed down in the foramen magnum.

Symptoms.—*Pressure symptoms* are divided into those occurring during the period of stimulation and those occurring during the period of increasing exhaustion. The symptoms of the first stage are headache, vomiting, flushing of the face, contraction of the pupils, choked disk, mental excitement, elevation of blood-pressure, restlessness, and slowing of the pulse. The pulse becomes slow, regular, and strong. The symptoms of the second stage are heaviness, dulness, drowsiness, passing into stupor, and finally into coma. The respirations are stertorous and after a time become Cheyne-Stokes. The pulse is weak, intermittent, compressible, and increasingly rapid. There are involuntary evacuations of feces and urine, and finally paralysis of respiration which causes death, the heart beating for a time after respiration has ceased (von Bergmann's "System of Practical Surgery").

The *headache* usually present in the first stage of compression is intense, persistent, sometimes general and sometimes more or less localized, and often aggravated by percussion of the cranium. It persists even in delirium, and the patient ceases to appreciate it only when unconsciousness begins. The *vomiting* is usually without nausea and is due to stimulation of the medullary center. At first vomiting may arise from taking food, but it soon continues independent of food. The tongue is probably clean. Cerebral vomiting is usually associated with severe headache. *Restlessness* is a pressure symptom in the stage of stimulation, and the patient rolls his head, tosses his body, and groans with pain. The *heart* does not begin to slow until the patient begins to be dull and drowsy, or until stupor arises, when the pulse slows and the

tension rises. Finally it becomes very slow—perhaps less than 40 in a minute. If the condition grows worse, the pulse after a time suddenly becomes rapid and of low tension, instead of slow and of high tension, a most unfavorable sign, indicating exhaustion and approaching paralysis of the vagus. In the stage of stimulation the patient is excited, unstable, delirious, and the condition of delirium gradually gives way to drowsiness, stupor, and coma. In some cases of compression there is distinct protrusion of the eyeballs. Before the patient becomes unconscious the pupils are contracted. When the patient is comatose, they are usually dilated, but may be contracted. In coma the pupils respond slowly to light or not at all. If the conjunctival reflex is gone, they will not respond at all (Gowers). In a lesion making unilateral compression toward the base the pupil on the side of the compressing cause is apt to be much dilated and even immobile. *Choked disk* begins in the stage of stimulation and continues to the end. That choked disk is due to intracranial pressure seems demonstrated by numerous operation reports, especially by Cushing, of Harvard, in which relief of pressure abated choked disk (see page 811). The existence of choked disk is determined by the use of the ophthalmoscope. The respirations become stertorous or snoring as coma develops because of the vibrations of the relaxed palate in the air-current, and the cheeks flap during expiration. As the activity of the respiratory center fails from increasing anemia, the respirations become shallow and infrequent, or, perhaps, of the Cheyne-Stokes type. Gowers defines Cheyne-Stokes breathing as "alternating periods of decreasing and increasing depth of breathing, separated by a pause" ("Lectures on Diseases of the Brain"). The *unconsciousness of compression* may be sudden or gradual, may be partial or complete. Apoplexy and many traumatisms cause immediate unconsciousness: the irritation of such a sudden lesion at once inhibits the cortex. A meningeal hemorrhage causes a gradually increasing unconsciousness. A brain tumor may cause heaviness, dulness, stupor, or, perhaps, after a long time, even coma. If compression comes on gradually, the brain more or less accommodates itself, and unconsciousness, if it occurs at all, is considerably deferred. A sudden increase of pressure may produce immediate unconsciousness. *Stupor* is partial unconsciousness, a condition in which a person lies as though asleep, though he arouses partially and temporarily when positively spoken to. In profound coma the limb reflexes are usually but not always diminished or lost. The superficial reflexes are impaired or lost. The muscles are flaccid and swallowing is impossible. In coma there is incontinence of feces and either incontinence or retention of urine. There may be the incontinence of retention. The *temperature* of a patient suffering from compression varies. In traumatic cases it may be at first subnormal and later normal or elevated. In inflammatory conditions it is elevated, except in abscess of the brain, in which it is subnormal, for a time at least, in half the cases. After an apoplexy it is for a time subnormal, but as shock passes away it becomes somewhat elevated. Any sudden compression causes shock and temporarily subnormal temperature. Lesions of the pons and medulla cause elevation—perhaps remarkable elevation—of temperature. In great or sudden brain compression complete coma always exists and there is no voluntary movement. In cerebral compression *paralysis* may exist, which may be very limited (monoplegia), may be of one side (hemiplegia), or may be general. In hemorrhage into the interior of the brain the unconsciousness is immediate or nearly so. In bleeding from the middle meningeal artery a period of consciousness intervenes between the injury and the coma, during which period blood collects and the coma comes on gradually. In compression from depressed fracture or from a foreign body the symptoms usually come on at once, but they may be deferred for some hours. Compression from inflammation or pus begins gradually after a considerable time has elapsed. The symptoms

described as pressure symptoms are those of pure compression. When traumatism causes the condition, the compression symptoms are mingled with those of concussion, or perhaps of contusion or hemorrhage. The brain adjacent to any lesion causing compression suffers more than the brain distant from it. The blood-supply of the entire brain is affected, but the adjacent brain has its capillaries particularly and directly compressed. Hence limited paralysis is sometimes produced by compressing lesions. The course of compression depends on the nature and persistence of the cause. Great temporary pressure may produce no permanent harm. Moderately severe pressure may be recovered from even after weeks of stupor. Great pressure, sufficient to induce coma, if not relieved quickly, will cause death. Persistent cerebral symptoms after a head injury, when no obvious lesion can be made out, are probably due to edema of the brain.

Determination of the Cause of Coma in a Patient.—A diagnosis must be made between coma due to brain injury and the comatose condition of apoplexy, uremia, epilepsy, hysteria, diabetes, opium-poisoning, and alcoholic intoxication. In hospital practice cases of unconsciousness without a known history are frequent. In attempting to diagnosticate, examine carefully for any evidence of traumatism, and inquire as to how and where the patient was found, if any fit occurred, and if a bottle or a pill-box was found near by or in the pockets. The surgeon should himself examine the pockets. Smell the breath to notice alcohol or opium, but always remember that an alcoholic is often a victim of Bright's disease, that a man with Bright's disease is liable to apoplexy, that a man may be stricken with apoplexy while he is drunk, and may fracture his skull by falling when under the influence of opium or of alcohol. The odor of acetone (violets) on the breath or in the urine indicates the existence of diabetes. Draw the urine with the catheter if any water is in the bladder. Examine the urine for albumin, acetone, and sugar, and take the specific gravity. In doubtful cases of coma have an ophthalmologist use the ophthalmoscope. He might find optic atrophy, indicative of Bright's disease, or choked disk, indicating compression. The cerebrospinal fluid obtained by lumbar puncture should contain blood if hemorrhage has taken place beneath the cerebral dura or in a ventricle of the brain. This test is valuable in fracture of the base of the skull, for in this condition cerebrospinal fluid is usually bloody. In *postepileptic coma* the temperature is never below normal, there are no unilateral symptoms, the condition resembles sleep, and the patient can be aroused. *Hysterical coma* occurs in boys and women; there are no objective symptoms, and the patient, though swallowing what is put into his mouth, cannot be aroused. In *uremia*, besides the condition of the urine (and always remember that a person with albuminuria is apt to develop apoplexy), there is a persistent subnormal temperature, and convulsions are prone to occur. There is perhaps edema of the legs, but paralysis and stertor are absent. In *apoplexy* hemiplegia exists, and the initial temperature is for a short time subnormal. A single convulsion may have ushered in the case. *Alcoholic unconsciousness* is often diagnosticated when apoplexy really exists. A man will smell of alcohol who has had one drink, but one drink will not produce coma; hence the smell of alcohol is not conclusive. In any case of doubt some hours of watching will clear up the diagnosis. Regard a doubtful case as serious until the truth is clear. In *opium-poisoning* the pupils are contracted to a pin-point, the respirations are usually slow, shallow and quiet, and may be stertorous, but there is no paralysis. Always remember that hemorrhage into the pons will produce pin-point pupils, but it also causes paralysis (crossed paralysis if in the lower half of the pons) and high temperature with sweating. In opium-poisoning the temperature is subnormal. In *diabetic coma* the pupils will react to a very bright

light, the temperature is subnormal, and the breath and the urine smell of acetone. (See Acidosis, page 1207, and Diabetic Coma, page 175.)

Treatment of Brain Compression.—The treatment of brain compression depends on the cause. Hemorrhage (extradural or subdural) requires trephining and arrest of bleeding; coma from depressed fracture demands trephining and elevation; foreign bodies must be removed; abscesses must be evacuated; some tumors are to be removed. In many tumor cases the growth is not removed, but a decompression operation is performed (see page 831). In cerebral compression, if death is threatened by respiratory failure, make artificial respiration and at once trephine over the supposed region of compression. Horsley has shown that irrigation of the head with hot water is of great value in bringing about reaction from shock in cases of brain injury.

Intracranial hemorrhage may be either *spontaneous* or *traumatic*. In the vast majority of instances spontaneous hemorrhage comes from the lenticulostriate artery (Charcot's artery of cerebral hemorrhage), and produces apoplexy, a disease belonging to the physician, except in some ingravescent cases, for which ligation of the common carotid on the same side as the rupture has been advised. In adults traumatism is almost always the cause of a meningeal hemorrhage. The blood may flow from a sinus, from the middle meningeal artery or one of its branches, or from vessels of the pia. Traumatism during delivery is an occasional cause of hemorrhage from the middle meningeal artery (Richardière) and a not unusual cause of hemorrhage from cortical veins. Violent paroxysms of coughing in whooping-cough occasionally produce extradural hemorrhage or subdural hemorrhage. Geo. S. Brown reported such a case. He diagnosticated the condition and operated successfully ("New York Med. Jour.," April 25, 1903).

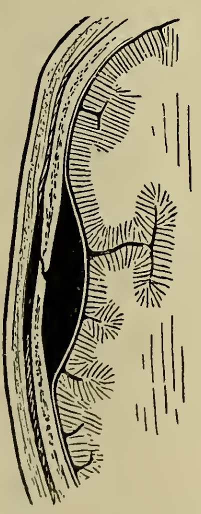

Fig. 511.—Fracture of skull with middle meningeal hemorrhage. Compression of brain by blood (Scudder).

Traumatic Intracranial Hemorrhage.—Hemorrhage may take place—(1) between the bone and the dura (*extradural*); (2) between the dura and the brain (*subdural*), and (3) in the brain substance (*cerebral*).

Extradural meningeal hemorrhage arises usually from the middle meningeal artery or from one of its branches. A spicule of bone may penetrate a venous sinus and produce extradural hemorrhage, or a sinus may rupture. Rupture of the meningeal artery or one of its branches is usually, but not always, accompanied by fracture (Fig. 511); in fact, in some cases not even a bruise can be found (Fig. 512). The ruptured vessel may be upon the opposite side to that on which the force was applied, hence the evidence of scalp injury is not a certain sign of the side of the skull involved. The accident may or may not cause temporary unconsciousness; but even if it does, from this unconsciousness the patient almost always reacts unless there are other grave injuries, and there is usually a *distinct period of consciousness* between the accident and the lasting coma, the coma being due to pressure from a continually increasing mass of extravasated blood (Fig. 513). If the main trunk or a large branch is ruptured the period of consciousness is short; if a small branch is ruptured the period of consciousness is prolonged for hours or perhaps for days. As the clot forms and enlarges the patient becomes heavy, dull, stupid, and sleepy; he sleeps so soundly he can scarcely be aroused, and snores loudly, and finally passes into stupor and then into coma.

The other signs of this condition are paralysis of the side opposite the blood-clot (not necessarily of the side opposite the point of application of the force, for the artery may rupture from contre-coup on the uninjured side); this paralysis is apt at first to be localized, but it gradually and progressively widens its domain. If the clot extends toward the base, the pupil on the same side as the clot ceases to react to light, and the immobile pupil dilates widely. If the clot be on the left side, aphasia may be noted. As the clot enlarges adjacent centers become involved. The face becomes paralyzed, then the arm, and finally the leg. Not unusually epileptiform attacks occur, starting in discharges from the centers which are irritated by the advancing clot before their function is abolished by pressure. The pulse becomes full, strong, usually slow, but occasionally frequent; the breathing becomes stertorous; the temperature rises, that of the paralyzed side exceeding that of the sound side. In a compound fracture the pressure of escaping blood may force brain matter out of the wound. In extradural hemorrhage from a sinus the symptoms cannot be differentiated from those produced by arterial rupture.

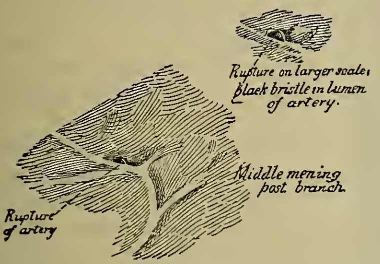

Fig. 512.—A case of rupture of middle meningeal artery. Preparation of dura. In the Warren Museum. The specimen is viewed from the outer side (Scudder).

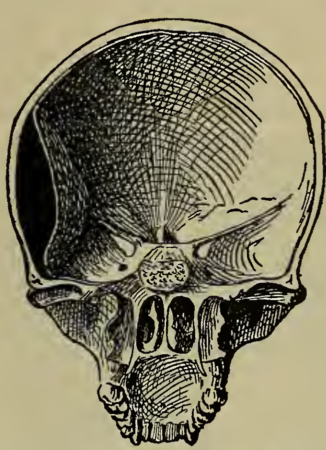

Fig. 513.—Frontal section of skull. Middle meningeal hemorrhage. The dura bulges inward toward the skull cavity (diagram) (Scudder).

Treatment.—In treating extradural hemorrhage localize the clot, not by the seat of the wound or contusion, but entirely by the symptoms. In a doubtful case endeavor to bring about reaction; but if the state of shock deepens or does not improve and if pressure symptoms increase, operate at once. To reach the middle meningeal artery or its anterior branch trephine $1\frac{1}{4}$ inches back of the external angular process, at the level of the upper border of the orbit (see Figs. 502, 509, 510). If the incision does not expose the clot, trephine again at the level of the upper border of the orbit and just below the parietal eminence (see Figs. 509, 510). The first incision gives access to the main trunk and to the anterior branch; the second incision exposes the posterior branch. If signs indicate that the clot is traveling to the base, the trephine should be used $\frac{1}{2}$ inch lower than the point first directed. Arrest bleeding by a suture ligament or by packing (see page 452), and always open the dura and inspect the brain. By this procedure a subdural hemorrhage may be discovered which, without it, would have been missed. Drainage must be employed.

Subdural meningeal hemorrhage is usually due to depressed fracture and rupture of the middle cerebral artery or of a number of small vessels.

The *symptoms* are identical with those of extradural bleeding, but are usually very rapid in onset and are accompanied by a more distinct drop in temperature and graver depression. The cerebrospinal fluid obtained by lumbar puncture is bloody.

The *treatment* is trephining for exploration at a point $1\frac{1}{4}$ inches back of the external angular process, enlarging the opening upward and backward by a rongeur, opening the dura, turning out the clot, ligating the bleeding point or packing, elevating any depression of bone, draining, and stitching the dura by catgut. Hemorrhage from internal pachymeningitis requires the same treatment.

Cerebral Hemorrhage.—The *symptoms* of cerebral hemorrhage are identical with those of apoplexy. The *treatment* is the same as that for apoplexy, except in ingravescent cases, when the common carotid on the same side as the clot may be ligated.

Rupture of a sinus may arise without a bone injury, but is usually due to a compound fracture. A sinus may be wounded during a brain operation. The **treatment**, if the rupture happens from fracture, is trephining. Enlarge the bone opening by the rongeur, pack with *one large piece* of iodoform gauze, or catch the rent with hemostatic forceps, leaving them in place for three or four days, or apply a lateral ligature or a suture ligature. Elevate depressed bone. If during an operation a sinus should be wounded, use a lateral ligature, a suture-ligature, or control hemorrhage by packing.

Intracranial Hemorrhage in the Newborn.—Certainly most of the cases of birth palsy seen in children are the result of subdural and subarachnoid hemorrhage at birth and damage of the cortical motor area. In such conditions there is spastic paralysis of the hemiplegic type, or if both hemispheres suffered there is plastic diplegia and usually amentia (Cushing, in "Amer. Jour. Med. Sciences," Oct., 1905). It has not been the custom to operate for hemorrhage in the newborn; most of the cases do not die, but remain for life weakened and paralyzed, epileptic, or idiotic.

The hemorrhage in cases of birth palsy is, as Cushing points out, usually venous and due to "rupture of some of the delicate and poorly supported venous radicles of the cerebral cortex" (Ibid.). It may result from traumatism due to bone overlapping or forceps pressure during parturition, or may arise during asphyxia after birth. Cushing discovered in examining stillborn infants and infants that died soon after birth that many of them died from cortical hemorrhage. In some the extravasations were very large, in fact, completely overlying a cerebral hemisphere. In some they were much smaller. In one the clot was in the cerebellar fossa.

The vessels usually torn are on one side and are the unsupported venous radicles which enter the longitudinal sinus, hence the leg center of one side is the cortical area most apt to be gravely damaged. If the vessels of both sides are torn, a bilateral cortical lesion results.

Symptoms of Hemorrhage in the Newborn.—In Cushing's masterly paper (Ibid.) the symptoms of recent hemorrhage are set forth. There is the history of a long and difficult labor, forceps perhaps having been used, or a history of postpartum asphyxiation. The fontanel bulges and perhaps does not pulsate. The fluid obtained by lumbar puncture contains blood-corpuscles. There is usually twitching and, as a rule, convulsions occur. They may occur soon after birth or not for several days. When they occur soon, they may be general; when they occur later, they may be unilateral. Paralysis is rare in the early days after birth. There may be alterations in the circulation and respiration. Pupillary alteration and ocular palsy seldom occur. If the child is not operated upon it may die or it may apparently recover. If it apparently recovers after a considerable hemorrhage, several months may pass before ominous symptoms are recognized. The late manifestations of the disease may be "spastic palsies, or blindness, or deafness, or feeble-mindedness, or, in severe cases, even complete amentia" (Cushing). Epilepsy may be a result.

Treatment.—Osteoplastic craniotomy in the parietal region, on one side or both, according to the unilateral or bilateral nature of the hemorrhage;

opening of the dura; washing out and turning out the clot; suturing the dura and closing the scalp without drainage. Cushing reports 4 cases, in 1 of which operation was done on both sides. He says chloroform should be given and that the parietal bone can be cut with blunt, curved scissors.

Fractures of the skull may be *simple, compound, depressed, non-depressed,* or *punctured. Fracture by diastasis* means separation of a suture or of sutures by violence. A fracture of the skull may be produced by a *bending* force, by a *bursting* force, or by an *explosive* force (see Gunshot-wounds).

A bending force is usually applied by the forcible impact of a body of small area. It produces a fracture and seldom causes distant injuries. The fracture may be of the inner table only, or of both tables. If both tables are fractured the broken bone is displaced and remains so.

In fracture by bursting, lines of fracture run to distant points from the seat of application of the force. Such an injury is inflicted by the impact of a flat surface of considerable area. In some cases we have a force which first is bending in character, but causes bursting to also occur, because there is no rebound.

Falls of large heavy objects or falls on the head, blows on the head from large flat objects, crushes in railroad accidents, etc., may burst the skull. In bursting fracture there is often widespread injury. The skull may be fractured during labor.

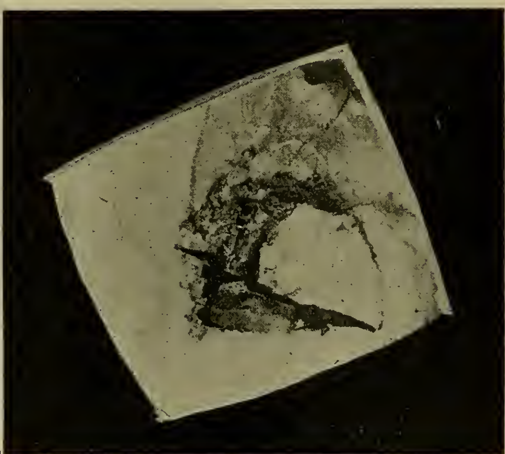

Fig. 514.—Fracture of the vault with extensive depression of the inner table ("American Text-Book of Surgery").

Fractures are divided into fractures of the *vault*, usually due to direct force, and fractures of the *base*, due to extension of fractures of the vault, to indirect violence (a fall upon the feet, the buttocks, or the vault), to forcing of the condyles of the lower jaw against or through the base, or to foreign bodies breaking through the orbit, vault of the pharynx, the ear, or the roof of the nostrils. *Fracture by contre-coup* was the name long given to a fracture which was supposed to occur on the side opposite the point of application of the violence. It is very doubtful if such a fracture ever occurs. I have seen meningeal hemorrhage by contre-coup, but not fracture. Fractures of the skull are uncommon in early youth, but they are much more frequent in the aged. Usually the entire thickness of the bone is fractured, but either the outer or the inner table (Fig. 514) may be broken alone. In complete fractures the inner table is broken more extensively than is the outer table, because the inner table is the more brittle, because the force diffuses, and also, as Agnew taught, because the inner table is part of a smaller curve than is the outer table, and violence forces bone-elements together at the outer table, but tears them asunder at the inner table (Figs. 515, 516).

Fractures of the Vault.—A fracture may involve the vault alone, but in over 60 per cent. of such fractures the base is involved. A fracture of the vault of the skull may be simple and undepressed, or it may be depressed (Fig. 514), compound, or comminuted (Fig. 517). A mere crack may exist in a bone, and if a rent exists in the soft parts, a bit of dirt or a hair may be caught in the crack. Fractures of the vault arise from direct force. A *fissure* may escape recogni-

tion, although in some cases percussion gives a "cracked-pot" sound. Any considerable depression can be detected. In a simple fracture occasionally the cerebrospinal fluid collects under the scalp and forms a tumor which pulsates and becomes tense on forcible expiration (see Spurious Meningocele, page 777). Compound fracture can be readily recognized, but do not mistake a suture, a

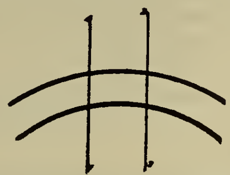

Fig. 515.—Section of outer and inner tables, with two parallel lines (after Agnew).

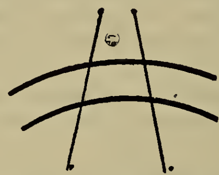

Fig. 516.—Greater yielding of the inner table than of the outer after the application of violence (after Agnew).

Wormian bone, or a tear in the pericranium for a fracture. A fracture bleeds, a suture does not. Even a narrow fracture is marked by a dark line of blood which *sponging will not remove.* Fracture of the inner table alone can only be suspected unless the x-rays make it evident. The prognosis of fracture of the vault depends upon the extent of intracranial injury rather than upon the extent of bone injury. Simple fractures may unite by bone; compound fractures with loss of bone unite only by fibrous tissue. The dangers may be *immediate* (hemorrhage, brain injury, and septic inflammation) or be *distant* (epilepsy, insanity, and persistent headache). In an open fracture the danger of infection is added to the danger of brain injury.

Fig. 517.—Fracture of skull with depressed fragments. Compression of brain by bone (Scudder).

Treatment.—The mortality of fracture of the skull was formerly much greater than at present. Before the days of antisepsis it was 51 per cent. (Harte). Trephining is performed much oftener than was once the custom, and is vastly safer. Out of 26 trephined cases, 3 died (Harte). In any case of fracture of the skull endeavor to bring about reaction before operating, unless the signs of pressure continually increase or the evidences of shock remain unimproved or become graver. A *simple fracture without depression* and *without brain symptoms* is treated expectantly (by rest, quiet, low diet, purgation, moderate elevation of and cold to the head, and arterial sedatives). A *simple fracture with moderate depression* and *without cerebral symptoms* is treated expectantly, and so also is a *simple fracture* in which *symptoms existed but are abating. Simple fracture with marked depression* requires immediate trephining, even when brain symptoms are absent. We make an exception in young children, and wait a while before trephining, in the expectation that the expansile brain will lift the depressed but elastic bone up to the level. Trephining in cases in which no symptoms exist, although there is marked depression, often prevents disastrous consequences arising in the future, and is known as *preventive trephining* (Agnew, Keen, Horsley, Macewen, von Bergmann, and others). In all *compound fractures* shave and asepticize the entire scalp, enlarge the incision, and explore the bone. If a fissure exists, it must be asepticized, and if a hair or other foreign body is found in it, in order to effect removal and secure asepsis the outer table of the

skull at this spot must be cut away by a chisel, the fissure being thus converted into a broad groove. In a *compound fracture with much depression* trephine, elevate, and irrigate. In any fracture trephine if distinct symptoms exist. In punctured wounds of the brain (*punctured fractures*) *always* trephine, open the dura, and disinfect. In a comminuted fracture the usual custom is to remove loose fragments. Schaak has recently advocated their reimplantation ("Archiv. für klin. Chir.," April 6, 1912). My usual custom has been to remove them. In any case of fracture of the vault in which trephining has been performed it is wise to open the dura and examine the brain. In an open fracture and after every operation of trephining in which the dura was opened administer urotropin in order to make the cerebrospinal fluid bactericidal.

Fractures of the Base.—A fracture of the base of the skull may exist in only one of the three fossæ, in two of them, or it may involve all. Figure 518 shows an extensive fracture of the base of the skull. The middle fossa is oftenest involved. Fracture of the posterior fossa is the most fatal. These fractures may be due to direct violence, to indirect force, and to extension of a fracture of the vault. Extension from the vault is always by the shortest route. Fractures of the base may extend up into the vault, and do so in over 80 per cent. of cases. Fracture by direct violence may arise from the penetration of the nasal roof, the orbital roof, or the pharyngeal roof by a foreign body. The posterior fossa may suffer from a fracture by direct violence applied to the neck. Fractures by indirect force may arise from blows upon the frontal bone (the orbital portion of the frontal or the cribriform process of the ethmoid breaking), from falls upon the chin (the condyle of the jaw breaking the middle fossa), or from falls upon the buttocks, the knees, or the feet (fracture occurring in the posterior fossa). The base is not broken by contre-coup.

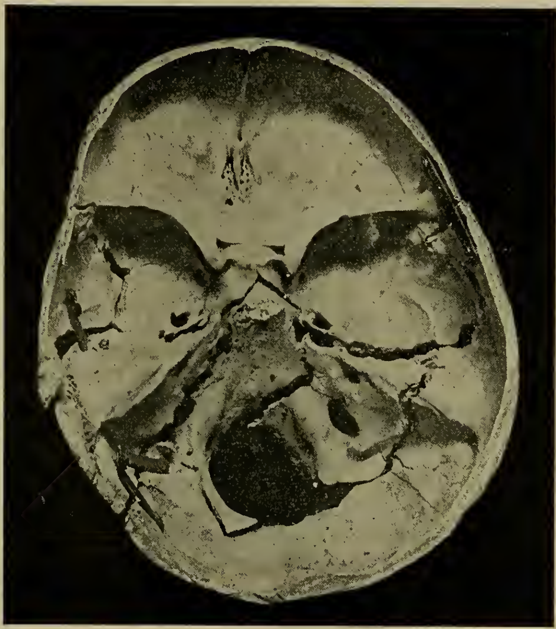

Fig. 518.—Extensive fracture of the base of the skull ("American Text-Book of Surgery").

Symptoms.—Fractures of the base of the skull are apt to be compound. A solution of continuity in the pharynx, roof of the nares, orbit, or ear permits access of air to the seat of fracture and allows blood and cerebrospinal fluid to flow externally. In *fracture of the anterior fossa* the fracture may be compound because of laceration of the mucous membrane of the nares or of the conjunctiva. Blood may run from the nose, its source being the vessels of the mucous membrane or the dura, the fracture being compound. Epistaxis does not prove the fracture to be compound, but only suggests it; but if the epistaxis is prolonged, the probability is greatly increased; and if the flow of blood is succeeded by a flow of cerebrospinal fluid the diagnosis of compound fracture is positive. Cerebrospinal fluid appears only when the mucous

membrane, the dura, and the arachnoid are each lacerated. In fractures of the anterior fossa blood is apt to flow into the orbit, producing *subconjunctival ecchymosis*, and perhaps pushing the globe of the eye forward. Some blood is often swallowed and vomited. In *fractures of the middle fossa* blood may flow from the ear through a tear in the tympanum, its source being the vessels of the tympanum, the meningeal vessels, or a sinus. Blood may flow through the Eustachian tube and come from the nose, may be spat up, or may be swallowed and vomited. In some cases a quantity of cerebrospinal fluid flows from the ear, the discharge being increased by expiratory effort and a position which favors gravity. Cerebrospinal fluid is at first blood-stained, but later becomes clear. The cerebrospinal fluid must not be confused with either blood-serum or liquor Cotunnii. The cerebrospinal fluid, if it flows at all, is always present in large amount; the liquor Cotunnii can be present only in minute amount. Blood-serum is highly albuminous; cerebrospinal fluid is a serous fluid of very low specific gravity, never shows more than a trace of albumin, and contains considerable chlorid of sodium and a carbohydrate now known to be a dextrose which reduces the copper of Fehling's solution and reacts to Trommer's and to Moore's tests, but does not refract polarized light nor easily ferment with yeast. Treves[1] states that cerebrospinal fluid cannot flow from the ear in fractures of the middle fossa —(1) unless the line of fracture crosses the internal meatus; (2) unless the prolongation of the membranes into the meatus is torn; (3) unless a communication exists between the internal ear and tympanum, and (4) unless the drum-membrane is torn. Miles, of Edinburgh,[2] claims that bleeding from the ear followed by a flow of cerebrospinal fluid is not pathognomonic of fracture of the middle fossa of the base. He maintains that when the drum is ruptured we may have these signs; when bone is not broken the chief source of the blood being the vessels of the pia and temporosphenoidal lobe, the blood and cerebrospinal fluid flowing inside the sheath of the auditory nerve, passing into the vestibule, through the lamina cribrosa, and from the vestibule into the middle ear, finding exits from this space by way of the Eustachian tube and also through the rent in the drum-membrane. Profuse mucous discharge may flow from the ear after an injury without fracture when the drum is ruptured, the fluid coming from the cells of the mastoid. It must be understood that fracture of the base may exist when there is no flow of blood or of serous fluid. A fracture of the middle fossa is usually compound, made so, even when the drum is not ruptured, by the Eustachian tube, and there is often paralysis of the seventh or eighth nerve or of both of them. In *fracture of the posterior fossa* there is usually respiratory derangement and blood accumulates beneath the deep fascia and produces discoloration in the line of the posterior auricular artery (*Battle's sign*), the discoloration first appearing near the tip of the mastoid. The discoloration appears in the line of nerves and vessels which emerge from the deep fascia, the vessels passing through openings and the extravasated blood emerging from the same openings. Fractures of the posterior fossa are apt to be compound through the pharynx, and in such cases the patient spits or vomits blood. Fractures of the posterior fossa are more fatal than fractures in either of the other fossæ because of the adjacency of vital centers. Fractures of the base are apt to be associated with *paralysis of cranial nerves*. The palsy indicates the situation of the fracture. In fracture of the anterior fossa the olfactory nerve may suffer. In fracture of the middle fossa the fascial nerve most often suffers. The eighth is sometimes injured. Other nerves which may suffer alone or in combination in fracture of the base are the abducens, the motor oculi communis, the trigeminus, the pneumogastric, the optic, the spinal accessory, the hypoglossal, and the glossopha-

[1] "Applied Anatomy." [2] "Edinburgh Med. Jour.," Nov., 1895.

ryngeal. *Optic neuritis* often arises after the first week. In fractures of the base the temperature is subnormal during the shock, rises to 100° to 101° F., falls again to about normal, and remains normal or subnormal unless there is inflammation or sepsis. Lumbar puncture may obtain bloody fluid. Such a finding means subarachnoid bleeding and indicates fracture. In any fracture injury of the brain may exist. Such an injury will be made manifest by symptoms, and we may or may not be able to diagnosticate and localize it. The prognosis is greatly influenced by the nature and extent of the intracranial damage. Harte ("Annals of Surgery," Oct., 1901) has collected 46 positive cases of fracture of the base of the skull from the records of the Pennsylvania Hospital; 35.5 per cent. recovered. Ransohoff collected 190 cases of fracture of the base of the skull. The mortality was 65 per cent. Over one-half of the fatalities were within twelve hours. Only 15 per cent. died after the second day. Of 98 cases with profound coma and respiratory disturbance 70 per cent. died ("Annals of Surgery," July, 1910). According to Hartley, in cases treated expectantly the mortality is 90 per cent., in cases treated by operation it is less than 35 per cent. ("Am. Jour. of Surgery," Dec., 1910).

Treatment.—In fracture of the base I now always do a subtemporal decompression, usually on both sides, as Cushing advocates. This is, first of all, exploratory, and may disclose a bleeding meningeal artery. After the dura is opened it enables us to evacuate fluid causing pressure and in which bacteria could multiply, and to prevent recurrence of pressure after the wound has been closed. If there is bleeding under the dura the brain should be lifted to let the blood out, and a drain of rubber tissue should be inserted. If there is only brain edema no drain is required. In some cases drainage has been obtained from the anterior fossa by breaking through the cribriform plate and introducing a tube by way of the nostril (Allis), and from the middle fossa by trephining above and behind the external auditory meatus. In a compound fracture of the orbit disinfect and drain. It may be necessary to trephine the roof of the orbit to secure drainage.

In addition to performing decompression I always give urotropin, as advised by surgeons in Johns Hopkins Hospital (S. J. Crowe, in "The Johns Hopkins Hospital Bulletin," April, 1909). This drug renders the cereborspinal fluid bactericidal. Other methods of treatment are secondary to the above. My experience is that this plan saves many cases which would otherwise perish. In treating a compound fracture of the base of the skull disinfect any cavity involved. In fractures of the middle fossa with ruptured drum clean the ear mechanically, wash it out by a stream of warm salt solution (turn the head toward the affected side while washing, so that the solution will not run down the Eustachian tube), insufflate iodoform, insert a piece of iodoform gauze, and apply an antiseptic dressing. Several times daily the ear is to be irrigated and insufflated with iodoform. The nasopharynx must be frequently irrigated by normal salt solution or boric acid solution and insufflated with iodoform. The conjunctival sac is frequently irrigated by boric acid solution. If after a head injury blood accumulates back of the drum, this membrane should be incised to permit of drainage and disinfection. In fractures of both the middle and anterior fossæ and in fractures of the posterior fossa communicating with the pharynx the nasopharynx must always be cleaned. The exact method depends on the choice of the surgeon. We may wash out these cavities frequently by hot water, next by peroxid of hydrogen, and finally by boric acid solution, or can simply use normal salt solution. After washing, insufflate the nasopharynx with iodoform. Repeat the cleansing at regular intervals and also cleanse the conjunctival sac frequently. In fracture of the posterior fossa examine to see if the fracture is compound, into the pharynx, and if it is, cleanse with great care the nasopharynx

and mouth, as previously directed. In a very extensive fracture of the base, besides use of the methods set forth above, the entire head should be shaved and a plaster-of-Paris cap be applied. A patient with fracture of the base must be put into a quiet and darkened room and be kept upon a low diet, sleep being secured, and the bowels and bladder being attended to. If we are uncertain as to whether a fracture exists or not, keep the patient quiet, in a darkened room and on a low diet. Attend to the bladder, keep the bowels loose, examine the nasopharynx with a mirror and the ear-drum through a speculum, and make a lumbar puncture.

Obstetric Depressions of the Skull.—These lesions seem to have been first studied by Danyau in 1849. The depression may be of the parietal or frontal bone and may or may not be accompanied by fracture. It may have been caused by the promontory of the mother's sacrum or by obstetric forceps. A slight depression does no harm, because it is gradually and spontaneously corrected. A marked depression, especially if accompanied by fracture, places the child in danger of epilepsy, idiocy, and non-development of body, and requires treatment. The usual treatment is trephining and elevation. Some claim to elevate by an apparatus making pneumatic suction. Some make a small incision, insert a screw (Heine's screw), and elevate by making traction on the screw. Hanch elevated by means of a corkscrew. (See Frazier, in "Progressive Medicine," March, 1913.)

Fig. 519.—Extensively comminuted gunshot-fracture of the skull (after von Bergmann).

Wounds of the brain are produced by violence and especially by foreign bodies (knives, bullets, etc.). Except when due to penetration of a fontanel in a child or of a parietal foramen in adults, wounds of the brain are accompanied by fracture of the skull. These wounds are very dangerous; foreign bodies (bone, hair, clothing, etc.) are often lodged in the brain, hemorrhage is usually severe, and without proper treatment sepsis is almost inevitable. Such cases are very fatal, though some astonishing recoveries are on record. Figs. 519 and 520 show gunshot-fractures of the skull.

The **symptoms** of a brain wound may be slight and long deferred or may be immediate and overwhelming; they depend upon the site and extent of the injury. Localizing symptoms may exist, and encephalitis with coma is apt to arise. Abscess may follow.

In treating wounds of the brain always shave the entire scalp and examine the weapon, if possible, to see if a piece were broken off. Asepticize, enlarge the wound, trephine, arrest bleeding, elevate any depression, remove foreign bodies, irrigate the wound with salt solution, drain by gauze, suture the dura, and dress.

Wounds in War.—When the bullet of a military rifle, fired at very close

range, crosses the brain it may blow the skull into fragments, but often it does not, but produces fracture of the skull and wound of the brain. The "explosive effect" is far less marked on the head of a living man than on the head of a corpse and may even be absent when the range was only 100 yards. At moderate range, at the point of initial contact of the bullet with the skull, a fracture is produced, the opening is slightly larger than the bullet, and short fissures commonly radiate from it. Fragments from the internal table are usually displaced and driven into the brain. The wound of exit is more irregular and is apt to exhibit more and longer fissures than the wound of entrance. When a bullet strikes a glancing blow it may fracture the outer table alone; it may produce a "gutter-fracture" (two scalp openings, and "a gutter ploughed" through both tables of a portion of the skull, as O'Reilly expressed it), *very seldom* a fracture of the inner table only, *penetration* of the skull, and lodgment of the bullet, or *perforation* of the skull, the bullet passing through the head and emerging. Nearly half the cases are instances of perforating wound.

Fig. 520.—Gunshot-fracture of internal table of the skull (after von Bergmann).

In all of these injuries there is great shock and usually concussion, but concussion symptoms may be absent. The patient may die at once or almost at once, but if he is alive a few hours after the injury he has still to face the danger of infection and resulting inflammation. The danger depends on the brain injury and the amount of infection and not on the extent of the bone damage. The symptoms vary according to the part of the brain injured and the extent of the damage.

In practically all cases bone-fragments are driven into the brain, and as the scalp is a dirty region, the wound is more or less infected.

The mortality from these injuries is very large. In the American Civil War it was 61.2 per cent. In the Franco-Prussian War it was 51.3 per cent. In the Boer War, among the British it was only 33.1 per cent., a very notable improvement. (See "Military Surgery," by Surgeon General Robert M. O'-Reilly, U. S. A., in "Keen's Surgery," vol. iv.) In the Russo-Japanese War the mortality seems to have been something over 37 per cent.

In estimating mortality those killed outright and those dying before reaching the hospital are not counted by makers of statistics. Much brain matter may ooze out from such a wound. Cerebral hernia (Fig. 522) is common after these injuries, especially if much bone was destroyed by the injury or removed by the surgeon.

Treatment of Wounds in War.—At the first-aid station antiseptic dressings are applied. On reaching the field hospital the wound is explored, if time, situation, and military necessities permit. Every wound of this sort is regarded as being complicated by infection and by depression or wide dispersion of bone-fragments. The patient is reacted from shock and a flap of scalp is turned down to permit of exploration. Depressed fragments of bone are elevated or removed and loose pieces are removed. Treatment is the same as for wounds from revolver bullets (see page 796).

Wounds from Revolver Bullets.—The bullet may strike the skull and glance (if fired at an angle) with or without the production of a fracture. A small bullet (No. .22) may even strike perpendicularly and fail to enter, sometimes causing a fracture and sometimes not doing so. Even a No. .22 may enter the skull. I removed a bullet of this size which had entered and crossed the skull and lodged beneath the cortex on the opposite side of the brain. A bullet may cause a "gutter-fracture"—may enter the cranium and lodge—or may cause a complete perforation. A revolver bullet is much more apt to lodge than a military bullet.

The wound of entrance is small; the wound of exit is larger. At the wound of entrance the inner table is more extensively fractured than the outer table; at the wound of exit the outer table is more widely broken than the inner table. In these cases there is always great shock and usually concussion, and concussion symptoms may exist even when the bullet has not entered the brain. In moderate concussion the action of the heart is retarded; in severe concussion it is accelerated (see page 781). A bullet may be lodged within the cranium when merely a fracture without a bullet-hole can be detected. In these cases the bullet produced a fracture and entered the cranium, and then the depressed bone flew back into place (von Bergmann). In such cases, if complete perforation occurs, the one existing opening in the bone is the opening of exit. A bullet may lodge in the bone, between the dura and the bone, between the dura and brain, in the brain, between the dura and the brain or the dura and the bone of the opposite side, or in the bone of the opposite side, in the nasal fossa, maxillary antrum, or orbit. Always examine the side of the head opposite to the wound of entrance to determine if there is a wound of exit or any bulging or fracture. A bullet may pass across the brain and be deflected from the inner surface of the skull. Ruth does not believe the bullet can rebound from the opposite wall.[1] If certain regions are injured, localizing symptoms may arise. Much brain matter may ooze out from the wound. Loss of brain matter sometimes causes great impairment of function, sometimes little or none. The secondary **symptoms** of gunshot-wounds of the head are varied and uncertain, and may not be observed at all before death. Fowler wisely points out that a patient with a gunshot-wound of the head may have also received other injuries, and the other injuries may be in part, at least, responsible for cerebral symptoms.

Treatment of Wounds from Revolver Bullets.—Endeavor to bring about reaction (see Concussion). In severe cases apply heat to the head and make artificial respiration. It will sometimes be necessary to operate while artificial respiration is being made. In treating gunshot-wounds of the head shave and asepticize the whole scalp, disinfect the entire track of the ball, and arrest hemorrhage at the wounds of entrance and exit, using the rongeur to expose the bleeding points if the bullet be large, employing the trephine if it be small. If the bullet has emerged and has been picked up, examine it to see if it is entire. The bullet, if retained, is to be sought for. The *x*-rays are invaluable in locating the missile. Place the head in such a position that the track of the ball will be vertical, then introduce Fluhrer's aluminum probe or Senn's probe, and let it find its way by gravity. The probe may find the ball near the wound of entrance, in which case extract the ball with forceps; or the probe may find the ball near the opposite side of the head, in which case make a counteropening through the bone at a point the probe would touch if it were pushed entirely across. Take a new and *clean* rubber catheter (No. 9, French), insert a stylet, and carry the catheter through the wound (Keen). Knowing the depth of the ball, search for it around the catheter-tube as an axis, and when found, extract it. After extraction drain the wound by means of a tube. When

[1] See the instructive article by Fowler, in "Annals of Surgery," Nov., 1895.

a counteropening exists, drain through and through. If the ball cannot be detected, drain by a tube carried to the depths of the wound. After dressing always place the head in a position favorable to drainage. Fluhrer tells us that when a counteropening fails to disclose the bullet, use the new opening as a doorway through which to search for the ball. He believes the bullet is not unusually deflected. The angle of deflection is somewhat greater than the angle of incidence, and the bullet is apt to fall a little toward the base. Splinters

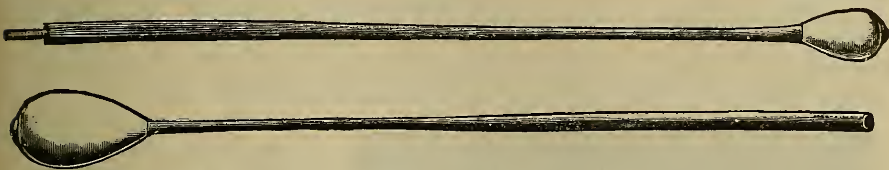

Fig. 521.—Senn's modification of Nélaton's bullet-probe.

of bone are often driven into the brain by a bullet, and these should be removed whether the ball is found or not. Several varieties of probes have been recommended. Fluhrer uses a large-sized aluminum probe. Senn used an instrument shaped like the Nélaton probe, but of the same diameter as the bullet (Fig. 521). (Of course, the porcelain probe will not show a black mark from contact with a hard-jacketed bullet.) Fowler uses a graduated pressure probe; so long as the pressure is within the limits of the spring, as shown by the scale, the probe is in the bullet-track. Girdner's telephonic probe has been used as an aid to localization. Bullets are now certainly located by the Röntgen rays. There can be no doubt that many gunshot-wounds have been recovered from without operation, and it is beyond question that many deaths follow operation (about $33\frac{1}{3}$ per cent., according to Hahn). Von Bergmann is so impressed with these facts that he does not operate when cerebral symptoms are absent. I usually operate.

Fig. 522.—Hernia cerebri under scalp after operation for brain tumor (W. W. Keen).

Prolapse of the Brain and Hernia of the Brain.—In a compound fracture, especially a gunshot-fracture, with torn dura and pia, brain matter may emerge from the wound. In fracture of the base brain matter may enter the orbit, the nose, or the ear. A flow of brain matter may continue from a wound for many hours. A week or more after an injury a portion of the brain may protrude or prolapse. To this condition the term *prolapse of the brain* should be applied. In many instances the protrusion is covered with pia, but if the pia were torn or cut, it will not be a covering. This protrusion emerges from the opening in the skull, mounts up, growing larger and larger, until it may become the size of a fist. It usually pulsates. When bare it is soft, lobulated, of a dirty-white color, pulsating, painless to the touch, often bleeding, and sometimes discharging cerebrospinal fluid. Death may soon follow such protrusion, but the protruding mass may become necrotic and be sloughed off, a granulating surface

remaining, which heals. *Hernia cerebri* (Fig. 522) sometimes follows operations upon the brain or injuries of the skull and dura, when large pieces of bone have been removed or when the dura has been widely cut or torn and has not been carefully sutured. The condition is due to increased cerebral pressure. Hernia of the brain is protrusion through the dura, but not through the scalp, the scalp wound being healed above the protrusion. In a decompression operation we deliberately create a hernia of the brain. Prolapse of the brain is treated by antiseptic dressings and perhaps by a decompression operation. Skin-grafting benefits some cases. Pressure is dangerous. Excision by the knife or cautery seldom does any good. Hernia in some cases can be treated by repeated lumbar punctures, in some others by craniotomy of the opposite side of the skull.

Fig. 523.—Fungus cerebri (W. W. Keen).

Fungus Cerebri (Fig. 523).—When the brain is exposed, a granuloma may grow from the neuroglia and fungate through the opening in the skull. This condition is fungus cerebri and is not composed of brain matter. It is due to infection of the brain, and is most frequent when a bit of bone or some other foreign body is retained. A fungus is soft to the touch, is livid in hue, bleeds easily, frequently contains multiple foci of suppuration, and pulsates. It often attains the size of a small orange. It is treated by removing the granulations and any foreign body, and applying, with moderate pressure, aseptic dressing soaked in alcohol. After healing, a depression marks the site of the fungus.

Traumatic inflammation of the brain and its membranes is divided into *encephalitis* or *cerebritis*, inflammation of the cerebrum; *cerebellitis*, inflammation of the cerebellum; *meningitis*, inflammation of the meninges; *arachnitis*, inflammation of the arachnoid; *pachymeningitis*, inflammation of the dura; and *leptomeningitis*, inflammation of the arachnoid and pia.

Meningitis.—Of recent years our views regarding meningitides have changed. We no longer regard each form as a separate and distinct disease, but we regard all the forms as different phases of one disease, that disease being a reaction to infection on the part of the membranes of the brain and cord. We must still, for clinical convenience, classify meningitides into many types. We speak of meningitis as serous or purulent, local or diffuse. We speak of it as basilar, leptomeningitis, etc., or as tuberculous, meningococcic, etc. But, after all, meningitis is an infection for which many varieties of bacteria may be responsible, and in which there are many different routes for the entrance of the causal micro-organisms, but the effects of these organisms upon the tissues are similar and the variety of the symptoms produced depend upon the region diseased and the power and nature of the toxins.

This view has been most ably set forth by Kopetzky ("The Laryngoscope," June, 1912). The same careful observer points out that in every form of meningitis there is increased tension of the cerebrospinal fluid and poisoning of the central nervous system by toxins and products of tissue metabolism.

The chief factors in causing increased tension of cerebrospinal fluid are edema of brain tissue and edema of the membranes.

Kopetzky ("The Laryngoscope," June, 1912) further points out that very early in the progress of every case of meningitis there is a disappearance from the cerebrospinal fluid of the copper-reducing substance dextrose. Bacteria are greedy for carbohydrates and eat up dextrose. The disappearance of dextrose is highly significant of the existence of meningitis. Its reappearance indicates abatement of the inflammation.

Treatment.—Kopetzky (Ibid.) in acute cases advocates the administration of serum or antitoxin and the early performance of an operation to reduce intracranial tension. Lumbar puncture is of high diagnostic, but small therapeutical, value. The most promising operation is one which drains the cisterna magna (see Haynes's Operation, page 832).

Pachymeningitis Externa.—Inflammation of the external layer of the dura is called *pachymeningitis externa.* It may arise from tumor, caries, necrosis, middle-ear disease, sunstroke, or traumatism. Syphilis is a not unusual cause. The other membranes may become involved. Suppuration may arise, having extended by contiguity from neighboring parts.

The **symptoms** of pachymeningitis externa are uncertain. They resemble often those of leptomeningitis (see page 800). Pressure symptoms may arise. Headache is always present. Paralysis may or may not exist. If pus forms, the ordinary constitutional symptoms of suppuration are evident (high temperature and sweats), not the usual symptoms of abscess in the brain. In a severe case the other membranes become involved.

The **treatment** consists in removing the cause (carious bone, pus, middle-ear disease). In pachymeningitis from traumatism it is sometimes advisable to trephine in order to drain inflammatory products; in a case with localizing symptoms always trephine; in an ordinary case, without pus and with no evidences of traumatism, use wet cups back of the mastoid processes, apply an ice-bag to the head, and purge by means of calomel. Administer iodid of potassium in most cases. If sunstroke is the cause, treat according to ordinary medical rules.

Pachymeningitis Interna.—This term means inflammation of the inner layer of the dura. Inflammation may extend from the pia or from the outer layer of the dura. The disease is most often met with in infants and in the chronic insane, but may occur in those not insane in late middle age or beginning old age. The form known as *hematoma of the dura mater*, or *pachymeningitis interna hæmorrhagica*, may arise during infectious disease (typhoid fever or rheumatism), in persons of the hemorrhagic diathesis, in diseases causing atrophy of the brain, in chronic diseases of the heart and kidneys, and in syphilitics. Among the exciting causes are traumatism, inflammation in adjacent parts, and, especially, the abuse of alcohol. In this disease blood is extravasated on the inner surface of the dura. Many observers do not class hemorrhagic pachymeningitis as inflammation, but regard the hemorrhage as primary.

The **symptoms** of internal pachymeningitis are very chronic, come on gradually, are not characteristic, and may be absent. They consist usually of mental irritability or excitement, followed perhaps by hebetude and persistent headache; and apoplectiform attacks, with contraction of the pupils, slow pulse, and vomiting; there may also be muscular rigidity and spasm of the extremities. Choked disk is not infrequent; localizing symptoms may be made out, and coma is apt to arise. Cranial nerves are seldom affected.

The **treatment** is operation, which removes the clot. This is unpromising, but Munro saved 1 case out of 5 ("Chicago Med. Recorder," Dec., 1902).

Acute leptomeningitis is a purulent inflammation of the soft membranes of the brain. The pathological changes can be noted in the pia and in the brain substance. The brain is edematous, the pia purulent, the convolutions are flattened, the ventricles are distended with fluid, and hemorrhages occur into the brain substance. Pus may be localized upon the pia, but it is usually diffused over one hemisphere or over both. Various organisms may be found, especially streptococci, staphylococci, and diplococci. In some cases we find the Bacillus pyocyaneus or the Bacillus pyocyaneus fœtidus, which is identical with the colon bacillus and with the Bacillus meningitidis purulentæ (Park). Saprophytic organisms are occasionally present. This disease may be acute or chronic, and a severe case is spoken of as *encephalitis. Secondary leptomeningitis* is apt to affect the convexity; *primary leptomeningitis* is apt to affect the base.

The **causes** of leptomeningitis are epidemic cerebrospinal fever, tuberculosis, acute general diseases (pneumonia, typhoid, erysipelas, and rheumatism), bone diseases, traumatism, middle-ear disease, syphilis, and sunstroke. In diplococcic meningitis the tissues of the *pia* and the cerebrospinal fluid contain diplococci identical with pneumococci. Infection may take place by various avenues. It may pass from the pharynx by way of the Eustachian tube to the ear, or from the nose to the frontal sinus or ethmoid sinuses (Hirt), and from these situations to the brain. It may pass from the middle ear or mastoid to the membranes of the brain. In fractures at the base the organisms enter by way of the pharynx and the Eustachian tube, or the ear. The **symptoms** of acute leptomeningitis early in the case are: rising blood-pressure (determined by the sphygmomanometer), edema of the optic papillæ, absence of carbohydrates from the cerebrospinal fluid (obtained by lumbar puncture), "an irritable or clouding sensorium" (Irving S. Haynes, in "The Laryngoscope," June, 1912). The same author adds that vagus pulse and respirations irregular in depth and rate may also be present. As the case progresses there are violent headache persisting during delirium, flushing of the face, rigidity of the neck, cerebral vomiting, a pulse small and irregular in force and frequency, but often slow, elevated temperature, leukocytosis, photophobia, contraction and perhaps inequality of the pupils, intolerance of sound, hyperesthesia of the skin and muscles, and delirium passing into stupor and coma. There are rigidity of the muscles of the neck, retraction of the head, retraction of the abdominal muscles (boat-shaped abdomen), inability to extend the legs when sitting up, though it can be done when recumbent. If, while lying down, the thigh is flexed on the belly the leg cannot be extended on the thigh (*Kernig's sign*). If a dull point is drawn along the skin a red line follows it (*tache cérébrale*). A chill or a succession of chills may occur. Choked disk, strabismus, and nystagmus are not unusual. Twitching convulsions or paralyses may occur. Death is the rule within one week. In a case of meningitis the fluid obtained by lumbar puncture may contain bacteria and may be actually purulent. The presence of numerous leukocytes is usual, there being an excess of polymorphonuclear forms in pyogenic infections.

Treatment.—Flexner's serum is valuable in cerebrospinal meningitis, a condition caused by the Diplococcus intracellularis, but is useless in all other conditions. Lumbar puncture is of immense diagnostic importance, but is useless therapeutically. It is not entirely safe. The rapid withdrawal of fluid may cause death by allowing the foramen magnum to be plugged by the brain stem. Ordinary trephining with tapping of the ventricle is practically useless. An operation which promises is the exposure and drainage of the cisterna magna (see page 832). If employed it should be done early, that is, when what we regard as early symptoms are present. Late operations are of no avail. Any causal condition, for instance, suppurative otitis media, must also be treated by

operation. After operating administer urotropin. Should the patient recover, he must be guarded for a long time from physical exertion, mental excitement, worry, irritation, constipation, and insomnia.

Chronic Leptomeningitis (*or Chronic Encephalitis*).—The causes of chronic leptomeningitis are the same as those of the acute form. If traumatism is the cause, the inflammation arises at a later period than it would in acute encephalitis. The symptoms of concussion follow a head injury. Days, or even weeks, after the accident a series of symptoms may occur, namely, localized pain at the seat of injury, often accentuated by tapping; listlessness; irritability; apathy regarding business affairs and home obligations, or profound depression and hypochondria with inability to attend to business. Choked disk may exist. In any case acute encephalitis may arise, with or without a chill. The **treatment** of this disease is symptomatic unless local symptoms exist. Always trephine if localizing symptoms are found. Intense local pain justifies trephining.

Tuberculous Meningitis (Acute Hydrocephalus; Water on the Brain).—This inflammatory condition is due to the bacilli of tuberculosis. In a child affected with tuberculous meningitis there is often a record of a fall, the injury acting as an exciting cause by establishing an area of least resistance. Prodromal symptoms lasting several weeks are common (restlessness, irritability, anorexia, loss of flesh, change of character). The attention of the physician is attracted to the meninges by a convulsion or, what is more common, by headache, fever, and vomiting. The fever is persistent, but irregular. The child cries out from pain (*the hydrencephalic cry*) and the bowels are constipated. The pulse is rapid in the beginning, but later becomes slow, irregular, and of high tension. The pupils are contracted, there is muscular twitching, and the sleep is impaired. The temperature is about 103° F. There is usually edema of the optic papillæ and carbohydrate disappears from the cerebrospinal fluid (see page 799). In the second period of the disease the vomiting ceases, constipation becomes more marked, the belly retracts, headache is not so violent, and the patient lies in a soporose condition interspersed with episodes of delirium. In this stage the pupils dilate and are often unequal, the head is retracted, convulsions occur or limited rigidity is noted, the respirations are sighing, and if a finger-nail is drawn along the skin, a red line develops (the *tache cérébrale*, due to vasomotor paresis). Kernig's sign is present (see page 800). Squint and consequent double vision are usual. In the last stage coma becomes absolute and general convulsions or limited spasms are apt to occur. Optic neuritis exists, and the child passes to death along a road identical with that of typhoid collapse. In some cases the examination of cerebrospinal fluid withdrawn by lumbar puncture throws light upon the diagnosis. The fluid is devoid of carbohydrate and usually contains an excess of lymphocytes. It may contain the bacilli. It may be sterile. Sterile fluid from a patient with symptoms of meningitis suggests that the condition is tuberculous. In children the base of the brain is usually involved, and the disease is apt to last from two to four weeks; in adults the convexity is usually involved, and death is apt to occur in a few days. When the meningitis is basilar, occipital headache, rigidity of the neck, and vomiting are severe, paralysis of various cranial nerves may occur, and there may be hemiparesis from pressure on the crus. Absence of leukocytosis points to a tuberculous cause for a meningitis. The existence of leukocytosis does not disprove the tuberculous cause of the disease.

The **treatment** is like that for traumatic meningitis. The operation of trephining, perhaps with tapping a ventricle, seldom offers any chance of improvement, and never does unless the process is limited in area and confined to the convexity. Lumbar puncture is performed for diagnostic rather than

for therapeutic reasons. Draining the cisterna magna should be tried (see page 832).

Abscess of the brain is a localized collection of pus. The bacteria which may be found are noted upon page 800 (Acute Leptomeningitis). The **causes** are suppurative otitis media (in half of all the cases), fracture of the skull, osteomyelitis of the cranial bones, erysipelas of the scalp, subaponeurotic abscess of the scalp, abscess of the lung, gangrene of the lung, empyema, concussion or wound of the brain, and general infections. As Ballance points out, abscess of the brain complicating head injury is not really an abscess of the brain unless the wounding material entered into the brain substance. In most cases the abscess is "a local meningeal suppuration with participation of the adjacent brain cortex, a meningocortical abscess rather than a brain abscess proper" ("Some Points in the Surgery of the Brain," by Chas. A. Ballance). General infections may cause abscess (pyemia, tuberculosis, and specific fevers). A tuberculous mass may caseate (tuberculous abscess). The abscess may be between the dura and the skull (extradural), adhesions forming and preventing general leptomeningitis, between the dura and brain (subdural), or in the brain substance (cerebral or cerebellar). Leptomeningitis may arise because no adhesions are created, because septic clots form in veins or sinuses, or because infected blood regurgitates into the sinuses (Park). A traumatic abscess is generally beneath the area to which the traumatism was applied, but it may be on the opposite side. Source of infection may be the nose, the orbit, or the middle ear (see page 800). Roswell Park says infection may pass along blood-vessels, lymph-vessels, nerve-sheaths, or the prolongations of the membranes which extend outside of the skull. An acute inflammation of the middle ear rarely causes abscess, because an acute inflammation in sound tissue causes the formation of granulation tissue, which acts as a barrier to infection. Chronic inflammation of the middle ear is the most frequent cause of abscess. Park tells us that if the roof of the tympanum is involved, it may perforate and abscess of the middle fossa may form; if the tympanum is perforated toward the mastoid antrum, the abscess arises in the temporosphenoidal lobe; if the perforation is toward the sigmoid groove the abscess forms in the cerebellum.[1]

Chronic bone disease is seldom followed by spreading meningitis, often by abscess. When infection reaches the brain by direct extension from a suppurating bone it must pass through the membranes, but it is usually limited by adhesions. The cortex is very vascular, strongly resists infection, and is seldom extensively destroyed, but the white matter is far less resistant and abscess tends to form in it (Ballance, Ibid.). In some cases of abscess of the temporosphenoidal lobe following ear disease the cortex seems normal, in others the membranes and cortex are fused over a narrow area which constitutes the stalk of an abscess in the white substance of the lobe. This is the *mushroom abscess* of Ballance. An abscess may increase rapidly in size and finally break into a ventricle or through the cortex. It may become encapsulated and latent. A slow-growing abscess may push aside nerve-fibers as does an encapsulated tumor, but a rapidly growing abscess destroys them.

In the cerebrum, multiple abscesses, except in cases of general infection, are seldom seen. In the cerebellum they are not uncommon. One or several abscesses may arise from a primary one. If they are adjacent to the primary one they are called satellite abscesses and tend to break into the older purulent area.

Ballance, in considering the onset of abscess, adopts the views as to the five types set forth by Brissaud and Souques. These types are as follows (Ballance, Ibid.):

(1) A subacute evolution. In this there is a febrile onset, like the onset of a

[1] Park, in "Chicago Med. Record," Feb., 1895.

specific fever, with headache, vomiting, and elevated temperature. After a few days there comes a remission, the period of delusive calm. In this period symptoms are absent or trivial. Though there may be progressive emaciation, there is no elevation of temperature in this period.

Suddenly convulsions occur which are followed by coma, or coma arises without antecedent convulsions. The patient may die in coma or the coma may pass away, "the symptoms indicating a local brain lesion" (Ballance, "Some Points in the Surgery of the Brain"). In this stage elevated temperature may appear again.

(2) Evolution with violent general infection, the symptoms of abscess being merged and usually lost in the symptoms of general infection.

(3) Evolution with complete latency. The patient presents no symptoms until a few hours before death, or he may die suddenly without a symptom having been observed. In this connection Ballance speaks of the difference between "symptoms not noticed and symptoms not present" (Ibid.).

(4) Only when symptoms were not present does he use the term "complete latency" to indicate the condition. Ransohoff has reported the case of a boy in whom an abscess in the frontal lobe was latent for three years, and another case in a man due to gunshot-injury, which was latent for four and a half years and in which nearly ten years elapsed between the injury and death ("Annals of Surgery," July, 1909).

(5) Onset not to be distinguished from a brain tumor.

(6) Onset with headache and fever, or with mental excitement. Then the patient appears to get completely well and remains so for weeks, for months, or for a year or more. This condition may occur in abscess secondary to influenza (Ibid.).

Symptoms of Abscess of the Cerebral Substance or of the Cerebellum.—The symptoms due to pus-formation are as follows: There is an initial rise of temperature, but (except in extradural abscess) the temperature may quickly become normal or even subnormal. Years ago Sir Samuel Wilks called attention to the depression of temperature frequently noted in cerebral abscess. Subnormal temperature is not nearly so common as is supposed. It has been present in about one-half of the cases I have seen. Toward the end of the case the temperature may rise and the fever become linked with delirium. Surface elevation of temperature over the seat of the abscess is occasionally observed. A chill may occur, but seldom does. Anorexia and vomiting are present. Urinary chlorids are diminished and the phosphates are increased (Somerville). Certain symptoms are due to pressure: Headache begins (which at first is general, then local, and grows worse later in the case, and exists even in delirium; this fact distinguishes it from the headache of fever, which ceases in delirium); pulse is full, regular, and, in the absence of complications, becomes very slow; respiration tends to alterations of rhythm and the Cheyne-Stokes type; drowsiness lapses into stupor and stupor passes into coma; paralysis of the sphincters takes place; superficial reflexes gradually disappear on the side opposite to the lesion; convulsions are common; sensation is rarely impaired, and paralysis of the basal nerves may occur (third and sixth especially). The pupil on the same side as the abscess is sometimes dilated and fixed. Choked disk is not invariably found. It may be more marked on the same side as the abscess. It is more moderate in degree than in meningitis. Localizing symptoms, spasmodic and paralytic, depend upon the center which is irritated or destroyed. In abscess of the temporosphenoidal lobe hemiplegia of the opposite side is apt to develop. The face is most and first involved, next the arm, next the trunk, and finally the leg (Sir Victor Horsley, "Lancet," Jan. 27, 1912). In an abscess far posterior the motor palsy may be so slight as to almost escape recognition, but there is loss of the sense of position of a limb

and loss of power to localize touch. In cerebellar abscess there are vertigo, vomiting, occipital headache, rigidity of the postcervical muscles, and incoordination. Choked disk may be present or absent. A cerebral or a cerebellar abscess causes a decidedly high leukocytosis.

Meningitis arises soon after an accident; a *traumatic abscess* cannot arise until more than a week has elapsed after an accident, and many weeks may elapse. Meningitis presents high temperature and the general symptoms before outlined. *Mastoid disease* may occasion cerebral symptoms without abscess, or it may cause abscess. It is curious that in some cases of mastoid disease without brain abscess choked disk arises. In *sinus-thrombosis* there is septic temperature, the veins of the face and neck are enlarged, and a clot can usually be felt in the jugular. A *tumor* grows slowly, may present localizing symptoms, and double choked disk is frequently present. In tumor the temperature is apt to be normal.

Treatment.—If abscess is due to ear disease with implication of the mastoid cells, at once open and clear out the mastoid (see Fig. 535), and after doing this proceed to trephine the skull in order to reach the abscess. In any case, if symptoms of abscess exist, trephine the skull at once. If localizing symptoms are present, open over the suspected region. If localizing symptoms are not present, and the cause is ear disease, trephine at Barker's point (see Fig. 535). If no pus is found between the bone and dura, open the membrane. When the dura is opened, if the abscess is subdural, pus will be evacuated; if the abscess is in the brain substance, the brain will bulge very much and will not pulsate. A grooved director is plunged into the brain, in the direction of the abscess, for 2 or $2\frac{1}{2}$ inches. It is pointed to the external angular process of the opposite side. If pus is not found, withdraw the director and introduce it at another point, pointed to the nostril of the opposite side. If pus is not found, withdraw the director and introduce it again, pointing to the angle of the jaw of the opposite side. When pus is discovered, incise the brain with a knife, enlarge the opening by inserting a closed pair of forceps and withdrawing the instrument with the blades open. Scrape away the granulation tissue lining the abscess-cavity, irrigate with hot salt solution, and introduce a rubber drainage-tube and suture it to the scalp; stitch the dura, but leave an ample opening for the tube; bring the tube out through a buttonhole in the scalp, and after the first two days pull the tube out a little every day and cut off a piece. If the first trephining does not find pus, trephine at another point. If we are seeking for an abscess due to middle-ear disease and fail to find it in the temporosphenoidal lobe, seek for it in the cerebellum. In cerebellar abscess make a flap with the base up, and trephine or gouge away the bone just below the line of the lateral sinus. Puncture the brain for exploration as for cerebral abscess.

Brain Disease from Suppurative Ear Disease.—Acute otitis media sometimes, and chronic otitis media much more often, cause meningitis (*otitic meningitis*). This may be a circumscribed inflammation of the dura eventuating perhaps in an extradural abscess, a serous leptomeningitis, or a purulent leptomeningitis. There may or may not be involvement of the mastoid. There is always fever and pain and tenderness over the region of meningitis. The pain and tenderness are above the zygoma or back of the mastoid (Dench, in "New York Med. Jour.," August 27, 1910). With these symptoms there may or may not be signs of mastoid involvement. Dench points out that the occurrence of sudden and profound deafness during middle-ear suppuration usually means beginning meningitis (Ibid.). Chronic disease of the middle ear is apt to destroy the bone between the tympanum and the middle fossa of the skull, and thus produce meningitis, thrombosis of the petrosal or lateral sinuses, abscess of the temporosphenoidal lobe or of the cerebellum, or extra-

dural abscess. In chronic otitis media the reflexes of the opposite side of the body are frequently altered (Russell Reynolds, Sir Victor Horsley). In some cases, even without any other evidence of cerebral involvement, there is choking of the disk. In many cases the infection is direct, by bone involvement or by the lateral sinus. In many other cases the infection is through the labyrinth. If labyrinthine infection arises, it produces symptoms (disturbances of equilibrium and nystagmus). Chronic otitis media is apt to induce inflammation or suppuration of the mastoid cells (*empyema of the mastoid*). Pus in the mastoid may discharge itself into the middle ear, and from this point into the external auditory canal, through a perforation in the drum-membrane (especially in acute cases). In some cases the pus becomes blocked up within the mastoid process. Pus in the mastoid may after a time break into the cavity of the cranium or into the groove for lateral sinus, or may find its way externally and open into the sheaths of muscles arising from the mastoid. It not unusually opens into the sheath of the digastric muscle (*Bezold's abscess*). These facts teach the surgeon that inflammation of the middle ear should never be neglected, but should, if possible, receive the closest attention of the specialist. If no perforation exists in the drum, the surgeon must make one. In ordinary cases cleanliness and antisepsis are sufficient, the ear being syringed every day with a warm 2 per cent. solution of common salt. If only a small drum-perforation exists, 10 drops of pure alcohol or of corrosive sublimate solution (1:5000) are dropped into the ear daily; but if a large drum-perforation exists, boric acid and iodoform (7 to 1) are insufflated. Never inject alum. A strong silver solution is not safe; if it is used, wash the ear out afterward with warm salt water. If granulations or polypi exist, they must be removed. Some cases require the removal of the drum-membrane and the ossicles of the ear. Some cases of mastoid necrosis are due to tuberculosis. If headache, vomiting, and mastoid tenderness exist, open the mastoid (see page 830) in order to prevent abscess of the brain. In acute otitis media it is very rarely necessary to open the mastoid. The middle ear is on a lower level than the antrum of the mastoid, and in most acute cases both the middle ear and mastoid cells drain safely through a drum-perforation. Because a man has chronic otitis media it is by no means always necessary to trephine the mastoid. In many cases removal of the ossicles and drum-membrane effects a cure. In chronic otitis media, even if the mastoid is trephined, the ossicles and membrane ought to be removed in most cases.

Cerebral abscess from ear disease (see page 804) is almost always in the temporosphenoidal lobe, but may arise in the cerebellum. The **symptoms** are a regular, full, slow pulse (except in complicated cases), a transient rise of temperature, followed in many cases by a normal or subnormal temperature; vomiting; mastoid, frontal, and temporal pain. The mind is dull, and stupor arises which passes into coma; the bowels are constipated; choked disk may be present; and convulsions or spasms or paralyses may exist. Trephine and clean out the mastoid, and asepticize (see Operations Upon the Skull and Brain). Also trephine at Barker's point, $1\frac{1}{4}$ inches behind and the same distance above the middle of the external auditory meatus, open the dura, and seek for pus in the brain. If pus is not found, open the cerebellum.

Extradural Abscess.—The eye-symptoms and pain are the same in this as in cerebral or subdural abscess, but the temperature is different, rising to 103° or 104° F., and never being subnormal. There is often considerable tenderness above and behind the mastoid. In extradural abscess following disease of the middle ear trephine and clear out the mastoid; follow up a bone-sinus to the abscess, rongeur away the bone, being careful to avoid injuring the lateral sinus; curet, irrigate, and drain.

Infective Sinus-thrombosis.—Any sinus may be attacked. The dis-

ease may result from scarlet fever, small-pox, diphtheria, influenza, typhoid, or any acute suppuration. In erysipelas of the scalp, subaponeurotic abscess of the scalp, and cranial osteomyelitis septic clots may form in the veins which pass through the bone and reach the longitudinal sinus. Infective thrombosis of the superior longitudinal sinus is thus produced.

In carbuncle of the lip and orbital suppuration the cavernous sinus may become involved.

In caries of the basilar portion of the occipital bone the circular sinus or the cavernous sinus may suffer. In caries of the petrous portion of the temporal bone, and in suppuration of the middle ear and mastoid process, infective thrombosis of the lateral sinus may occur.

In any case the symptoms are those of pyemia. The lateral sinus is the one most frequently attacked. In infective thrombosis of the lateral sinus there is usually a history of an old discharge from the ear.

Infective thrombosis of the lateral sinus may result from a specific fever, but is usually due to chronic suppuration of the middle ear associated in most cases with carious bone and pus in the mastoid process. Thrombosis of the lateral sinus occasionally follows an operation upon a suppurating mastoid, or develops in an individual who suffers from middle-ear disease, who has been struck upon the head, who has had the ear syringed with force, or who has had injected a corrosive or very irritant fluid. Tuberculous bone disease is an occasional cause.

Symptoms.—In most cases there is a history of chronic ear disease. In children the symptoms are more acute than in adults. In any case the symptoms may rapidly become violent. In some cases there are preliminary symptoms of extradural abscess, pus being lodged in the groove of the sinus. It has been pointed out that pus in the jugular foramen may make pressure upon the pneumogastric, spinal accessory, and glossopharyngeal nerves, producing aphonia, hoarseness, dyspnea, dysphagia, and slow pulse (George F. Cott[1]). Marked headache and often an initial chill usher in sinus-thrombosis. The pain is apt to be localized about the ear and mastoid process, but may become general. There is usually acute tenderness of the mastoid. There is high fever from the start, but when the clot begins to soften and break down, hard rigors develop and the temperature fluctuates violently. The temperature varies greatly each day, fluctuating it may be between subnormal and 106° to 107° F. A chill may occur once or even twice a day, and it lasts from ten to twenty minutes. The pulse is soft and usually rapid. The patient is nauseated, labors under vertigo, is very restless, is sometimes delirious, may become dull and stupid, and the muscles of the neck are stiff. Tenderness and marked edema are detected over the mastoid, and the veins of the neck and mastoid region may be enlarged. When the clot extends into the jugular vein there is pain on moving the head and on swallowing, the cervical glands are swollen, and a cord-like clot may be felt in the neck. Choked disk exists in about half of all cases. There is often a profuse discharge of pus from the ear, but in some cases a discharge is found to have abated or ceased. Exophthalmos and swelling of the eyelids point to involvement of the cavernous sinus in the process. In early cases there is thrombosis of the lateral sinus alone, or of the lateral sinus and jugular vein. In advanced cases other sinuses become involved (superior petrosal, inferior petrosal, both cavernous, the lateral sinus of the opposite side, the ophthalmic veins, and the torcular Herophili). In sinus-thrombosis there is leukocytosis unless the patient is profoundly septic. A patient with sinus-thrombosis is in great danger of developing pulmonary metastasis and septic meningitis (Jansen). Septic meningitis is accompanied by abscess about the sinus. Infective sinus-thrombosis is a very fatal disease

[1] "Am. Med.," April 19, 1902.

and usually runs its course in from seven to ten days, but occasionally lasts for several weeks. It is a form of pyemia, and death arises from the causes which have been referred to in discussing that disease.

Infective thrombosis of the cavernous sinus occurs when an infected clot comes from another sinus, from disease of the nasal sinuses, from orbital infection, or from a pyogenic process of the face or lids. It causes pain and the general symptoms of pyemia, and also edema of the lids, chemosis, and an extreme degree of exophthalmos. Choked disk exists. Vision may be normal or impaired. The condition almost invariably spreads to the other eye along the circular sinus.

Infective thrombosis of the petrosal sinus produces pyemic symptoms, but no characteristic signs.

The **prognosis** largely depends upon early recognition. The surgeon should, whenever it is possible, open a mastoid before sinus-thrombosis arises, and should evacuate an abscess about the sinus before a clot forms in the venous channel, or at least before that clot becomes septic (Jansen).

Treatment.—In 1880 Zaufal proposed the operation now practised, and Horsely did it in 1886. (See article by Geo. F. Cott, in "American Medicine," April 19, 1902.) Infective thrombosis of the lateral sinus is treated as follows: Open and clear out the mastoid, and expose the sinus by the use of the chisel or rongeur (see Fig. 535). Follow Mr. Ballance's advice and expose the sinus from the bulb to the torcular. The jugular vein should now be exposed at the level of the cricoid cartilage and ligated below any clot which may exist. This is done to prevent propagation of an infected clot and diffusion of sepsis. Even if a clot does not exist in the jugular, the vein should be tied in two places and divided, because the sinus contains infected clot or putrid material even when the vein as yet does not. According to Ballance, the portion of the vein above the point at which it was divided should be extirpated. Some surgeons after ligating the jugular do not excise it, but if it contains or comes to contain a septic clot, incise the vein up to the base of the skull and pack the wound. After attacking the vein open the sinus, and if a clot is found to exist, cut away the wall of the sinus. Introduce a small spoon into the lumen and carry it toward the torcular Herophili, and scrape away the clot until blood flows. Arrest hemorrhage by forcing a piece of iodoform gauze into the wound and toward the torcular. Jansen opposes removing the entire clot toward the jugular, and does not tie the jugular, believing that to do so increases the danger of thrombosis of the inferior petrosal and cavernous sinuses. He simply removes the soft clot, but does not disturb the solid clot toward the heart. Most surgeons differ from him. Surgeons are of the opinion that it is futile to do any operation if pulmonary metastasis has taken place. In a case of the author's in the Jefferson Medical College Hospital the patient recovered after operation in spite of the fact that endocarditis had developed.

Until recently it was thought that the lateral sinus was the only sinus which should be attacked surgically, but in one case Knapp, of New York, requested Hartley to remove from the cavernous sinus a clot which was causing blindness and was due to sarcoma. The operation was successfully executed by Hartley, the incision being the same as is employed to reach a Gasserian ganglion in the Hartley operation. This patient lived several months. Dwight operated upon another case by incision of the sinus (E. W. Dwight and H. H. Germain, "Boston Med. and Surg. Jour.," May 1, 1902). Some surgeons advise removal of the eyeball and curettement of the sinus.

Postoperative Insanity.—Various mental disturbances may follow surgical operation (delirium, obsessions, hysterical excitement, morbid fears, illusions, hallucinations, amnesia, confusion, hypochondria, psychasthenia, melancholy, and genuine insanity). Insanity is no more frequent after abdominal

operations than after other operations if we exclude operations involving the ovaries. Removal of the testicles and ovaries are peculiarly provocative.

Postoperative insanity is most common in females and in adults. The predisposing elements connected with a surgical operation are: Apprehension, fear, pain, insomnia, and exhaustion before operation. The effects of the anesthetic, shock, and hemorrhage. Postoperative pain, insomnia, worry, and perhaps homesickness. There is always predisposition, hereditary or acquired. The patient may have been on the brink of an outbreak when the operation was performed. The insanity may be apparent as the patient awakes from the anesthetic sleep (Savage), and in these very rare cases the anesthetic is blamed. Most acute insanities come on in from three to five days after operation.

If a man has ever had an attack of insanity operation exposes him to distinct danger of another attack. No special mental condition characterizes postoperative insanity. There may be mania, melancholia, stupor, delusional insanity, or acute confusion. Acute confusional insanity is the most usual form. In some cases sepsis is present, in others it is not. We must not mistake insanity for febrile delirium, delirium tremens, delirium from opium deprivation, delirium from taking morphin or cocain, delirium of iodoform-poisoning, delirium of the senile, traumatic delirium, hysterical delirium, uremic coma, or bromism.

Many cases of postoperative insanity must be sent to a hospital for the insane. Only cases of brief duration can be properly cared for in a general hospital.

Intracranial Tumors.—An encephalic tumor may originate within the skull. It may have arisen from an external growth invading the cranial cavity, or may be metastatic. A tumor that arises within the cranium may take origin from the periosteum, from one of the membranes of the brain, from the vessels, from the neuroglia, or from the brain substance.

No region of the body is so liable to tumors as the brain. During the course of a number of years the autopsies of the Munich Pathological Institute are stated by Bollinger to have shown 1 tumor of the brain in every 85 autopsies. Hale White's experience is that such tumors are even more common than this, and he estimates them at 1 in every 59 autopsies.

In endeavoring to determine the causes of intracranial tumors we must accredit heredity with considerable influence in tuberculoma, and possibly with some force in sarcoma and carcinoma. Tumors of the brain are decidedly more common in males than in females, probably because of the greater male liability to injury, syphilis, and alcoholism.

The majority of cases of tumor of the brain occur between the ages of twenty-five and fifty. Children are particularly prone to suffer from glioma and from tuberculous growths. In aged persons a tumor of the brain very rarely develops. In 100 cases of brain-tumor collected by Hale White only 2 were aged seventy or over. In 100 cases collected by Mills and Lloyd only 1 was over seventy.

Injury may be responsible for the development of sarcoma, of fibroma, and possibly of other forms; in fact, a syphiloma may arise in a syphilitic person at the seat of an injury.

We use the terms "intracranial" or "encephalic tumor" not only to include true neoplasms, but also to designate growths of parasitic, syphilitic, or tuberculous origin. It is of importance to attempt to make a diagnosis as to the form of tumor that is present, and this may be possible on account of the fact that in many cases the form affects the symptoms. A useful classification of these growths has been made by Knapp, and is as follows: (1) The infective granulomata, including tuberculous growths, gummata, and actino-

mycotic areas; (2) connective-tissue growths; (3) epithelial growths; (4) aneurysms. The most common of all these tumors is undoubtedly that due to tubercle. In fact, Gowers estimates that, if we exclude syphiloma, tubercle is responsible for one-half of the cases, and glioma and sarcoma together for one-third.

Tuberculous Tumors (*Tuberculous Gummata; Tuberculomata*).—Tuberculous growths may be primary, but are usually secondary to tuberculosis in some other region of the body. Tuberculous tumors are the most common form met with. They are at least four times as common in children as in adults. They may be single, especially in adults, but are often multiple, especially in children; and multiple growths may be very widespread. According to Allan Starr, these growths are most common in the cerebral axis (especially in the basal ganglia), next in the cerebellum, next in the cerebral cortex, and are least common in the centrum ovale. A tuberculous tumor usually arises in the pia mater, particularly in an arterial distribution, but may begin in a ventricle, or even in the brain substance. Some of these growths are distinctly subcortical. The tubercle bacilli responsible for the condition are carried by the blood. Some of these growths are small aggregations of miliary tubercles in thickened pia. Others are large masses. A large tuberculous tumor is due to the coalescence of many foci. It undergoes caseation in the center, and is surrounded by a zone of softened or sclerotic brain substance. Tuberculous meningitis is present in two-thirds or three-fourths of the cases of tuberculoma.

Gummatous Tumors (*Syphilomata*).—As gumma seldom arises from inherited syphilis, the condition is very rare in children. There may be a single gumma, but, far more often, syphilitic growths are multiple. A gumma may be round or may be irregular in outline; in fact, the outline is frequently blurred and indistinct. Some of these growths are soft, and some, which contain a quantity of connective tissue, are hard. A syphiloma usually arises from the membranes, and, hence, is generally on the surface of the brain; and the membranes in the region of the growth usually show distinct inflammation. Soft gummata are most common at the base; hard gummata, in the cortex of the cerebrum or cerebellum.

Actinomycosis.—This is a very rare condition, in which the mass may remain solid like a tumor, but is far more apt to break down into an actinomycotic abscess.

Sarcomata.—Injury seems to play a considerable part in the production of intracranial sarcoma. Any variety of sarcoma may arise. It may be primary or secondary. As a rule, at least in the beginning, the growth is single; but it may be multiple or may become so. The majority of sarcomata arise from the membranes or from the periosteum, but some cases take origin from beneath the cortex. Early in their progress these growths may be encapsulated, but some of them, from the very start, are infiltrating; and even those that were at first encapsulated later infiltrate. The cortex and the cerebellum are the most common seats for sarcoma. *Endothelioma* is sometimes met with. What is called *angioma of the brain* is, in reality, *angiosarcoma*. A *psammoma* is usually sarcomatous.

Gliomata.—A glioma is a growth which is often so ill defined and so slightly differentiated in appearance from the brain substance that it may easily be overlooked in an exploratory operation. It arises much more frequently from the white than from the gray matter, and develops from the neuroglia of the cerebrum, of the cerebellum, of the pons, or of the medulla oblongata. A glioma may be soft or may be hard; and soft gliomata are probably, in reality, sarcomata (gliosarcomata). Hemorrhage is very apt to occur in these growths. They have a tendency to become cystic. They destroy tissue as they grow, hence pressure signs are late or absent.

Fibromata.—Intracranial fibroma is a rare growth. Tumors of the cerebellopontile angle are apt to be of this character. It is of firm consistence, is encapsulated, and may grow to a large size. Such growths can be readily enucleated. Injury seems occasionally to be responsible for their formation.

Osteomata.—Osteophytic growths not uncommonly take origin from the inner surface of the skull, but the osteomata arising in the dura or in the brain substance are rare. Such growths, however, occasionally occur.

Cholesteatomata.—These tumors are fibrous growths covered with endothelium and containing layers of cholesterin. They are particularly apt to arise in the pia mater, but may begin in either of the other membranes or in the brain substance. A cholesteatoma is commonly called a *pearl tumor.*

Enchondromata and *true neuromata* are rare, and *lipomata* are exceedingly uncommon.

Adenomata.—An adenoma occasionally springs from the conarium or the pituitary body.

Carcinomata.—Primary intracerebral carcinoma is rare, but does occur. Secondary carcinoma is more common, and may follow cancer of any part of the body, although it is most apt to follow cancerous growths about the face or neck. A primary growth may begin in the meninges or in the lining of the ventricle. Intracerebral carcinomata may be single or multiple. They are soft and non-encapsulated growths, infiltrating and very vascular.

Cysts.—Mills says that cysts arise about an old hemorrhage, are small retention-cysts of a vascular plexus, or are porencephalic. Dermoid cysts are extremely rare. Hydatid cysts are very rare in the United States. A cyst may result from the degeneration of a glioma or a sarcoma.

Symptoms.—They are divided into two sets: (1) *General*, due to increase of pressure, and (2) *local, localizing,* or *special*, arising because of the part of the brain involved.

In some cases general symptoms are absent, in some special symptoms are absent, in others even tumors of large size produce no recognizable symptoms, either general or special. A large infiltrating growth, a glioma, for instance, may produce no symptoms at all if situated in a silent region, and if it destroys brain substance as it grows, so that intracerebral pressure is not increased.

General Symptoms.—The chief general symptoms are headache, vomiting, and choked disc. All of these may be present, any one of them may be absent, any two of them may be absent, and in some cases all of them are absent. Other general symptoms that may or may not be present are vertigo, general convulsions, insomnia, mental failure, and somnolence or partial stupor.

Headache.—This is the symptom most commonly present. It occurs sooner or later in a very great majority of cases.

At first it may be noted only at certain times of the day and it is usually complained of most on rising in the morning. The headache of brain tumor when once established is intense in most cases, and as a general thing it is practically continuous, with episodes of increased violence. In rare cases it is paroxysmal. In some cases it is trivial, in some few cases it never arises at all. The headache of brain tumor usually interferes with sleep. It may be general, one sided, frontal, or occipital. The situation of the pain is without localizing value unless there is tenderness on percussion or pressure over the seat of pain, which is sometimes noted in growths of the meninges or cortex.

Headache is less common in children. In very young children the explanation of this is found in the open fontanels and the expansile cranium. In older children in the fact that gliomata are common in children and gliomata may not cause intracerebral pressure.

The dura is sensitive, as Cushing says, to "pull or pressure, not to an incision." The headache of brain tumor is due to stretching of the dura.

Vomiting is present at times in many of the cases. It may happen occasionally or it may never occur.

It is usually cerebral, that is, vomiting with a clean tongue without nausea, and without any relation to the taking of food. In some cases it is projectile, quantities of vomitus being suddenly projected from the mouth. It may, however, be associated with nausea, and in some cases there is nausea without vomiting. It is apt to be most severe on getting up, especially on rising in the morning. It is usually most severe when headache is most intense.

The worst attacks of vomiting occur in cases of cerebellar tumor.

The cause of vomiting is uncertain. Some believe it to be due to stimulation of the vagus center; others, to reflex stimulation of a vomiting center in the medulla. If associated with vertigo it may arise from the auditory centers.

Choked Disk (*Optic Neuritis, Papillitis, Descending Neuritis, Papilloedema*).—This is a most important symptom. When present it is, as Cushing says, one of the "most reliable" signs of tumor. It is present in 80 per cent. of all cases. It may be noted in a few weeks after a tumor begins to grow, in a few months, or longer. It may come on rapidly or gradually.

It is particularly common and severe in growths beneath the tentorium. It is decidedly less common in tumors of the motor cortex. It is nearly always bilateral, but it is common to find it more marked in one eye than in the other. That it is worse on one side *suggests*, but *only suggests*, that the tumor may be on the side on which the choked disk is worst. Monocular choked disk is very rare. When it exists it indicates that the growth, in all likelihood, is situated near the back of the orbit on the same side as the choking of the disk. Gowers recorded a case of unilateral choked disk due to a tumor compressing the left optic nerve ("Lancet," July 10, 1909).

Choked disk may exist for some time and attain a high grade without noticeably impairing vision, but ultimately it leads to retinal hemorrhage, white atrophy, and blindness. When atrophy begins, vision wanes. The presence of choked disk does not *prove* the existence of tumor. The cerebral edema of Bright's disease may cause a condition known as albuminuric retinitis, which practically is not to be distinguished from the choked disk caused by tumor. Cushing believes that the processes are identical in tumor and Bright's disease. Choked disk may occur in meningitis, brain abscess, cerebral syphilis, sinus-thrombosis, myelitis, infectious diseases (typhoid, influenza, diphtheria, and other conditions), toxemias from lead, arsenic, and alcohol, anemia, diabetes, or as an hereditary or family disease.

The cause of choked disk has been much disputed. Some believe that the condition is a neuritis due to a toxic condition of the cerebrospinal fluid. Others believe that it is not inflammatory, but is a papillo-edema due purely to mechanical pressure, and is an edema or dropsy. The latter theory is largely held by surgeons because they have become convinced by experience that relief of intracranial pressure relieves or cures choked disk. De Schweinitz and Holloway ("Therapeutic Gazette," July 15, 1909) make the following statement in regard to mechanical pressure causing choked disk: "That this is the *only* etiologic factor may with propriety be disputed; indeed, it seems certain that a combination of factors must be active in the production of this condition, but increased intracranial pressure is the one of which we have most certain knowledge."

Cushing, of Harvard, who has done such notable work on this subject, believes that "almost all, if not all, cases of choked disk are primarily of mechanical origin and do not justify the term 'neuritis'" ("Keen's Surgery," vol. iii). The presence of choked disk is disclosed by the ophthalmoscope.

Convulsions.—Generalized convulsions may occur, and children are especially liable to them. Many cases of supposed general convulsions have an unobserved local beginning which is a focal symptom.

Vertigo.—Mills says it is noted in one-third of all cases and is due to dural, ocular, or labyrinthine irritation.

Insomnia is often due to headache and is apt to be associated with restlessness, lack of emotional control, and irritability. It is most pronounced in cases of syphiloma and some forms of malignant disease, and is worse in adults than in children.

In rare cases there is *somnolence* or partial stupor rather than insomnia. In such cases slow speech is often noted.

Mental Failure.—There is often great lack of emotional control, characterized by irritability and outbreaks of anger. Failure of memory is common and change of character is the rule. There may be great slowness of thought and of mental response to stimuli, with defective power of orientation. Progressive mental deterioration may occur. There may be mental depression, apathy, or mental excitement. Tumors in certain regions may cause delusions, illusions, or hallucinations.

Hysteria and neurasthenia sometimes arise.

Pulse and Respiration.—Whereas the pulse is often slow, it is very variable, and I agree with Cushing that "pressure-symptoms which characterize acute lesions (namely, rise in blood-pressure; slow, vagus pulse, and Cheyne-Stokes respiration) are conspicuous by their absence" ("Keen's Surgery," vol. iii).

Special Focal or Localizing Symptoms.—These symptoms, when present, indicate the situation of the growth. If the tumor is in a silent region there will be no focal symptoms. General symptoms may exist without focal symptoms and focal symptoms may exist without general symptoms.

Among localizing symptoms we should mention various forms of aphasia, hemianopsia, paralysis, Jacksonian epilepsy, sensory disturbances (to touch, pain, or temperature), sensory aura, disturbances of taste and smell, impairment of muscular sense, alteration or impairment of reflexes, nystagmus, and incoördination.

Exophthalmos means direct pressure upon the cavernous sinus. A unilateral exophthalmos is nearly always upon the side of the tumor. In bilateral exophthalmos the protrusion is usually worst on the side of the lesion (Weisenberg, in "Jour. Amer. Med. Assoc.," vol. lv).

Diagnosis.—In many cases a diagnosis is made at a period so late that irreparable damage has already been inflicted. Early diagnosis is of the first importance. A careful and painstaking study of the patient and of his history will usually enable us to make a diagnosis before, and often long before, the attainment of a degree of pressure which causes papillo-edema, headache, and vomiting. In doubtful cases an exploratory operation should be performed. Exploration is always called for in advancing cerebral palsy and in focal epilepsy.

In *abscess* the symptoms usually develop much more acutely than in tumor. It is true that some cases of abscess last for months, but in them intervals of complete remission of symptoms occur, which is not the case in tumor. An abscess follows middle-ear disease or some other pyogenic process or perhaps a head injury. There may be fever and leukocytosis. Choked disk is far less common than in tumor.

Chronic meningitis from syphilis exhibits periods of increase and periods of subsidence of the symptoms, and usually palsy of one or more cranial nerves. The symptoms may pass away under the use of mercury and iodid of potassium. There may be clinical evidences of syphilis. There should be a positive Wassermann reaction.

Chronic tuberculous meningitis causes a headache which is apt to be general and more violent than that of tumor, and there is more commonly cutaneous hyperesthesia and hyperesthesia of the organs of sight and hearing. Optic neuritis may be absent. When present it is of less intensity than that observed in tumor. In some cases the ophthalmoscope discloses tubercles on the choroid. In meningitis there is a continued, irregular fever. The cerebrospinal fluid obtained by lumbar puncture usually exhibits an excess of lymphocytes. It may contain the bacilli. Carbohydrate is absent. It may be sterile. Of course, a tumor might exist with meningitis.

In *Bright's disease* symptoms strongly suggestive of tumor may arise (headache, vomiting, and choked disk) with, perhaps, but little change in the urine. The difficulty in diagnosis becomes evident when we recall that in cases

Fig. 524.—Professor Gibbon's case of brain tumor.

of brain tumor the urine may contain casts and albumin. A sudden onset and brief duration of the symptoms suggest uremia.

Ependymitis with ventricular dropsy may cause symptoms resembling tumor with hydrocephalus. Optic neuritis is not so common as in tumor. Bilateral spastic paralysis may arise.

Severe anemia is capable of producing symptoms which suggest tumor. It can even produce choked disk. A blood examination and the rapid improvement under proper treatment makes the diagnosis evident.

In some cases of brain tumor (especially frontal lobe tumors) there are striking evidences of hysteria and neurasthenia. Always think of this when inclined to make a diagnosis of hysteria or neurasthenia.

The *x*-rays may aid us in diagnosis and many brain tumors can be skiagraphed (Fig. 524). Lumbar puncture may aid in the diagnosis, but it must be

used with the greatest care, because in tumor the withdrawal of any considerable quantity of fluid may be followed by sudden death due to the brain stem sinking into the foramen magnum.

Cause, Duration, and Termination.—A brain tumor, unless caused by syphilis, is a certainly fatal lesion if not removed by operation.

Some brain tumors grow for years before they produce symptoms. Some grow with great rapidity. When pressure symptoms appear the patient's life will terminate within a few months unless an operation is performed. It is usually stated that the average duration of life is three years.

Sudden death may occur at any time.

Horsley states that in a very few cases brain tumors have disappeared after mere operative exposure, the tumor not having been removed. Cushing has had the same experience, and regards such an amazing disappearance as due to the cystic degeneration of a glioma.

Localization of a Tumor.—The situation of a tumor is determined not only by localizing symptoms, but also from their mode of onset and manner of combination. In some cases the symptoms are not characteristic, in others they are definite. The more marked the signs of compression, the less the value of localizing symptoms. The nature of the tumor, its depth, and whether it is single, and if other tumors exist is, if possible, determined. Localizing symptoms may be due to irritation or destruction of functionating power. Irritation causes spasm, and destruction induces paralysis. Convulsions which are local or which begin locally are known as *Jacksonian epilepsy*. A local convulsion points to an irritative lesion of, or immediately adjacent to, the center which presides over the muscular movements of the part convulsed. Local paralysis points to a destructive lesion of the center which presides over the movements of the paralyzed part. In some cases a center is damaged and the muscular movements it controls are paralyzed, but the adjacent brain-areas are irritated and the muscles they represent are attacked with spasms. In some cases an apparently paralyzed part becomes convulsed, the center not being completely destroyed and sudden hyperemia serving to awaken spasm. Always note the order of invasion of different regions and observe if spasm is followed by muscular weakness or anesthesia.

Lesions in the Cortical Motor Area.—A slow-growing tumor which irritates the cortex will cause tonic or clonic convulsions on the opposite side of the body. These convulsions have a local beginning (Jacksonian epilepsy). After a time paralysis may develop (monoplegias and perhaps, ultimately, hemiplegia). An irritative lesion of the lower third of this area causes spasm of the opposite side of the face, angle of mouth, or tongue; and this condition is often associated with tingling. The spasm may remain limited or may extend widely, and may even become general. An irritative lesion of the middle third of the cortical area causes spasm, which is limited to or begins in the fingers, thumb, wrist, or shoulder. An irritative lesion of the upper third of the cortical motor area causes spasm, which is limited to or begins in the toes, ankle, leg, or thigh. If such lesions exist, an aura is occasionally felt in the affected region before the spasm begins, and there is often numbness after the spasm. Destructive lesions of the motor area cause local paralysis, which may be preceded by local spasm of the same parts, and is often associated with local spasm of other parts. If paralysis comes on unpreceded by convulsions the lesion is *subcortical* rather than cortical, that is, it is in the white matter between the motor area and the internal capsule.

Tumors of the anterosuperior portion of the prefrontal region give no definite localizing symptoms, but produce general symptoms. Mental disorders may arise in tumors of any area of the brain, but in tumors of the prefrontal region they are most apt to occur. The intelligence is nearly always

impaired, and there is apt to be mental apathy, loss of memory, hysteria, irascibility, and pronounced change of character. As the tumor grows it may subsequently involve the motor region, which in all probability lies entirely in front of the fissure of Rolando.

In tumors of the prefrontal region there may be focal convulsions or local palsy on the opposite side, due either to a spread of irritation from a superficial tumor to the motor cortex or to involvement by a deep tumor of the commissural fibers which join the frontal lobe and the motor cortex.

Tumors of the Antero-inferior Portion of the Prefrontal Region.—In a right-handed man tumor of the second left frontal convolution causes *agraphia*, and of the third left frontal convolution, *motor aphasia*. In a left-handed person these localizations are on the right side of the brain.

Tumors of the parietal lobe may occupy a silent region of this lobe. The centers for general sensibility and for the muscular sense are back of the fissure of Rolando in the parietal lobes. Hence a tumor in this region may cause disturbance of muscular sense and general sensibility in the limbs without spasm or palsy (Durante). There may be word-blindness when the left angular gyrus is affected.

The extension forward of a parietal tumor will involve the motor zone and produce spasm or palsy. Extension backward will involve the occipital lobe and produce hemianopsia.

Tumors of the occipital lobe are apt to produce *lateral homonymous hemianopsia* (blindness of the nasal half of one retina and the temporal half of the other retina. If the right side of the brain contains the lesion the right side of each retina is blind, and vice versâ). Wernicke's pupillary sign is absent. By this sign we mean loss of pupillary light reflex when light is cast upon the blind part of the retina. This sign only occurs in lesion in or in front of the centers for pupillary reflex. Lesions of the cuneus and of the calcarine fissure are especially apt to produce hemianopsia. A lesion of the occipital cortex may produce it. Tumors of both occipital lobes cause blindness. In tumor of an occipital lobe color vision only may be affected (Cushing). Tumor of the optic radiation may produce hemianopsia (that is, growths of the chiasm, optic nerve, or pulvinar may, but it is not certain that a growth of the quadrigeminal bodies or of the external geniculate body can).

In a tumor of the occipital lobe (the left lobe in right-handed persons and vice versâ) there may be *mind-blindness*, that is, an inability to know what is seen. He may fail to understand written or printed words (*word-blindness*), the nature of things (*apraxia*), or signs (*asemia*).

Tumors of the temporosphenoidal lobe frequently produce no symptoms. In the temporal lobes the cortical centers for hearing are placed, and each center is connected with both auditory nerves, but the crossed auditory bundle is larger and more active than the direct (Francesco Durante, "Brit. Med. Jour.," Dec. 13, 1902). Tumors in the left lobe are particularly apt to cause deafness and may cause *word-deafness*. Tumors at the apex of the lobe may cause perversion or impairment of taste and smell. Tumors of the temporosphenoidal lobe may make pressure on the motor tract and cause paralysis of the opposite side.

Tumors of the Corpus Callosum.—These growths affect mentality as do tumors of the frontal lobes and frequently cause hemiplegia of each side.

Tumors of the Crus.—These tumors cause hemiplegia of the opposite side and paralysis of the third nerve on the side of the lesion. If the optic tract is pressed upon there will be hemianopsia. If the tegmentum is involved there will be hemianesthesia.

Tumors In or About the Optic Thalamus.—On the side of the lesion there are nystagmus and impairment in the movements of the eyeball. There

is muscular weakness and impairment of sensation in the limbs of the opposite side. There may be sudden and uncontrollable movements, astereognosis, mental dulness, emotional outbreaks, and impairment of emotional control of the facial muscles. A lesion of the posterior part of the thalamus causes hemianopsia and the pupillary reaction of Wernicke.

Tumors of any size in or about the **corpus striatum** cause hemiplegia of the opposite side by pressure upon the internal capsule. Pressure upon the *optic thalamus* produces homonymous hemianopsia and hemianesthesia. Growths near the basal ganglia produce intense choking of the disk and early pressure because of distention of the ventricles.

Tumors of the Corpora Quadrigemina.—These tumors produce cerebellar ataxia, palsy of the eye muscles, and sometimes, perhaps, hemianopsia. Hearing may be impaired in the ear opposite to the lesion. Tumors of the corpora quadrigemina are apt to involve the crura, and later the third nerve. Ocular symptoms are always present (loss of pupillary reflex and nystagmus). If the third nerve is involved there are paralysis of the motor oculi area on the side of the lesion (external strabismus, dilated pupil, and drop-lid) and hemiplegia of the opposite side of the body from pressure upon the crus. This condition is a form of *crossed paralysis.*

Tumors of the Pons.—Pontine lesions produce symptoms by pressure upon the particular nerves which come from this region, with or without the evidences of pressure upon the motor path. Forms of crossed paralysis may exist. Lesions in the lower half of the pons may affect the fifth, sixth, and seventh nerves on the side of the lesion and the limbs on the opposite side. The auditory nerve may be involved in the lesion. In crossed paralysis the face on the side of the limb paralyzed is usually not affected, but in extensive tumors it may be paralyzed. *Conjugate deviation* of the eyes may occur *away* from the *facial paralysis.* In tumors of the upper part of the pons the pupils may be first contracted because of irritation of the third nerve nuclei, and later dilated by destruction of these nuclei. Anesthesia as a result of pontine tumors is not nearly so common as motor paralysis, and convulsions are rare. There may be hemiplegia with crossed hemianesthesia. A tumor on the side of the pons which involves the peduncles causes ataxia and sudden, uncontrollable movements. Knee-jerk may be absent in a case of pontine tumor.

Tumors of the Medulla.—An extensive lesion inevitably causes death. Cranial nerves only may be involved, but crossed paralysis may take place. There may be hemiplegia with crossed paralysis of the hypoglossal nerve. Vomiting is common, retraction of the head is not unusual; respiratory and circulatory disturbances and dysphagia are usually noted; sometimes there is numbness and occasionally there are convulsions; usually there is incoordination because of pressure upon the cerebellum.

Tumors of the Cerebellum.—They often cause internal hydrocephalus. In general it may be said that tumors of the cerebellum cause headache, vomiting, vertigo, choked disk, and early blindness. *Tumors of the middle peduncle* cause sudden uncontrollable movements of the trunk, either toward the side of the tumor or away from it. Vertigo and nystagmus are common. Symptoms are frequently complicated by evidences of pontine disease proper.

Tumors of the middle lobe of the cerebellum cause a sense of lost equilibrium and obvious unsteadiness in attempting to walk or even to stand. The knee-jerks vary. The Babinski reflex is absent in an uncomplicated case. The patient has a tendency to fall backward; there are giddiness and vomiting, early and violent choked disk and occipital headache, nystagmus, inability to stand steady when the feet are together and the eyes shut, and perhaps temporary palsies of the eye muscles.

Tumors of the cerebellar hemisphere produce no localizing symptoms. The usual unsteadiness of gait is due to pressure upon the middle lobe (Nothnagel).

Tumors of the Cerebellopontile Angle.—Tumors of this region are usually attached to the acoustic nerve, sometimes to the fifth nerve. They produce general pressure-symptoms and may cause cerebellar or pontine symptoms by making direct pressure on those parts. If the tumor involves the acoustic nerve there will be tinnitus, objective vertigo (sometimes with, sometimes without, forced movements), a liability to sudden attacks of falling to the ground, failure of hearing or actual deafness, perhaps sudden blindness or sudden unconsciousness, and sometimes tonic extensor spasms. If the tumor involves the trigeminal nerve there will be violent neuralgia in the course of the nerve.

Tumors of the Hypophysis Cerebri.—The pituitary body may be subjected to pressure from, or become involved in, tumors of the region about it or tumors or cysts may spring from it directly. Tumors of or tumors making pressure upon the hypophysis may in some cases cause acromegaly, and in others impotence, genital infantilism, a tendency to fat deposit and stunted stature, and amenorrhea in women. There is intense headache, amblyopia due to primary atrophy (no preceding choked disk), appearing often as a bitemporal hemianopsia (Cushing, "Jour. Amer. Med. Assoc.," July 24, 1909). In some cases extreme drowsiness has been noted, and in some cases there has been binasal hemianopsia. When there is stimulation of the pituitary (hyperpituitarism) acromegaly develops; when there is lessened secretion (hypopituitarism) there are obesity and genital atrophy.

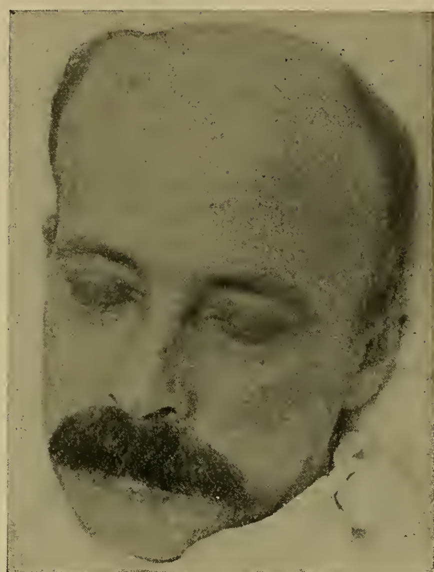

Fig. 525.—Case of cerebellar tumor. Bulging of flap after osteoplastic exploratory operation.

Any brain tumor which causes internal hydrocephalus may thus cause pressure on the hypophysis and lead to the development of hypophyseal symptoms. (For full information regarding the hypophysis see the classic monograph by Harvey Cushing, called "The Pituitary Body and Its Disorders").[1]

Treatment.—If any doubt exists as to the existence of brain syphilis, and if the Wassermann reaction is positive, give the patient a dose of salvarsan (intravenous) and a course of iodid of potassium. Give the iodid at first in small amounts, but rapidly increase it until heroic doses are taken (100 or more grains a day). Mercury should also be given hypodermatically or by inunction. If salvarsan, iodid of potassium, and mercury really relieve the symptoms, and if the improvement is not merely temporary, operation is unnecessary, although it may be demanded later in order to remove an irritant scar. If antisyphilitic treatment fails, the question of operation must be considered. The test of success is improvement in the choked disk. If this improves, the

[1] For full consideration of localizing symptoms see particularly the writings of Gowers, Mills, Allan Starr, Potts, Lloyd, Burr, Dana, Dercum, Osler, and Cushing, which have been freely used in the above section.

52

treatment is succeeding; if it does not, the treatment is a failure. It should not be persisted in over six weeks if there is no improvement in the eye-grounds. To delay operation further may mean blindness. We must always bear in mind that in certain cases of glioma the symptoms *temporarily* improve under antisyphilitic treatment. The term *operable case* does not of necessity mean a tumor which can be entirely removed by operation. Some tumors which can be only partially removed should be operated upon. An operable case is one in which an attempt may be made to remove the tumor and in which the tumor can be entirely removed or in which a part can be removed, the removal of this part promising relief. We are justified in being radical, because without operation a brain tumor is a certainly fatal malady. In many cases of undoubted tumor excision for cure is not attempted because of the absence of localizing symptoms or because of the inaccessible situation of the growth. In all cases operation is, first of all, exploratory. Tumors of the dura which have not infiltrated the brain, many cortical and some subcortical growths, are operable. Cerebral and cerebellar cysts may be opened and drained in hope that benefit will result. Tumors of the lateral lobe of the cerebellum and tumors of the cerebellopontile angle have been removed. Byrom Bramwell maintains that tumors at the base, tumors of the pons and medulla, of the corpus callosum, of the basal ganglia, and of the deeper parts of the centrum ovale are irremovable. Surgeons now regard some tumors of the cerebellopontine angle as operable, but agree with Bramwell's views as to growths in the other situations he mentions. Frazier has concluded that "if the tumor is found to be very vascular and of the infiltrating type, it is very questionable . . . as to whether any attempt whatsoever should be made to extirpate" ("University of Penna. Med. Bull.," April–May, 1906), and with this opinion I certainly agree. In tumors which are very extensive complete removal is usually out of the question. There is no use in removing secondary malignant tumors. It often happens that the brain itself (as in syphilis) is so extensively diseased, or that other organs (as in tuberculosis) are so involved, as to render attempts at removal of the tumor futile or actual removal useless. Mills thinks that 50 per cent. of cerebellar tumors can be attacked surgically ("New York and Phila. Med. Jour.," Feb. 11–18, 1905). He classifies operable tumors of the cerebellum as follows: 1. Tumors situated entirely or chiefly in the lateral lobe. 2. Tumors upon or even invading a part of the vermis or middle lobe. 3. Tumors of the cerebello-oblongatopontile angle. The most favorable tumors for removal are fibromata and encapsuled sarcomata. Gliomata and gliosarcomata have been removed, but are very apt to return. A syphiloma requires removal as truly as a real tumor. The cases are commonly unfavorable, as there is often widespread brain disease. The same is true of tuberculoma. Among inoperable tumors are most gliomata and all infiltrating sarcomata, metastatic tumors, and multiple tumors. Bramwell[1] tells us that he has studied 82 cases of intracranial tumor, and he considers that in only 5 of them could the tumor have been entirely removed. In 157 reported cases the tumor was either not found or not removed; in 104 reported cases the tumor was found, and in some of them it was removed (Ransohoff, in "Jour. Amer. Med. Assoc.," Oct. 11, 1902). The conclusion is that though some tumors of the brain may be successfully removed, extirpation is feasible in only a small minority of cases and is to be decided on only after careful study of all the indications and contra-indications offered by the case. When about to operate, apply an apparatus to the arm and take the blood-pressure just before the operation and at frequent intervals during it. Thus by noting a great fall in blood-pressure the surgeon gets early warning of dangerous shock, learns when to hasten, and if the operation should be temporarily abandoned and be completed at

[1] "Edinburgh Med. Jour.," June, 1894.

another time (two-stage operation). We may be driven to abandon operation after cutting the bone and dural flaps, and if we are forced to stop, we restore the bone and dura to position, and complete the operation after a day or two. I agree with Frazier that the lessening of hemorrhage by temporarily clamping the common carotids in the neck is not free from danger, and it is not proper to do more than apply Crile's clamp to the vessel on the side operated upon. In a brain tumor when the dura is first opened there is usually at once marked bulging of the brain, which is called *initial bulging;* after working for a time on a brain, even when there is no tumor, bulging occurs from traumatic edema, which is called *consecutive bulging.* That consecutive bulging may occur is a sound reason for operating rapidly (Frazier). The mortality from tumor operations is large, death being due to shock and hemorrhage. Haas collected 122 cases in which the tumor was removed; the mortality was 60 per cent. Operations completed at one séance give a larger mortality than two-stage operations. During the operation an erect posture causes the brain to recede and permits of extensive exploration under the dura (Ransohoff-Cushing). The same thing is accomplished by lumbar puncture (Cushing). The fibromata constitute the bext cases for operation. In operating on a cerebral tumor make a large osteoplastic flap. If on opening the dura the tumor is not visible, and if the localizing symptoms were reasonably positive, the surgeon is justified in making an exploratory incision through the cortex to see if there is a subcortical growth. Operations for cerebellar tumors are peculiarly difficult because of the large blood sinuses, because of the limited space obtained to work through, because of the great bulging after the dura has been opened, because of the impossibility of reaching the anterior, mesial, or upper surfaces through the incision, because of the liability to injure the pons and medulla, and because of the difficulty of retracting the parts (Frazier, "New York and Philadelphia Med. Jour.," Feb. 11–18, 1905). In approaching tumors which are not within a cerebellar hemisphere by a one-sided exposure of the cerebellum, it may be best to remove a considerable portion of the hemisphere in order to obtain free access to the growth. I prefer Cushing's "cross-bow" incision and bilateral exposure (see Fig. 537). This enables the surgeon to dislocate the sound lobe outward and so obtain room to work upon the lobe containing the tumor. The diagnosis of cerebellar tumor is usually doubtful, hence practically all operations are at first exploratory and are then made palliative or radical as the case demands. Operation must be early because cerebellar growths quickly cause blindness. Sir Victor Horsley, McArthur, Hochenegg, von Eiselsberg, Cushing, Frazier, and others have operated for tumor of the hypophysis. Removal of a healthy pituitary body from dogs is sure to be fatal, as the gland is necessary to the life of the dog. Removal of a healthy pituitary in man would in all probability prove fatal. The entire anterior lobe should not be removed. If the tumor is associated with acromegaly, removal of the tumor may arrest the acromegaly. One route of approach to the hypophysis is from the side, just as we reach the Gasserian ganglion (Carton, Paul, Horsley). Another route is by way of osteoplastic frontal resection, the longitudinal sinus being ligated and the frontal lobes lifted (Krause, Hartley, Borchardt). Another method involves osteoplastic resection of the anterior wall of the frontal sinus and nose. This is called the transphenoidal route. The transphenoidal route has been variously modified. Cushing's plan of approach through a sublabial incision is described on page 834. Though thorough extirpation of a brain tumor is feasible in only a minority of cases, operation should often be performed for palliative purposes when the tumor cannot be located, when it is in a region from which it cannot be removed, or when its nature forbids removal. Grainger Stewart, Annandale, Horsley, Macewen, Cushing, and Keen have advocated

palliative trephining in certain cases. Simple trephining is of little value. In order to really relieve pressure the dura must be opened and left unsutured, so that hernia cerebri may follow. Cushing has had some cases of extraordinary improvement in cases of cerebral tumor after trephining in the right temporal region and removing a piece of the dura. The operation is called by Cushing a *decompression operation.* The brain bulges through the dural opening, but the dense temporal fascia stitched together over it prevents fungation. It is the temporosphenoidal lobe that bulges, and the right side is selected because word-deafness might ensue if the operation were done on the left side. I have seen several of Cushing's cases. One of them, a colored man, had been almost blind for some time, and was unconscious and had rapidly failing respiration when the operation was performed. He was so much benefited that he returned to work and has useful vision and no pain. I have had several very gratifying results in my own practice. A decompression may, in rare cases, cause a glioma to degenerate and pass away. Horsley saw such a case. In cases of cerebral tumor subtemporal decompression, and in cases of cerebellar tumor suboccipital decompression, may be performed. Sir Victor Horsley believes that the opening for decompression should be near the tumor and not always in the subtemporal region. He believes an opening near the tumor possesses the advantage of aiding us later if the tumor should become operable. He maintains that subtemporal decompression may later confuse the localizing symptoms should such symptoms develop.

Decompression may relieve choked disk and thus retard or prevent optic atrophy and blindness. Cushing demonstrates that intracerebral pressure is the chief element in choked disk.

This procedure is of value in diminishing excessive intracranial pressure, and thus relieving headache and choked disk, and decreasing the tendency to sudden death from inhibition of the heart or from respiratory failure. The usual method of decompression will not relieve the headache caused by tumor of the hypophysis. This headache is due to distention of the dural box in which the gland is placed, and can be relieved only by incision of the dural box (Harvey Cushing, "Jour. Amer. Med. Assoc.," July 24, 1909).

We conclude that in most cases of brain tumor operation should be performed for exploration; in some cases extirpation may be performed; in most cases extirpation is impossible, and the surgeon must be content with the palliative influence of Cushing's decompression operation. A tumor of the brain if not cured by antisyphilitic treatment is of necessity fatal if unoperated upon, and exploratory operation is not very dangerous.

In a case of brain tumor if operation is refused, if extirpation is impossible, or if decompression fails, it may be necessary to use the bromids for convulsions and morphin for headache. The headache is often benefited by purgatives, courses of potassium iodid, and the ice-bag to the head.

Operative Treatment of Epilepsy.—The shock of an accident or a cerebral concussion may establish epilepsy, especially in those predisposed by heredity or other causes. Traumatic epilepsy, Le Dentu[1] tells us, may be due to: (1) Bone-fragments from skull fracture; (2) outgrowths of bone due to tumor; (3) cicatrices of meninges resulting from laceration of membranes by bone-fragments; (4) chronic meningitis which ends in sclerosis of membranes; (5) cysts resulting from intracranial hemorrhage at the point of fracture; (6) arteriovenous aneurysm. We would add: (7) tumors of the brain; (8) sclerosis of the cortex. We refer here, in speaking of traumatic epilepsy, purely to the condition when it follows a head injury, and this is the common meaning of the term. Remember that epilepsy, as shown by Sachs, may follow a long-forgotten injury. Before undertaking a brain opera-

[1] "La Presse médicale," June 9, 1894.

tion for epilepsy it is a sound rule to remove all sources of definite peripheral irritation. I have seen apparent cure follow the removal of a tender cicatrix and follow circumcision of a patient laboring under phimosis. Briggs reported a case of epilepsy in which there was a distinct depression of a portion of the skull. There was also necrosis of the tibia, and after the cure of the necrosis the convulsions ceased. The removal of supposed peripheral irritation, however, is only occasionally beneficial. Are operations upon the skull and brain curative? Surgeons are much less enthusiastic than they were a few years ago. I believe operation can cure less than 5 per cent. of cases, but it is important to remember that in some cases in which operation seems to have failed medical treatment becomes much more efficient than it was before the operation. The high rate of cure (70 per cent.) once claimed for operations was due to failing to follow the patient sufficiently long. A patient should not be reported as cured until at least three years or, better, five years have passed without any evidence of the disease. Another source of error was a failure to understand that any traumatism may improve epilepsy *for a time*. "The administering of an anesthetic, the shock of an injury, the traumatism of an operation, just like a febrile seizure, may interrupt an epileptic habit and cause a patient to go for weeks or months without an attack" (the author, in "Medicine," Feb., 1904).

Operation must never be indiscriminately applied. In some cases it gives hope of relief, in others it is obvious that it would be utterly futile. In order to determine if a case is or is not suitable for operation it must be studied with great care. The history must be carefully obtained, particularly as to hereditary predisposition, the first convulsion, and its *supposed* cause. The question of injury, recent or old, should be thoroughly investigated, and it is a sound rule to have the head shaved and then examine for a scar and for a depression. Convulsive seizures must be studied by an expert, hence the patient should be in a hospital, constantly watched by a trained nurse, until one or two fits have occurred. The nurse watches the convulsion and describes it in writing, noting particularly if it had a local beginning. The general health must be investigated. An x-ray should be taken.

I am accustomed, for surgical purposes, to make the following classification of epilepsy. It is a modification of Sir Victor Horsley's classification (the author, in "Medicine," Feb., 1904):

1. Reflex epilepsy, the surgical treatment of which I shall not discuss in detail.
2. The common non-traumatic, idiopathic, or essential epilepsy, in which the attacks are general and are without a local onset.
3. Idiopathic epilepsy with a local onset of attacks (focal or Jacksonian epilepsy).
4. Traumatic epilepsy. This may be subdivided into two forms: (*a*) attacks without a local onset, and (*b*) attacks with a local onset (focal or Jacksonian epilepsy).
5. Jacksonian epilepsy due to gross brain disease (tumor, aneurysm, etc.).
6. Epilepsy following infantile cerebral palsy.
7. The posthemiplegic epilepsy of adults.

1. **Reflex Epilepsy.**—Remove the supposed cause of irritation. When epilepsy follows traumatism and a scar is found on the scalp, excise the scar. This is an imperative duty if the scar is tender or the seat of an aura.

2. **Essential or Idiopathic Epilepsy.**—Operation upon the brain is useless. If persistent headache exists, it may be proper to trephine and open the dura for exploration. Such an operation is done to relieve headache. Some claim remarkable results from bilateral excision of the cervical ganglia of the

sympathetic (see page 761). The operation is a theoretical one and of doubtful utility. It was founded upon a misconception as to the cause of epilepsy, and favorable reports are no more favorable than have been set forth regarding various other now abandoned procedures.

3. **Idiopathic Epilepsy with Local Onset of Attacks** (*Focal or Jacksonian Epilepsy*).—Many of these cases begin in young children who have had infantile palsy, the traces of the palsy having disappeared. In such cases the convulsions may begin on one side, and, in fact, may be nearly limited to one side. If, from the very beginning, the attacks began in one group of muscles or in one extremity, whether or not they spread to the rest of the body, and if the case is seen within two years of the first attack, the surgeon is justified in exposing the brain and excising the irritated portion of cortex. This operation, it is true, cures very few cases, but it benefits many for a considerable time and seems to make them more amenable to medical treatment. In the vast majority of cases fits recur, but rarely as severely as before. After fits have been going on for two years operation offers no prospect of cure, as the association fibers have surely degenerated. But, even in very old cases, if the attacks are frequently repeated and thus threaten life, the excited center should be removed to save life.

In cortical excision more of the cortex than the excited center is of necessity removed, because, in order to get the entire center, we must go wide of it. Paralysis of the parts controlled by the extirpated cortical area follows. The paralysis is seldom permanent except to the finer movements. The operation gives the best prognosis in young persons, and when done early in the case. The return of fits after apparent cure is thought to be due, at least in some cases, to the formation of *adhesions* between the brain and its membranes. Various unsatisfactory attempts have been made to prevent adhesion by the insertion of silver-foil, gold-foil, rubber tissue, egg-shell membrane, and Cargile membrane. In operating for cortical epilepsy a large osteoplastic flap is required. In the previous remarks we dealt with partial epilsepsy and with generalized epilepsy in which, from the first, the attacks had a local beginning. If cases of apparent idiopathic epilepsy develop Jacksonian attacks (attacks with a local beginning), it is useless to excise the cortex. The entire cortex is diseased, though one region is particularly unstable.

4. **Traumatic Epilepsy.**—Always remember that a traumatism to a person who becomes epileptic may have been only a coincidence; the condition may be essential epilepsy and the traumatism may have had nothing to do with it. Epilepsy ensuing upon traumatism may not begin until months or even several years after the injury. In the earliest attacks consciousness may or may not be lost. The causative injury may have been slight or severe. "An injury may cause a hemorrhage or a depressed fracture; may be followed by a scar upon the membranes; may occasionally lead to the development of an innocent or malignant tumor or a cyst, or may merely induce some trivial change in the subtle chemistry of the nerve-cells" (the author, in "Medicine," Feb., 1904). Injury may produce general epilepsy or Jacksonian epilepsy. If an identified traumatism exists, the surgeon should operate even after years. When the traumatism has not left definite evidence, the surgeon is justified in making an exploration any time up to the termination of the third year after the accident. The earlier the operation, the better the prognosis. The best prognosis of any form of epilepsy is given by Jacksonian epilepsy of traumatic origin.

"In focal epilepsy with evidences of skull injury or depression, trephining is imperative and somewhat promising. The dura should invariably be opened, even if it seems in good condition. A dural scar should be extirpated.

The brain should be examined by sight and by touch, and should be explored with the little finger and with the dural separator to well beyond the limits of the opening in the dura. If a tumor is found, it should be removed; if a scar upon the brain exists, it should be extirpated; if a cyst is discovered, it should be drained; and if there is any obviously damaged area in the brain tissue, it should be unhesitatingly cleared away. If nothing obvious is found on exploration, and if the attacks have been distinctly local in origin, it is justifiable to extirpate the motor center from which the discharge seems to originate.

"When Jacksonian epilsepy has followed an injury in the motor region, the chances of effecting a cure are much better than they are when the epilepsy has followed an injury in the sensory region. When it has followed an injury in the frontal region, operation affords very little hope of cure.

"When the condition is not focal but essential epilepsy, the surgeon will remove a scalp scar; and if there is any evidence of bone injury, he will trephine the bone, open the dura, and explore the brain. It is needless to say, however, that in such a case he will not extirpate any of the cortex.

"In cases of focal epilepsy I use the osteoplastic method of operating. In cases of generalized epilepsy I use the simple trephine and leave the button of bone out, as a means of effecting a prolonged modification in the intracerebral pressure" (the author, in "Medicine," Feb., 1904).

Bramwell maintains that when traumatism is followed by epilepsy and the epileptic discharge starts from a cortical center which is not beneath the scar, the surgeon should trephine first at the seat of injury, and if this fails, he should trephine over the excited center.

5. **Jacksonian Epilepsy Due to Gross Brain Disease.**—The treatment of this condition is the treatment of the brain disease.

6. **Epilepsy Following Infantile Cerebral Palsy.**—In this group of cases the palsy is manifest. It is justifiable to operate upon a child, but not later in life. The prospect of benefit is poor even in a child.

7. **The Posthemiplegic Epilepsy of Adults.**—Operation is useless.

Our conclusions are that these operations sometimes seem to cure epilepsy, but so, occasionally, does any operation. White[1] records 90 trephinings in which, though no cause was found for the epilepsy, great relief followed, and 2 cases were apparently cured; he mentions benefit or apparent cure following tracheotomy, ligation of the carotid artery, incision of the scalp, etc. The same effect may be obtained by a great shock, high fever, the administration of an anesthetic, or an accident. The fact seems to be that any operation, by means of nervous shock, may interrupt the epileptic habit; but in ordinary operations the fits tend after a time to recur and soon reach their old standard of frequency. In the special brain operations with removal of obvious lesions or extirpation of discharging centers the fits usually recur, but they will rarely reach the old standard of frequency, and will be more amenable to medical treatment.

In non-traumatic chronic epilepsy without localizing symptoms trephining is not justifiable unless persistent headache calls for it as a means of relief from intracranial pressure. Annandale advised us to consider experimental operation in such cases when the drug-treatment has failed and when the patient's condition seems hopeless. He says there is no chance of improvement without operation, and operation may possibly disclose a removable lesion.[2] After trephining for epilepsy five years should elapse without a convulsion before cure is resaonably assured; and if convulsions arise, they must at once be met by medical treatment. A man having once had a convulsion may at any time have others; hence he should always be watched. It is not

[1] "The Supposed Curative Effects of Operations *per se*," "Annals of Surgery," Aug. and Sept., 1891.
[2] "Edinburgh Med. Jour.," April, 1894.

unusual for a few convulsions to occur soon after an operation for epilepsy, and then to cease for a considerable time. These early fits result from habit (*habit fits*). Among the operative procedures suggested for the treatment of epilepsy may be mentioned circumcision, clitoridectomy, ocular tenotomy, ligation of the vertebral arteries, removal of the cervical ganglia of the sympathetic (see page 761) (Alexander, Jonnesco, Jaboulay), and the actual cautery to the head (Féré).

Operative Treatment of Insanity.—(See the author, in "Journal of Nervous and Mental Diseases," June, 1904.)

1. **Epileptic Insanity.**—The conditions which call for operation on a non-insane epileptic (see page 821) call for it on an insane epileptic. It is sometimes justifiable to operate if there has been a head injury, and operation may lessen the number and diminish the violence of the attacks. If focal seizures exist, we may proceed as for focal seizures in the sane. In status epilepticus we may operate to relieve pressure. It will be observed that operation is for the convulsions and not for the insanity.

2. **Paresis.**—I do not advocate operation in paresis. If we believe in traumatic paresis, we may be inclined to advise operation. Personally I do not believe that genuine paresis is ever cured; the lesions of the disease are widely disseminated; the pons, medulla, and even the cord may be diseased and the lesions cannot be removed.

3. **Non-traumatic Insanity and Paranoia.**—Operation cannot cure the insanity and is not to be advised.

4. **Hypochondriacal Delusions.**—Operation is useless. Some practice it with the idea of getting rid of a delusion by removing a part to which the attention is directed. Such attempts always fail, because it is the insanity which causes the delusion, not the delusion which causes the insanity.

5. **Operations for Traumatic Insanity.**—A psychosis constructed on the basis of a traumatic neurosis never calls for operation. The only cases in which operation is ever justifiable are those in which traumatism is the direct cause. Insanity may begin at once or soon after an injury, but is often unrecognized for weeks or even months. Nearly all of these cases are predisposed to insanity and the injury has been only an exciting cause. Traumatism is the direct cause in about 2 per cent. of cases of insanity.

"An antecedent injury may have directly induced the alienation; it may have had no bearing at all upon the latter; or it may have produced an insanity by fear and shock, and not by creating a direct brain lesion. Again, the head injury, by increasing the individual's susceptibility to alcohol and to the effects of the sun, may, if this person drinks alcohol or exposes himself to the rays of the sun, be indirectly responsible for lunacy.

"In insanity following an injury to the head there may be various supposed causative lesions: A fracture of the skull, with or without depression; the development of an exostosis; sclerosis or softening of the cortex; edema of the membranes or of the brain itself; cerebral hyperemia or congestion; thickening of the membranes; adhesion of the membranes to the skull, to each other, or to the brain; new growth; inflammation of the membranes; or minute, slowly developing, widespread nutritive changes. The injury may be assumed to be the cause of the insanity if the insane condition becomes manifest almost at once or soon after the accident; but if the symptoms do not appear until long after the accident the traumatism may be considered to be the directly exciting cause in some cases, and not in others. It may be blamed if, between the time of the accident and the appearance of the insanity, there has been a marked change in the patient's disposition, temperament, or character; if he has developed headache, insomnia, irritability, passionate outbreaks of temper, moodiness, or lapses of memory; if he has plunged into

immorality or excesses in alcohol; if he has displayed a tendency to neglect business or family obligations, and if he has shown increased susceptibility to alcohol and to the sun. Sometimes epilepsy may develop during this period, (Richardson, 'American Journal of Insanity,' July, 1903. The author's 'Address on Surgery,' delivered before the meeting of the Medical Society of the State of Pennsylvania, May 18, 1897). If there was none of these intermediate changes in the normal mode of thinking and way of acting, one cannot count the traumatism as causative. Many persons that have received severe head injuries have shown these changes, but have never gone insane. I have been studying this point for a number of years, and have decided that quite a few patients that have been trephined for fracture or for meningeal hemorrhage have subsequently shown pronounced and permanent changes in character and disposition. Of the number that show such changes, many never go insane, but some do. Such an insanity is distinctly traumatic in origin" (the author, in "Journal of Nervous and Mental Diseases," June, 1904). The prognosis is very unfavorable; some recover sanity after operation, many do not. Some recover sanity without operation. Sometimes operation cures by removing a lesion; sometimes by shock, etc. Some cures following operation did not result from the operation.

On what cases should we operate?

We should operate on cases "in which insanity has soon followed a head injury. If the site of the trauma is indicated by a scar, a depression of bone, local tenderness, fixed headache, or some localizing symptom—motor or sensory—operation should positively be undertaken. In a case in which the insanity has developed later, in which the intermediate period between the injury and the development of the insanity has shown the change from the normal mode of thinking and way of acting previously alluded to, and in which the site of trauma is indicated by any of the evidences mentioned above—operation should positively be performed. One should not operate upon a case simply because there is a dubious record of an antecedent fall or blow, which merely suggests the possibility of a traumatic origin for the insanity. In any case in which there are positive signs of increased pressure it may be considered proper to trephine as a palliative measure" (the author, Ibid.).

Abdominal, Gynecological, and Genito-urinary Operations.—If an insane person has a disease which is dangerous to life or which is productive of pain, discomfort, or ill health, he or she is entitled to be cured, if possible, by a surgical operation. The removal of pain and other depressing influences may result in great improvement in the general health and in notable mental improvement. The operation may thus indirectly exercise a beneficial influence on the insanity, but the influence is not direct and it is never justifiable to do such an operation as oöphorectomy upon an insane woman unless the condition of the ovaries would call for it in one not insane.

Operations On the Skull and Brain.—As a preliminary it is well to note that urotropin (hexamethylenamin) given by the mouth quickly appears in the cerebrospinal fluid, and that the fluid contains the maximum amount in from one-half hour to an hour after ingestion. The presence of this drug decidedly inhibits the growth of bacteria in the fluid. This is Crowe's discovery. We believe it wise to give this drug in all cases in which meningitis is threatened or exists (S. J. Crowe, in "Johns Hopkins Hospital Bulletin," April, 1909). It should be given for twenty-four hours preceding and for several days after an operation upon the brain or spinal cord. From 40 to 60 gr. a day are given by mouth. Cushing has subjected this drug to the severest test in his operations to reach the pituitary body. He gave 60 gr. a day of this drug "on the day preceding and for some days after the operation" ("The

Pituitary Body and Its Disorders," by Harvey Cushing). After 33 transsphenoidal operations there were 2 cases of meningitis. One of these cases (which was inaugurated by violent sneezing) was fatal.

Trephining for a Fracture of the Skull.—The patient should be anesthetized unless he is unconscious, and should be placed upon the back with the shoulders a little raised. A sand-pillow is placed under the neck, and his head is turned away from the side to be operated upon. The position of the surgeon is such that the patient's head is a little to his left. A large semilunar incision is made with the base down, which incision goes through the periosteum, and the flap is lifted. The bleeding vessels of the flap are caught by forceps. The fracture is sought for and found. The pin of the trephine is projected beyond the crown and is set upon sound bone, the crown overhanging the line or edge of the fracture. The surgeon tries to avoid the region of a sinus or large artery. A gutter is cut in the bone, the pin of the instrument is withdrawn, and the trephining is completed. In going through the diploë bleeding is copious. The inner table feels very dense. Stop from time to time, clean out the gutter in the bone with gauze, and try the bone with an elevator to see if it is loose. When the fragment is loose enough, pry it out. If the surgeon desires to replace the button, hand it to an assistant, who places it at once in a bowl of warm normal salt solution, kept warm by standing in a basin of water at 105° F., or in warm carbolized towels. The edges of the opening should be rounded by a rongeur, and the bone, if depressed, must be elevated. Sometimes it may be necessary to remove splinters and fragments of bone. After removing the fragments the edges of the opening should be smoothed by the use of the rongeur forceps. The dura should be examined to see if injury exists, and hemorrhage must be stopped. Bleeding from the dura is arrested by passing a ligature of silk or catgut threaded in a small curved needle under the vessel on each side of the wound, and tying the ligatures (*suture-ligatures*). Bleeding from the pia is arrested by direct ligation, by suture ligature, or by gauze packing. Bleeding from the diploë is arrested by the use of Horsley's wax. The wound is cleansed, the edges of the dura are sutured by catgut or fine silk; in some

Fig. 526.—Galt's conical trephine.

Fig. 527.

Fig. 528.

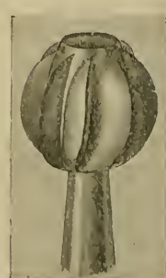

Fig. 529.

Figs. 527–529.—Hudson's burrs.

cases the button of bone is reintroduced; in other cases some chips are cut from the bone and scattered upon the dura, but in most cases no attempt is made to fill up the gap in the bone. The scalp is sutured by silkworm-gut, and horse-hair or gauze drainage is employed for a day or two. Sterilized gauze dressings are put on, a rubber-dam is laid over them, and a gauze bandage wet with bichlorid of mercury is applied.

Instead of the trephine some surgeons use the chisel or gouge and hammer to remove a portion of the bone. Other operators, believing that this procedure may cause concussion, employ the surgical engine.

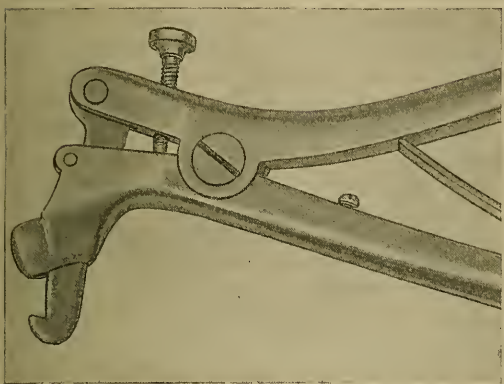

Fig. 530.—Hudson's modified DeVilbiss forceps.

Fig. 531.—Combined osteoplastic operation. First step. Incision through superficial tissues and bone. Flap held in place on the bone by tacks.

I now seldom use the old trephine, preferring instead the instruments of Hudson (Figs. 527–530).

Osteoplastic Resection of the Skull.—Wolff suggested this operation, and in 1889 Wagner performed it. It is employed for the removal of tumors and the Gasserian ganglion, for focal epilepsy, and for exploration. It is the operation of choice when a large opening is needed, as when the operation is, first of all, for diagnosis. The incision shown in Fig. 531 is made through the scalp and periosteum, and the flap is tacked to the bone, ordinary long

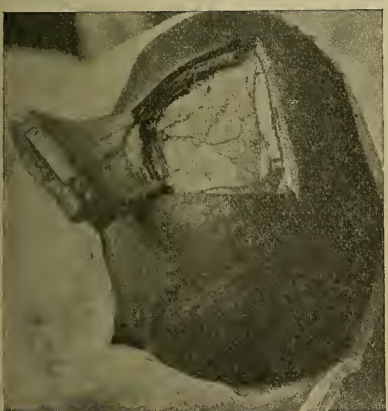

Fig. 532.—Combined osteoplastic operation. Second step. Bone flap turned down.

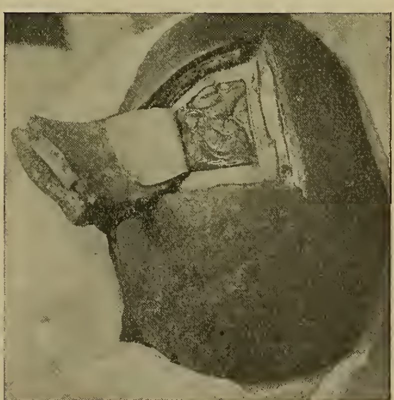

Fig. 533.—Combined osteoplastic operation. Third step. Showing exposure of brain by removal of dural flap.

tacks being used. Otherwise our manipulations may separate the flap from the bone (Fig. 531). A groove corresponding to this incision may be cut in the bone by special gouges or chisels. I do not use chisels. I am convinced that the blows of the mallet add to shock, may cause hemorrhage or add to existing hemorrhage, may extend a line of fracture or cause a fracture, may diffuse a purulent collection, or produce concussion of the brain. Some surgeons use the surgical engine. It is difficult to keep it sterile, it runs at too high a speed to be readily controlled, and it is troublesome to cut a bevel with it. The instrument is dangerous except when in very skilful and highly trained hands. Some surgeons make trephine openings and then cut from within outward by the Gigli wire saw (Obalinski). Cushing, of Harvard, does what is called the *combined* method. I prefer this to any other plan. It is rapid and free from all danger of wounding the dura. I make two or several openings with Hudson's burr. This excellent instrument divides bone with great rapidity, but does not divide the dura. In fact, one cannot divide the dura with it, for the burr binds as soon as it is through the bone. Figs. 527 to 529 show Hudson's burrs. The sides of this bone-flap are rapidly cut by Hudson's improvement of the DeVilbiss forceps (Fig. 530). The upper margin is cut on a bevel with the Gigli saw. Because of this bevel when the flap is restored to place the upper edge of the flap rests on a shelf of bone and does not press on the brain. By whatever method performed, three sides of the bone-flap are cut through, but the bone is left attached to the scalp. It is a good plan to save the scalp from detachment by temporarily nailing it in place (Fig. 531). The bone is then broken outward, the fracture taking place at the base of the bone-flap, the dura is opened a little distance from the edge (sufficient space being retained for sutures), and the exploration is made and the operation is performed (Figs. 532 and 533). When we are ready to suture the dura we note if the brain bulges greatly. If it does, manipulation will surely injure it, and we should cause the brain to recede before suturing by placing the patient nearly erect or by performing lumbar puncture. After suturing the dura the bone which is still adherent to the pericranium and scalp is restored to its proper place, and the scalp is sutured.

Besides restoring a flap of bone into position, or replacing a button of bone, or strewing the dura with bone-fragments, other methods of closing the opening have been practised—for instance, heteroplasty with a decalcified bone-plate, with a celluloid plate, or other foreign material.[1]

Trephining the Frontal Sinus.—This operation may be employed for inflammation of the lining membrane of the sinus or for empyema. Make a vertical incision in the middle of the forehead, starting $1\frac{1}{2}$ inches above the nasion and terminating at the root of the nose. The button of bone is removed and the opening is enlarged if necessary. The mucous membrane is incised, the opening into the nose is found and is dilated, and a drainage-tube is passed into the nose from the sinus, the upper end being left in the sinus. In some severe cases Jacobson advises us to curet the sinus, to disinfect it by the use of silver nitrate or chlorid of zinc, and to insufflate an "aseptic powder." In some cases resect the mucous membrane. I prefer an osteoplastic resection to trephining the frontal sinus.

Trephining the Mastoid.—(See Operation for Mastoid Suppuration, page 830.)

Technic of Brain Operations.—In focal epilepsy a faradic battery is required. Always shave the scalp and always antisepticize it. In localizations, mark out the fissure upon the scalp with an anilin pencil, with iodin, or with silver nitrate. Have the patient semirecumbent. Mark three points upon the bone with the

[1] See Bretano, in "Deutsche med. Woch.," May 17, 1894.

center-pin of the trephine before incising the scalp (both ends of the Rolandic fissure and the point at which the trephine is to be applied). Make a semilunar flap 3 inches in diameter, with the base below. Control bleeding in the flap by forceps pressure. If the operation is by trephining the $1\frac{1}{2}$-inch trephine should be employed, but if a smaller trephine or the Hudson burr is used the opening must be enlarged with a rongeur. Before enlarging the opening separate the dura from the bone by a dural separator. In most cases an osteoplastic flap is preferable to trephining. It is always employed in explorations for tumor. As a rule, open the dura and examine the brain. The dura is lifted by mouse-toothed forceps and is opened by scissors along a line $\frac{1}{4}$ inch from the bone edge, a broad pedicle of dura being left uncut. Hemorrhage is arrested by pressure and hot water or by passing suture-ligatures of silk or catgut around any bleeding vessel by means of a curved needle. In some cases packing must be retained or forceps must be kept on. In packing, endeavor to use but one piece of gauze, so as to avoid leaving in a forgotten piece. Upon opening the dura cerebrospinal fluid flows out, the stream being increased at each expiration. Absence of pulsation of the brain points to abscess or tumor, and a livid color indicates subcortical growth. An old laceration is brownish. If the brain bulges through the opening, it means increased pressure (tumor, abscess, effusion into the ventricles, etc.). After opening the dura employ no antiseptics, especially when the surgeon intends using electricity to locate a center. Irrigate only by warm salt solution. In operating for tumor the dura is opened and in some cases the brain is incised. The tumor is turned out by the finger or, if this

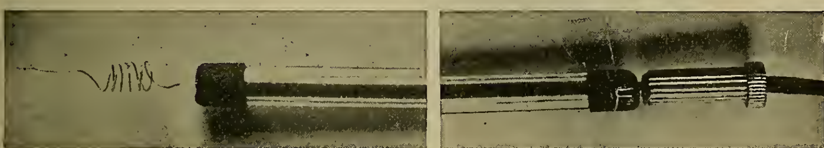

Fig. 534.—Showing terminal and connection of Cushing's electrode ($\frac{3}{4}$ natural size). Instrument should be 16 inches or more in length.

is impossible, by the dry dissector, the scissors, the dull knife, or the sharp spoon. If the entire tumor cannot be removed, it is sometimes proper to take away as much as possible. The removal of a portion may retard the growth of the remainder, and the trephining, by lessening cerebral pressure, may relieve the symptoms and prolong life. After removing a tumor arrest distinct points of bleeding by ligatures or by suture-ligatures. Pack the tumor cavity with gauze and bring the end of the strand out of the wound. Stitch the dura with silk and suture the scalp with silkworm-gut. In electrifying the brain faradism is employed of a strength about sufficient to move the fibers of the exposed temporal muscle. The best electrode is that of Cushing (Fig. 534). It is a "glass unipolar electrode carrying a fine platinum wire core, coiled into a spiral at the end" (Cushing, in "Keen's Surgery," vol. iii). The other pole is attached to an extremity, "preferably on the homolateral side." During the electrical test the patient must not be deeply anesthetized. A careful observer watches the muscular movements. If, for instance, the surgeon wishes to remove the thumb center, he moves the electrode from point to point until he obtains thumb movements. The region is sliced away bit by bit until the center which is responsible for the conclusive movements is removed. It will be found impossible to remove only the thumb center. Adjacent centers are sure to be more or less damaged, and a certain amount of paralysis follows the operation. If we wish to *tap the ventricles,* Keen directs the trephine opening to be $1\frac{1}{4}$ inches behind the external

auditory meatus and the same distance above the base-line of Reid (Fig. 535, *a*). A grooved director or metal tube is passed into the brain in the direction of a point "$2\frac{1}{2}$ to 3 inches above the opposite meatus." The normal ventricle will be entered at a depth of 2 to $2\frac{1}{4}$ inches, but the dilated ventricle will be entered sooner. The moment of entry is marked by lessened resistance and a flow of cerebrospinal fluid. Drainage can be maintained by introducing a rubber tube. This operation has been employed in hydrocephalus. Kocher punctures the ventricle $2\frac{1}{2}$ cm. from the midline and 3 cm. in front of the fissure of Rolando. After an aseptic cerebral operation, as a rule, do not drain unless hemorrhage has been considerable. In many cases after trephining replace the bone, but not when the bone is diseased, is infected, is very compact, or if we desire to alter pressure.

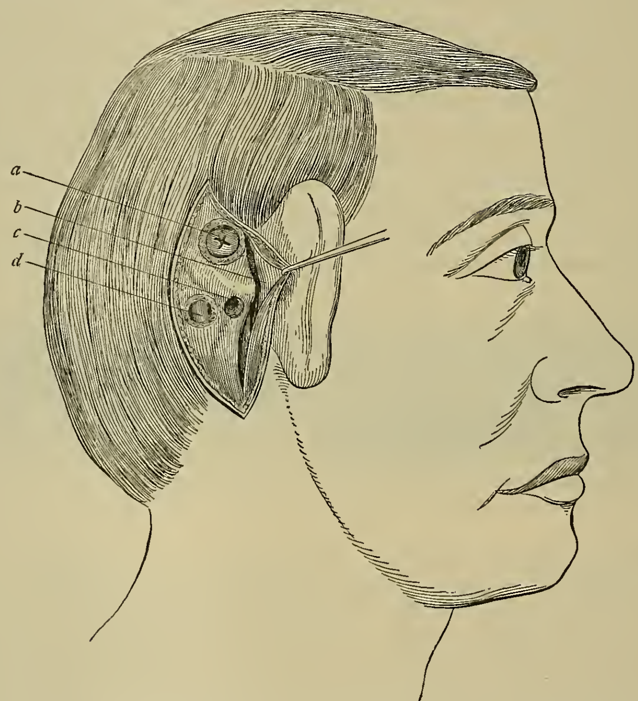

Fig. 535.—Opening the mastoid antrum and the lateral sinus; exposure of the temporosphenoidal lobe and puncture of the descending horn of the lateral ventricle: *a*, Temporosphenoidal lobe (descending cornu of lateral ventricle is 1 cm. deeper); *b*, inner surface of periosteum; *c*, mastoid antrum; *d*, lateral sinus (Kocher).

Operation for Mastoid Suppuration.—Place a sand-bag under the neck. An incision is made $\frac{1}{4}$ inch posterior to the auricle and down to the bone, and in the direction of the long axis of the mastoid. The bone is bared and examined, especially at a point in the line of the incision, which is on a level with the roof of the meatus (Fig. 535, *c*). The bone will usually be found softened. Gouge it away and thus open the mastoid antrum. The bone-opening is within the limits of *Macewen's suprameatal triangle*, a space bounded by the posterior root of the zygoma, the posterior bony wall of the meatus, and an imaginary line joining the two. If the mastoid is opened in this triangle the antrum is entered directly and there is no chance of wounding the lateral sinus. If, in the adult, pus is not found on opening the mastoid antrum, gouge downward and backward, but with great care, so as to avoid the

lateral sinus. If there be any possibility of the existence of pus in the groove of the sinus, the sinus should be unhesitatingly exposed. After evacuating the pus from the mastoid, gouge away bony septa, enlarge the opening between the mastoid and the middle ear with the gouge and remove the superior half of the posterior bony wall of the meatus (avoid the facial nerve on the floor of the meatus), turn the head toward the side operated upon, and irrigate the mastoid with salt solution, dust with iodoform, pack with iodoform gauze for a few days, and then introduce a silver drainage-tube. Treat the causative ear disease. Sheild and Macewen operate on inveterate cases of mastoid disease as follows: A thick flap is raised behind the auricle, the flap including the orifice of any sinus and being "left attached by its stalk." The auricle is "detached forward and the soft parts over the mastoid are turned backward by horizontal incision." The "lining membrane of the canal is separated from the bone." The mastoid is opened and dead bone and caseous matter are removed, overhanging edges are chiseled down, and the posterior bony wall of the external auditory meatus is gouged away. The skin-flap is pushed into the cavity and is held in place by pads of gauze. The margins of the flap may be sutured, but this is not necessary. Macewen calls this procedure "papering" the cavity with skin.[1]

If mastoid suppuration has established *abscess in the temporosphenoidal lobe,* trephine, 1¼ inches behind and 1¼ inches above the middle of the external meatus (Barker's point), and search for pus as directed on page 804. If *abscess of the cerebellum* exists, trephine below the line of the lateral sinus. "The position of the lateral sinus is indicated by a line running horizontally outward from the occipital protuberance to within about 1 inch of the external auditory meatus, and thence downward to the mastoid process" (Owen's "Manual of Anatomy"). If *infective sinus-thrombosis* exists, break into the lateral sinus (Fig. 535, *d*) from the mastoid opening and proceed as directed on page 807.

Linear Craniotomy.—Make a large flap. Trephine the skull a finger's breadth from the sagittal suture, and the same distance back of the coronal suture. Rongeur the bone away in a line parallel with the sagittal suture and a safe distance from the longitudinal sinus, up to a point in front of the lambdoidal suture. Remove the pericranium which covered the bone excised. Insert the dural separator or pass it along the margins. In some cases an additional portion of the bone is removed over the fissure of Rolando. Various suggestions have been made as to the direction and situation of bone-sections. Bleeding is arrested and the flap is closed without drainage.

Removal of Gasserian Ganglion.—(See page 766.)

Operation for Infective Sinus-thrombosis.—(See page 807.)

The Decompression Operation (*Decompressive Trephining*).—This operation is employed particularly in cases of inoperable brain tumor. It differs from palliative trephining in the fact that the dura is incised and an opening left to permit of bulging of the brain. The bulging relieves pressure. By Cushing's method we get a hernia of the brain, but not a fungus cerebri. I have followed Cushing's recommendation in tumors, and have used it in fractures of the base of the skull, and I believe it often saves vision and life (in the latter condition it is done on both sides).

Cushing and Bordley have performed it in cases of uremia and improvement has followed ("Amer. Jour. Med. Sciences," Oct., 1908). They suggest that the operation be used in certain cases of renal disease when medical treatment and lumbar puncture have failed to abate uremic symptoms, or when blindness is impending. It has been used in apoplexy.

The effect of the operation in cases of brain tumor is sometimes extraordinary. Its most prominent benefit is in abolishing choked disk. It must

[1] "Lancet," Feb. 8, 1896.

not be done directly over a tumor, because the bulging tumor might become the seat of hemorrhage. It may, however, be done near the tumor (see page 820).

It is, of course, useless in relieving blindness, for blindness means atrophy, but it is often very valuable in *preventing* blindness. When choked disk exists operation should be done early even if there is good vision. If in advanced cases any sight remains, it should be performed. Now and then there is an unfavorable result, for instance, the development of retinal hemorrhages or the loss of vision, which was good previous to operation. (See deSchweinitz and Holloway on "Operative Treatment of Papillo-edema Dependent Upon Increased Intracranial Tension," "Therapeutic Gazette," July 15, 1909.) The permanence of the relief to the choked disk is variable. It is not always permanent.

Cushing's subtemporal decompression is done upon the right side, as a rule, but in some cases on the left side. An objection to doing it on the left side is

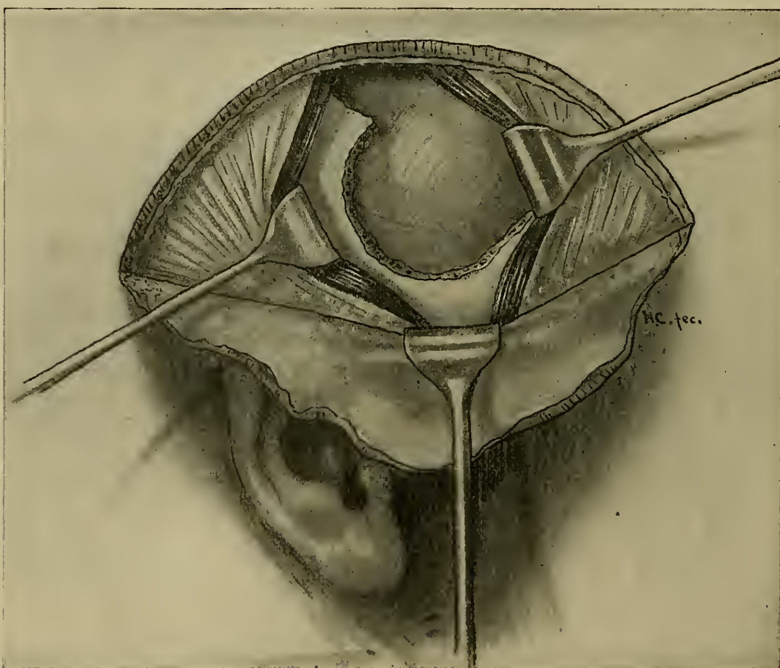

Fig. 536.—Sketch of the intermusculotemporal field of operation, showing exposure with subtemporal bone defect partly made (Cushing, in "Keen's Surgery").

that the bulging of the left temporosphenoidal lobe may cause word-deafness. A curved incision is made through the skin and subcutaneous tissue, the flap is turned down, the temporal fascia is incised in the direction of the muscle-fibers beneath it, the temporal muscle is split and not cut, the periosteum is separated from the bone, the soft parts are retracted, the bone is opened as the surgeon prefers, and the opening is enlarged by a rongeur (Fig. 536). The dura is opened and radiating incisions are made through it toward the edges of the bone gap. The wound is closed by four layers of fine silk sutures.

Figure 537 exhibits the exposure for suboccipital depression as done for subtentorial tumors. The same exposure is obtained in order to remove a cerebellar tumor.

Drainage of the Cisterna Magna (*Haynes's Operation*).—An incision is made in the middle line from the occipital protuberance to the posterior arch

of the atlas. The periosteum is stripped from a portion of the occipital bone at and above the foramen magnum. The bone is trephined and is cut away into the foramen magnum. The occipital sinus may not be present. If present as a double sinus, incise the dura between the two sinuses. If there is one sinus, divide the dura between two ligatures. Open the dura and arachnoid by a very small incision. As soon as excess of fluid has escaped enlarge the incision. By lifting and separating the cerebellar lobes the surgeon can determine if the foramen of Magendie is patent. Gutta-percha tissue is used as a drain. The muscles are sutured together by catgut. The skin is closed below the drain

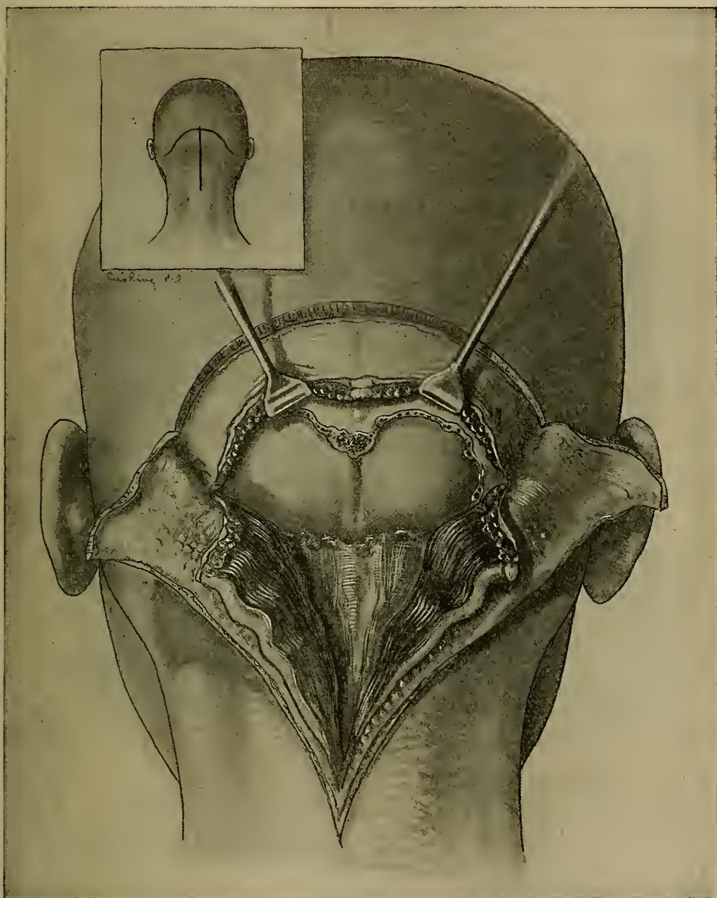

Fig. 537.—The suboccipital exposure, showing opening partly made and Cushing's "cross-bow" incision (Cushing, in "Keen's Surgery").

by silkworm-gut (abbreviated from Haynes's description in "The Laryngoscope," June, 1912).

Methods of Reaching the Pituitary Body.—The subtemporal route was suggested by Carton and Paul. Horsley has operated in this way. The bone is removed from the subtemporal region, the dura is opened, the brain is lifted, the dural box of the hypophysis is incised. It may be necessary to remove bone from each subtemporal region and raise the brain from both sides. Borchardt performed osteoplastic frontal resection, ligated the superior longitudinal sinus, and lifted the brain.

Giordano suggested a transsphenoidal operation, and Schloffer improved his method. Schloffer freed the nose so as to turn it toward the right side and then excised the turbinates, orbital wall, maxillary sinus, the middle septum, the left nasal process of the superior maxillary, and the ethmoid cells (Cushing, "The Pituitary Body and Its Disorders"). In the inferior route of Kanavel most of these structures are preserved and the incision is within the mouth.

McArthur ("Jour. Amer. Med. Assoc.," June 29, 1912) trephines the frontal eminence of one side 4 cm. above the supra-orbital notch and preserves the button in warm salt solution. By means of the DeVilbiss forceps and the chisel he cuts away a bone-fragment, which brings with it a considerable part of the roof of the orbit. This fragment, too, is placed in warm salt solution. The rest of the orbital roof is cut away by a rongeur. The dura covering the inferior surface of the frontal lobe is separated from the bone, while the lobe is raised and the orbital contents are held out of the way. Between the clinoid

Fig. 538.—Horner B. Smith's head-rest for operations upon the cerebellum (modified by William J. Taylor).

processes the dura is divided by Krause's hook-shaped knife. An enlarged hypophysis will now be accessible. At the conclusion of the operation on the hypophysis the bone-fragments are replaced. Frazier has modified McArthur's operation ("Annals of Surgery," Feb., 1913).

The Combined Method of Harvey Cushing (From Cushing's "The Pituitary Body and Its Disorders").—This surgeon, whose experience is very large, operates as follows: Intratracheal anesthesia. Place the patient with the shoulders slightly raised so that the head drops back. Pack the posterior nares with a sea-sponge. Insert cotton wet with adrenalin in each nostril. Lift the upper lip. Make a transverse incision across the frenum, and carry it down to the anterior nasal spine. By blunt dissection raise the soft parts on each side from the inferior margin of the osseous nasal opening until the cartilaginous septum is exposed. From now on the operation is submucous. Separate the membrane on each side from the bony and cartilaginous septum. Introduce a retractor on each side between the separated mucous membrane and the septum. Separate the blades of the instrument. Remove "most of the vomer,

the lower edge of the median plate of the ethmoid, and a small strip of cartilage." It may be necessary to remove by means of a rongeur the anterior maxillary spine. With the retractors retained, a series of dilating plugs are introduced. These "flatten the turbinates." The largest dilator has a diameter of 1.8 cm. The retractors are removed and a bivalve speculum is inserted. An electric head-light must now be used. It may now be found necessary to remove "the prow of the vomer."

The body of the sphenoid is identified and "the anterior and lower walls of the sinuses are chipped away with long-handled nasal rongeurs." The lining of mucous membrane is removed, when the protrusion of the sella can be identified. The floor of the pituitary fossa is then clipped away. The dural case of the gland (or tumor) is divided by a hook-shaped knife.

Removal of the entire anterior lobe must never be done, as this lobe is necessary to life.

XXV. SURGERY OF THE SPINE

Congenital Deformities.—Myelocele or Rachischisis.—This condition is due to deficiency in the formation of the vertebral arches, the cord being rudimentary, the medullary plates having failed to coalesce, the central canal not having formed, and the endothelium which should line it being exposed. If the entire cord is involved, the condition is called *amyelia* or *total rachischisis*. If a part of the cord is involved, the condition is called *partial rachischisis*. In partial rachischisis a portion of skin is absent in the midline. At this area is a circular, dark-red focus surrounded by a very thin and glistening membrane which becomes continuous with the skin. A dimple at the upper part and a dimple at the lower part of the dark area indicates the situation of the central canal above and below. Victims of rachischisis are usually stillborn or, at most, live but a few days.

Spina Bifida.—This is a deformity similar to the one just discussed, but in it the cord is much more developed. The first accurate description of it was given by Tulpius in 1685. It is a congenital sac of fluid due to vertebral deficiency, permitting protrusion of the contents of the spinal canal in the median line. In this condition the cutaneous epiblast is adherent to the spinal exiblast, because structures from the mesoblast have failed to grow between. The laminæ or spines of one vertebra or of several vertebræ or of many vertebræ may be deficient, most frequently in the lumbosacral region. In very rare cases there is division of the vertebral bodies and the projection is forward and to the side. A case in which there are ununited laminæ but no protrusion is called *spina bifida occulta*. Sometimes there are two protrusions in one person. In spina bifida the dura does not cover the sac because it is cleft as well as the laminæ. There are three distinct varieties of spina bifida: 1. *Meningocele*. In this condition the dura is cleft (Hildebrand), there is a protrusion of the arachnoid, fluid gathers in the arachnoid meshes and "distends this so as to form one continuous cavity which is traversed by nerve-roots" (Henle, in "A System of Practical Surgery," by von Bergmann, Bruns, and von Mikulicz. Translated and edited by Wm. T. Bull and Carlton P. Flint). The cord is not in the sac. 2. *Meningomyelocele* (the commonest form) is a protrusion of arachnoid, the sac containing cerebrospinal fluid, nerves, and cord-substance. The cord may spread upon the sac wall or it may pass through the sac and re-enter the canal. A cutaneous dimple or furrow indicates that the cord is attached and hence is within the sac. 3. *Syringomyelocele* is great distention of the central canal, the sac wall being formed of the thinned cord and the spinal membranes. A spina bifida varies in size from that of a walnut to that of

an infant's head; it grows rapidly during the early weeks of life; it is usually sessile, but may present, where it joins the body, a definite constriction or even a pedicle, the base of the sac is covered with healthy skin, and the fundus is covered only by thin epidermis or by the spinal membranes themselves. Pressure upon the tumor may diminish its size and increase the tension of the anterior fontanel, and possibly cause convulsions or stupor. The cyst is translucent and the margins of the bony aperture are distinct. Crying, coughing, or pressure upon the anterior fontanel makes the tumor more tense. Spina bifida is apt to be associated with club-foot, with hydrocephalus, and with rectal or vesical paralysis. Spina bifida usually causes death (90 per cent. of cases die during the first year of life). A few meningoceles and a very few meningomyeloceles undergo spontaneous cure by growth of the vertebral arches constricting the neck of the sac. The sac may remain distended with fluid or may shrink. Syringomyelocele is invariably fatal. The cause of death may be rupture of the sac or marasmus. The *x*-rays show the bony gap. *Spina bifida occulta* is a cleft in the vertebral column without any protrusion of the cord or the membranes. In this condition there is usually a profuse growth of hair in the skin over the bony gap and the hairy condition may be much more widespread. In some cases the hair is present at birth; in others it appears at puberty. Trophic changes and deformities may exist in the lower extremities.

Treatment.—Very small protrusions which grow slowly and are covered with sound skin may be treated by the use of a compress and bandage, by an elastic bandage, or by applications of contractile collodion. It was formerly regarded as proper to tap and drain the sac. Injection was used by many. The skin being cleansed, the child was placed on its side and a little chloroform was given. A fine trocar was plunged obliquely in at the side of the sac through sound skin, little or no fluid being drawn off, and 1 dram of Morton's fluid injected (iodin, 10 gr.; iodid of potassium, 30 gr.; glycerin, 1 oz.). The trocar was withdrawn and the puncture was sealed with a bit of gauze and iodoform collodion. The child was put to bed. If injection proved successful, the sac was found to shrink; if the injection failed, it was the custom to repeat it at intervals of from seven to ten days (Jacobson, White). Surgeons now prefer excision of the sac (see page 859). Whenever possible the incision should be through healthy skin. If the sac contains nerves they should be placed within the canal. Bayer treats it as he would a hernia. Robson in some cases excises the entire sac. Operations upon children much under the age of five have an enormous mortality. Operations are comparatively safe when the child reaches the age of five. Operations for spina bifida have been done successfully immediately after birth (Lovett, in "Amer. Jour. Orthop. Surg.," Oct., 1907). We should not operate if there is hydrocephalus or extensive paralysis, if the mass is very large and growing rapidly, or if there are other marked deformities. A ruptured sac should be operated on at once, otherwise death is practically certain.

Sacrococcygeal Tumors.—Dermoids external to the sacrum are occasionally seen in this region. Dermoids also arise between the rectum and sacrum. In the lower sacral or coccygeal region the cutaneous structures sometimes fail of complete coalescence and a *postanal dimple* or *sinus* is the result. Such a sinus is lined with skin and its wall contains numerous glands and often hairs. It may inflame or suppurate. If it blocks up at the outlet, a form of dermoid develops. Teratomata, lipomata, and hydatid cysts may develop in the sacrococcygeal region.

Treatment.—Dermoids require extirpation. If a postanal dimple causes no trouble, it is let alone; otherwise it should be dissected out. It may or may not be possible to remove teratomata. Lipomata and hydatids are extirpated.

Anosacral Cysts.—These cysts develop between the sacrum and rectum and originate from remnants of the postanal gut and neurenteric canal. Such cysts may be multilocular or unilocular. They can be detected by a finger in the rectum.

Treatment.—Some of these growths are removed after osteoplastic resection of a portion of the sacrum; others are removed by incising the rectal wall.

Tumors of the Spinal Cord.—Tumors may arise from the cellular tissue, fatty tissue, the nerve-roots, the membranes of the cord, or from the vertebra (*extramedullary tumors*). They may arise within the cord (cord tumors proper or *intramedullary tumors*).

Extramedullary Tumors.—Syphilomata, hydatid cysts, tuberculomata, and inflammatory masses or adhesions may compress the cord and produce symptoms indistinguishable from genuine tumor. Among extramedullary tumors are secondary carcinoma, sarcoma (primary or secondary), fibroma, myxoma, lipoma, chondroma, and neuroma. Dermoid sacral cysts may exist. Lipoma, fibroma, and certain cysts may be congenital. Injury of the back sometimes seems to bear a causal relation to extramedullary tumors.

The *symptoms* are due to pressure upon nerve-roots and the cord. The most prominent symptoms are pain in the back and evidences of nerve-root irritation.

The early or irritative symptoms are pain and stiffness of the back, usually very severe and interfering with sleep, shooting pains in the area of the implicated nerve-roots, and sensory abnormalities in the same area. There may be hyperesthesia of a limited area. The area of distribution from one or two roots is involved in pain, sensory disturbance, and slight motor impairment. In some cases the nerve-roots of one side only exhibit irritation and the symptoms are strictly unilateral. In other cases the symptoms are bilateral, but are most marked on one side. In some cases the symptoms are symmetrically bilateral and indicate pressure upon the cord rather than upon nerve-roots. Muscular spasms may occur. There may be lateral curvature of the back, the concavity of the curve being on the side of the tumor. Sooner or later paralytic symptoms come on (motor and sensory paralysis). They may be due to pressure upon and destruction of nerve-roots or to compression of the cord. When anesthesia exists there may be a zone of hyperesthesia above its upper limit. As motor palsy develops from root compression the pain usually abates. The muscles undergo atrophy.

A tumor may, by cord pressure, produce the symptoms of compression-myelitis, locomotor ataxia, or myelitis. Contractures or paraplegia may arise from tumor. The location of the growth can be inferred by a study of the territory of paralysis and the zone of sensory disturbance. The tumor is always situated somewhat above the upper limit of anesthesia. In many cases the diagnosis is impossible. Gradually increasing painful paraplegia, with pain in the back and with hyperesthesia or anesthesia after a time appearing and ascending from the feet toward the trunk, points to tumor as a cause. The paralysis is usually spastic, but may be flaccid, or it may be spastic at first and become flaccid. In spastic paraplegia the reflexes are increased. In flaccid paraplegia they are decreased. In spastic paraplegia there are ankle clonus, the Babinski sign (extension of the great toe or all the toes when the sole of the foot is irritated), Gordon's paradoxical reflex (extension of the great toe or all the toes when pressure is made upon the deep calf muscles), and Oppenheim's reflex (extension of the great toe or all the toes when the handle of the percussion hammer is drawn along the inner edge of the tibia so as to make pressure from above downward). Trophic lesions are apt to arise in the trajectory of nerve involvement. The sphincters are usually involved. Growths outside

the membranes produce particularly pain and spasm; growths within the membranes produce especially motor paralysis and anesthesia. Symptoms that are unilateral, were at first unilateral, or which are most marked on one side, are very significant.

Intramedullary Tumors.—These tumors develop in the substance of the cord. They are far less common than extramedullary growths and are more often benign. These growths are, as a rule, primary and solitary and do not produce symptoms of pressure until they attain the size of a hazelnut. The most common tumors are glioma, sarcoma, and tuberculoma. Syphiloma occasionally arises. Most tumors in cord-substance are small, but the glioma may involve practically the entire cord. A tumor is often for a time limited to one side of the cord, but later it presses upon and finally involves the opposite side. When the cord is pressed upon, degeneration occurs. In some cases a wrench or bruise of the back is supposed to be causal. Glioma may be congenital.

Symptoms.—They are at first, in most cases, very uncertain. In some cases, however, paralysis develops early.

There is often pain in the back, but it is not nearly so severe as in extramedullary tumor. The most prominent symptom is a slow-developing motor palsy. In some cases the palsy is at first unilateral, but later becomes bilateral. Irritative root symptoms are absent (spasm and darting pain). Anesthesia or hyperesthesia develop. The sphincters are involved and trophic disturbances arise. There may be spastic paraplegia or flaccid paraplegia. If the tumor is in or presses upon the anterior cornu there will be limited muscular atrophy. Tuberculoma produces the symptoms of transverse myelitis.

In glioma there are paresis and muscular atrophy. Although sensibility to pain, heat, and cold are lost, sensibility to touch is preserved (sensory dissociation).

Treatment of Tumors of the Cord.—If syphilis is suspected, give the patient a course of heroic doses of iodid of potassium, and administer mercury hypodermatically or by inunction. Intravenous injection of salvarsan is advisable. In a focal lesion not due to dissemination of a known malignant growth, perform the operation of laminectomy to permit of exploration and possibly of removal. The laminæ of at least three vertebræ should be removed and the tumor looked for distinctly above the upper level of the zone of anesthesia. It is not necessary for the patient to wear a spinal support after the performance of laminectomy. Extramedullary tumors are usually removable. Localized intramedullary tumors should be removed if they can be located and if removal can be accomplished without serious injury to the cord. After exposing the cord and discovering an intramedullary tumor, follow the advice of Elsberg and Bier ("Amer. Jour. Med. Sciences," Nov., 1911) and make a short incision in the posterior median column a little external to the posterior median fissure. The cut reaches the tumor, which bulges through it. Do not attempt removal now. Suture the skin and muscles and wait one week. On opening the wound the tumor will be found almost completely extruded from the cord. In order to remove it it is only necessary to divide a few strands of tissue. Extrusion by this method probably inflicts little injury upon nerve-fibers. McCosh truly said that operation for spinal-cord tumor was decidedly more hopeful than for brain tumor, because localization was much more accurate and removal could be effected with less permanent damage. Lloyd collected 51 operations: 10 per cent. died and 31 per cent. were actually cured or improved. Joseph Collins ("Med. Record," Dec. 6, 1902) collected 70 cases of spinal tumor, 30 of which were operated upon. In 12 the operation was a success, that is, the pain disappeared and motor power returned; in 8 the operation was partly successful, that is, the pain disappeared

and the motor power improved; in 10 the operation failed and death occurred within a few weeks. If the tumor is found to be irremovable, McCosh suggests division of several nerve-roots to relieve the pain.

Acute osteomyelitis of the vertebræ is a rare disease; it may be associated with osteomyelitis of other bones, may be secondary to some distant suppurative focus, or may occur alone. Infections of the viscera not unusually accompany it. In many cases there is a history of trauma. Any part of a vertebra may suffer from it. This condition may follow cold, over-exertion, or traumatism, and is more common in the first two decades of life than in elderly people. The process may be superficial or it may involve the bone deeply and widely. Suppuration always occurs; sequestra generally form, and phlebitis is a dangerous complication. Any region of the spine may be attacked, but the lumbar region is particularly liable to invasion, next the dorsal, next the cervical. The sacral region is least often affected. The situation of the abscess varies with the situation of the disease. If the vertebral bodies are diseased the pus passes forward (retropharyngeal, mediastinal, psoas, or pelvic abscess). If the vertebral arches suffer the pus passes backward (lumbar or dorsal abscess). The membranes of the cord, the cord itself, the nerves, and the vertebral articulations are frequently involved in the process. Staphylococci, streptococci, or other pyogenic bacteria may be cultivated from the pus.

Symptoms.—The general symptoms are those of osteomyelitis. The local symptoms depend on the seat of disease. If the posterior portion of the column is diseased there is a hard swelling which, in the neck, is in the middle line; in the dorsal and lumbar regions, in the middle or to the side; and in the sacral region, invariably to one side.

Rigidity of the spine always exists. If the vertebral bodies are affected, rigidity is noted, the spine is tender, and special symptoms appear, their nature dependent on the region affected (retropharyngeal abscess, etc.). Occasionally symptoms of meningomyelitis are noted. The constitutional symptoms of sepsis are marked. The condition is sudden in onset, and purulent collections diffuse widely and rapidly. These points enable the surgeon to make a diagnosis between osteomyelitis and Pott's disease. In osteomyelitis angular deformity very rarely arises, because the patient is obliged to be recumbent and because hyperostosis is taking place. The mortality, according to Hahn, is 60 per cent. Death may be due to pachymeningitis, pneumonia, empyema, retropharyngeal abscess, invasion of the cord, or amyloid disease (H. S. Warren, "Boston Med. and Surg. Jour.," May 7, 1903).

Treatment.—The patient is kept recumbent. His constitutional treatment is such as will combat sepsis (food, stimulants, etc.). A puriform area must be incised and disinfected. If bone denuded of periosteum is found, it is touched with a solution of chlorid of zinc or with the actual cautery. If a sequestrum exists, it is removed. A drainage-tube is inserted and dressings are applied (Müller, Makins, Abbot, and Chipault).

Typhoid Spine.—It was pointed out by Gibney in 1889 that typhoid fever may leave as a legacy a painful, stiff, and weak back; 74 cases of the condition have been reported (F. W. White, in "Jour. Amer. Med. Assoc.," Feb. 13, 1908). The muscles of the back are found to be rigid and there is tenderness of one or more vertebræ. The pain may only be appreciated on motion, but in some cases there is aching even when the patient is at rest. The pain may be localized, may run into one or both thighs, or may be felt in the abdomen. The symptoms arise at an uncertain period after the fever, develop rapidly, and are occasionally associated with transient episodes of fever. Kyphosis or lateral curvature may develop. (See L. W. Ely, "Medical Record," Dec. 20, 1902.) Many of the patients are hysterical. The condition

is due to osteitis and periosteitis, or chronic osteomyelitis. The prognosis is excellent.

Treatment.—The use of a plaster or leather jacket; counterirritation by the hot iron; later, massage and electricity.

Cervical Rib.—This condition was first described by Hunauld in 1743. The anterior limb of the transverse process of the seventh cervical vertebra, which has an independent center of ossification, may develop into a separate bone of large size, known as a cervical rib. Such a rib may form on one side or on both. It may scarcely reach beyond the transverse process, it may project well beyond the transverse process and have a free end, or it may constitute a complete rib which fuses anteriorly with the sternum, the cartilage of the first rib, or with a cervical rib of the opposite side.

Most instances described were found in the dead body, although Tillmanns collected 26 cases among the living (Carl Beck, in "Jour. Amer. Med. Assoc.," June 17, 1905). Of late x-ray findings indicate that the condition is much

Fig. 539.—Cervical ribs.

more common than was formerly supposed. I have seen 4 cases. It may never produce any uneasiness, and hence may escape detection and seldom does produce trouble in youth. It may lead to damage of the subclavian artery (Keen's case developed aneurysm), or gangrene of the hand may result from bending or blocking of the vessel, or neuritis of the brachial plexus may arise from pressure. When sufficiently large to produce venous or vascular trouble, a cervical rib can be felt and the pulsating artery over it is very distinct and higher than natural in the neck. The x-rays confirm the diagnosis. The treatment, when the rib is causing trouble, is excision of the rib with its periosteum (see page 707). (See Kammerer, in "Annals of Surgery," Nov., 1901, on "The Diagnostic Difficulties.")

Spinal Curvature.—There are four chief forms of spinal curvature: (1) Lateral curvature (the scoliosis of the older surgeons); (2) posterior curvature (the excurvation, gibbosity, or kyphosis of the older surgeons); (3)

anterior curvature (the lordosis of the older surgeons), and (4) angular curvature (from spinal caries). The normal spine has four curves: the *cervical* curve, the convexity of which is forward; the *dorsal* curve, the convexity of which is backward; the *lumbar* curve, which is convex anteriorly, and the *pelvic* curve, which is concave anteriorly. The dorsal and the pelvic curves, which are primary, are due to the formation of the cavities of the chest and pelvis, and depend upon the shape of the bones (Treves). The cervical and lumbar curves, which are compensatory, depend upon the shape of the intervertebral disks, and only appear after birth when the erect position is assumed.

CONDENSED DIFFERENTIAL DIAGNOSIS TABLE OF SPINAL DISEASES AND CONDITIONS WITH WHICH THEY MAY BE CONFOUNDED.

	Scoliosis.	Rachitic Spine.	Pott's Disease.	Hyperesthetic Spine.	Arthritis Deformans.	Torticollis, Congenital.	Hip Disease.
Age.	8 to 16.	4 to 6.	4 to 6.	16 to 20.	After 30.	Any age.	4 to 6.
Onset.	Insidious.	Insidious.	Insidious.	Sudden.	Insidious.	From birth.	Insidious.
Pain.	In back.	None.	Referred to anterior abdomen.	Severe in spine.	In spine.	None.	In knee.
History.	None.	Rachitic.	Tuberculous.	Trauma.	None.	From birth.	Tuberculous.
Posture.	Free.	Excessively free.	Guarded spine.	Guarded.	Guarded spine.	Typical.	Guarded hip.
Muscular rigidity.	None.	Free.	In spine.	In spine.	In spine.	In one direction only.	In hip in all directions.
Temperature.	Normal.	Normal.	1 degree rise.	Varies.	Normal.	Normal.	1 degree rise.
Local tenderness.	None.	None.	In spine.	Painful all over.	All over spine.	None.	In hip.
Night cries.	Absent.	Absent.	Present.	Absent.	Absent.	None.	Present.
Tendency to abscess.	None.	None.	Probable.	None.	None.	None.	Probable.
X-ray.	Characteristic deformity.	Normal.	Focus in spine.	Normal.	Late bridges of bone.	Distortion of cervical spine.	Spine normal.
Hot-water test.	No tenderness.	None.	Localized in spine.	Sensitive all over spine.	No necrosed sensitiveness.	No tenderness.	No tenderness in spine.
General symptoms.	Constant.	Constant.	Intermittent.	Constant.	Constant.	Constant.	Intermittent.

Scoliosis is a non-pathological distortion of the spine characterized by rotation and lateral bending, hence the name, rotary lateral curvature (Plate 9). It is either functional or organic.

Functional scoliosis is caused by any prolonged alteration in the relationship normally existing between the axis of the shoulders and the axis of the hips. The etiological factors depend upon the maintenance of faulty postures in occupations, especially during period of growth. School-life is especially influential in producing the condition because school furniture is adapted to the average requirements of a given class, and therefore a very small proportion of pupils are able to find desks and benches that are suitable. Properly furnished modern schools are supplied with desks and seats that are adjustable to each occupant. Gould ("The Ocular Factors in the Etiology of Spinal Curvature," H. Augustus Wilson, "New York Medical Journal," July 12, 1906) has directed attention to the errors of refraction that produce head tilting and thereby induce scoliosis. In adults, scoliosis is observable in blacksmiths, fencing masters, and waiters, in whom excessive use of the right arm produces an asymmetrical posture of the body.

When functional scoliosis is not corrected or occurs in rachitic or indolent children, it results in organic or permanent changes in the contour of the bones composing the spinal column. Organic scoliosis may be congenital, caused by prenatal deficiencies or augmentations of the spinal column.

Postmortem examinations reveal a confirmation of Wolfe's law that prolonged alteration of the normal functions always results in changes of

anatomical structures. In extreme cases the bones of the spinal column become extensively altered in shape, the ribs are altered in contour, and the thoracic and abdominal viscera are forced into unnatural positions and assume abnormal shapes, their functions often being materially altered.

Diagnosis.—The patient is usually taken to the physician because of apparent elevation of one shoulder, or because one hip is thought to be larger than its mate, or one mamma higher than the other. Dressmakers and corset makers are generally the first ones to direct attention to the faulty posture (as scoliosis occurs in 8 girls to 1 boy). A patient suspected of having scoliosis should be nude at the time of inspection, as clothing hampers the normal action and tends to conceal the movements of the body. The accompanying diagnostic table (see page 841) is a condensed comparative statement of the important features in diseases and conditions that may resemble scoliosis in some respects. It is only by carefully studying the symptom-complex that a definite decision can be reached. It is frequently observed that patients with mild types of functional scoliosis can sit or stand erect for a few minutes and thereby deceive even a critical observer. The habitual posture, and also the rapidity with which the patient returns to the distorted position after temporary voluntary correction, demand careful attention. Young children, when chided by parents or teachers, often temporarily assume an approach to a normal posture without actual correction. The ease with which their surrounding joints yield in compensatory action is often overlooked. A patient with contracture of the pectoral muscles will elevate the shoulders into an apparent correction of stoop or round shoulders instead of throwing the shoulders well back, a posture that is to them impossible.

Fig. 540.—Lateral dorsal curvature to the right, and compensatory lumbar curve to the left.

Goldthwait has directed attention to forward curves of the scapula that are often present in patients who are stoop-shouldered and has devised an operation for correction.

In the same way, a patient who has preternatural contracture of the hamstring tendons, either unilateral or bilateral, will often conceal that condition by bending the knee or knees enough to permit the pelvis and trunk to bend forward.

Treatment consists especially in removing the cause. If the eyes produce head-tilting, proper refraction will be necessary. Adenoids should be removed. The clothing should be regulated to avoid constriction and the shoulder straps should fit close to the neck and not be allowed to slip on to the shoulder-joint.

Contractures of the pectoral muscles should be stretched by corrective manipulations. Hamstring contracture should be removed by corrective manipulation. Hoke ("A Study of a Case of Lateral Curvature of the Spine: A Report On an Operation for the Deformity," "Amer. Jour. Orthop. Surg.," vol. i, November, 1903, p. 169) has devised an operation of rib resection for cosmetic purposes. Every effort should be made to prevent the *occurrence* of scoliosis. The successful treatment of scoliosis depends on preventing its progress. Each individual patient requires careful study to determine the special characteristics that may be present.

Remedial measures should be employed that meet the peculiar individual requirements of each case.

School gymnastics are generally more harmful than beneficial in cases of scoliosis. No one but a physician should prescribe the gymnastic work. The soft bones may be still further distorted by injudicious exercises.

Rotary lateral curvature of the spine.

The first requirement in the application of applied physical culture is to secure the hearty coöperation of the patient. Without such coöperation progress cannot be expected.

No gymnastic apparatus of any kind is required when the patient can be instructed in the proper methods of autoresistance. There are over four thousand movements of the body that may be employed in remedial physical culture. From this vast assortment those may be selected that are suitable to the peculiar conditions of the patient. At first the least tiresome forms are to be employed, and gradually and progressively others are resorted to until the patient presents a strong robust development. Usually about a year is required for the purpose, as the progress must be essentially educational. Training in developing muscle action goes hand in hand with instruction in walking, in sitting, and in all the postures assumed by the human body in the various occupations of the patient.

In organic scoliosis, in which the distortion is more or less of a permanent character, much can be accomplished in preventing the progress of the condition as well as in aiding correction by removing any rigidity that may be present. By increasing the flexibility we facilitate muscular development in much the same manner as in functional scoliosis.

When rigidity is present it must be considered in the same light as rigidity of any other joints. Its presence prevents muscular development. Manipulative measures are similar in effect to those employed in fibrous ankylosis of any joint, and are peculiar to the parts involved. In the majority of cases the force for manipulative correction must be applied through the interposition of the ribs, and the great danger of producing fractures of these structures should be realized.

If, however, there is any tendency to increase of the deformity, a suitable brace or removable jacket of plaster or celluloid should be applied to maintain correction until the musculature has been strengthened and trained to perform its full functions.

Organic or structural scoliosis has been shown by Abbott, of Portland, to be capable of correction by several types of fixed jackets (E. G. Abbott, "New York Med. Jour.," 1912, and A. M. Forbes, Ibid., July 6, 1912). The keynote of the treatment in each method is flexion of the spine, as in that position the vertebræ are unlocked. Partial correction is secured by means of bandages pulling in various directions and, after proper padding, a plaster jacket is applied. Further progress to overcorrection is continued by means of pads of felt slipped under the jacket to increase the pressure in certain directions. After overcorrection has been obtained, a celluloid jacket is worn to maintain this and exercises are assiduously employed to restore muscle function. These methods of treatment constitute the greatest advances in this work in many years, but to secure the best results they must be followed out most carefully by a skilled physician. Special forms of apparatus are essential in the application of these jackets. The combination of the gymnastic and mechanical treatment in severe functional and in organic scoliosis proves the most satisfactory in that it not only restores muscle balance, but also corrects deformity, and secures as great correction of the deformity as possible before ankylosis occurs. Any appliance used in these cases should be made to order to fit the peculiarities of the patient and should never be the shop-kind that are so extensively advertised. Much valuable time is often lost while unmechanical and unsuitable apparatus is being used, during which time the bony changes may become permanent and beyond repair.

Anteroposterior curvature (not from spinal caries or from hip-joint disease) is an increase of the normal anteroposterior curves. Increase of the dorsal curve is *posterior curvature, kyphosis,* or *excurvation* (Fig. 541, A); in-

crease of the lumbar curve is *anterior curvature*, *lordosis*, or *saddle-back* (Fig. 541, B). Both lordosis and kyphosis are apt to be present. Scoliosis has nearly always some anteroposterior curvature associated with it. Lordosis is apt to be compensatory, to prevent the center of gravity going too far forward. Lordosis is found in pregnant women and in very fat men. In an old man kyphosis arises because of flattening out of the vertebral disks from pressure. Rheumatic gout may cause anteroposterior curvature. Anteroposterior curvature is often due to paralysis of the erector spinæ mass (from infantile paralysis). Pseudohypertrophic paralysis causes lordosis.

Fig. 541.—Kyphosis (A) and lordosis (B).

Symptoms and Treatment.—The *symptoms* of anteroposterior curvature are as follows: the thorax is flattened or pigeon breasted; the shoulder-blades are widely separated and the scapular angles project; the abdomen is protuberant; the patient complains of backache and soon tires. A recent kyphosis disappears when the patient lies upon his stomach. The facts that the erector spinæ muscles are soft and that pain is absent on concussion transmitted to the back separate kyphosis from caries. Lordosis is unmistakable. When the spine is movable, employ the same plan of *treatment* as in lateral curvature, suiting the gymnastics to the deformity. In painful kyphosis with partial ankylosis endeavor to make the ankylosis complete in order to prevent pain, obtaining this result by applying a plaster jacket which laces up and letting the patient wear it for several years.

Angular curvature (*spinal caries; spondylitis; Pott's disease*) is usually due to tuberculous caries of the vertebral bodies, and occurs particularly in children who are the victims of tuberculosis, but it may arise at any age. Any portion of the spinal column may be attacked. The dorsolumbar region is most prone to suffer. The chief *cause* is tuberculosis, but syphilis and secondary cancer of the vertebræ are occasional causes, and acute osteomyelitis is a very rare cause (see page 839). Blows or sprains appear to have a causal influence in some cases (see Trauma in Tuberculosis, page 223). Angular curvature may develop after an exanthematous fever.

The cancellous tissue of the anterior portion of the vertebral body becomes primarily carious, or the inflammation begins in an intervertebral disk. (The changes of tuberculous osteitis have previously been set forth—see pages 249, 494, and 495.) The body of the vertebra and the vertebral disk are destroyed, and the process extends to adjacent vertebræ. The weight which rests upon the spinal column causes softened bone to crumble, compresses the diseased vertebræ and disks, and produces angular deformity (the anterior part of the column formed by the vertebral bodies is shortened, the posterior part is not, and hence the spines project). In some cases the disease is spontaneously arrested by organization of inflammatory products, and ankylosis (fibrous or bony) in deformity is Nature's cure. In most cases, however, the disease spreads and caseous pus is formed, which, according to the point of formation and the route it takes, causes lumbar abscess, dorsal abscess, psoas abscess, or postpharyngeal abscess (see pages 241 and 242). In some cases the spinal cord is compressed, but in most cases it is not, and even when it is compressed paraplegia is rare and is usually temporary. Compression of the cord may be caused by the displaced vertebræ, by inflammatory material or caseous matter between the bone and dura mater, but is most often due to pachymeningitis. Caries of the cervical region constitutes a more dangerous disease than caries of either the dorsal or the lumbar region (*dangerous* pressure occurs more easily). Death may be caused by exhaustion, sepsis, hemorrhage,

amyloid disease, pneumonia, peritonitis, pleuritis, tuberculous dissemination, pressure upon the cord, or inflammation of the cord or its membranes.

Symptoms.—The sufferer from Pott's disease, if a child, grows tired easily. The disposition alters. The victim becomes moody and irritable, and complains of vague pains in many places, is disposed to lean, rest, or lie down, and walks with the back rigid, which produces a peculiar gait. A painful spot may be found by pressing upon the spines. Faradism to the back causes pain. Spasm of the erector spinæ mass is detected (Hilton, Golding-Bird). It is not proper to seek to develop pain by jarring the back or by pressing the head downward. The posture of the child and the muscular rigidity prove the existence of inflammation, and to seek to develop pain by the methods referred to may do harm, and at best can only call attention to what is already known. Pain in the back, which is increased by motion, by pressure, and by vertebral jars, may be absent until late in the case. Distinct pain and tenderness in the back often mean abscess formation. Neuralgic pains pass into distant parts (sciatica, intercostal neuralgia) and are often linked with muscular spasm. A chronic bilateral pain in the trunk or extremities is suggestive of Pott's disease. "Chronic bilateral bellyaches in children are almost diagnostic" (Jordan Lloyd). The pain of dorsal caries can be relieved by lifting the shoulders; the pain of cervical caries, by traction on the head. Cramp in the legs occurs in dorsal and in lumbar caries. The presence of the knuckle due to bending the spine at an acute angle is a very important sign of the disease. In many cases angular deformity appears late; in some cases it does not appear at all. An angular deformity is detected sooner in those regions where the normal curves are posterior than where the normal curves are anterior. The deformity appears early in the dorsal region, but late in the cervical and lumbar regions. In many cases lateral deformity occurs. Rigidity is an early sign of great importance. It is always present. Rigidity is manifest very early in cervical caries, tolerably early in lumbar caries, late in dorsal caries. Lloyd gives the following practical rules to enable us to detect rigidity.[1] In the cervical region: seat the patient in a chair and tell him to nod the head affirmatively. Stiffness in nodding points to occipito-atloid disease. Tell him to look far to the right and then far to the left. Stiffness of these motions suggests atlo-axoid disease. Tell him to place his shoulders against the back of the chair and carry his eyes back along the ceiling. Stiffness in this movement indicates disease below the second cervical vertebra. It is practically useless to examine the dorsal region of an adult for rigidity, but such an examination can be made in a child. Place the patient prone on an adult's lap, mark the tip of each spinous process with an anilin pencil, then make the child stand up straight on the floor, and observe if any of the pencil marks fail to come nearer together. If it is seen that two or more marks do not approach each other, there is rigidity which prevents approximation. To test for rigidity in the lumbar region lay the naked patient prone upon a couch. Grasp the patient's ankles and raise the pelvis from the couch. If the lumbar spine is flexible, the pelvis can be lifted without raising the chest from the bed, and the maneuver deepens the hollow of the loin. If the lumbar spine is stiff, the maneuver lifts the trunk and produces no alteration in the vertical outline of the lumbar spines. If a child with Pott's disease is asked to pick up something from the ground, because of rigidity or pain on movement he will not bend the back, but will bend the knees or get upon the kness. Paralysis may exist, and it is due to pachymeningitis more often than to pressure from bone. Cervical caries causes dyspnea and torticollis, the head requiring support with the hands. Dysphagia indicates abscess. In adults the first signs of

[1] "Birmingham Med. Review," April, 1897.

Pott's disease to attract attention are headache, backache, neuralgia, girdle-pain, cramp, or even paralysis. In abscess due to caries of the dorsolumbar vertebræ the pus usually enters the psoas muscle and passes out of the pelvis below the junction of the middle and outer thirds of Poupart's ligament. It may point here or may pass to the inner aspect of the thigh and point a little below the spot where a femoral hernia is met with if it exists. In a psoas abscess a mass is always felt in the iliac fossa above Poupart's ligament; in a hernia no such mass exists (J. T. Rugh). In sacral caries there is no deformity and frequently no pain. The diagnosis becomes apparent when bilateral abscess is detected in the buttocks or groins (Jordan Lloyd). If an abscess due to spinal caries opens spontaneously, healing will not occur, mixed infection takes place, and death often follows.

Treatment of Caries of the Spine.—When recent caries of the spine is active and affects a child; when it is accompanied by pain and fever; and when paralysis threatens, insist upon perfect rest. Place the child supine on a hard mattress, and, if possible, take it, while in a rolling bed, out of doors daily. Leeches, blisters, or the hot iron over the area of pain may do good.

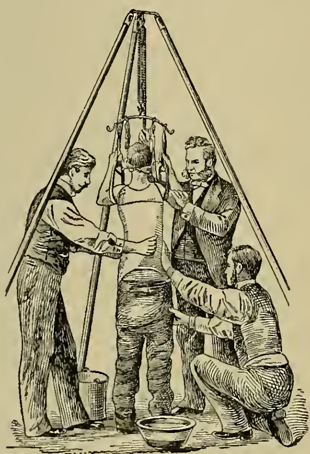

Fig. 542.—Plaster-of-Paris jacket (Sayre).

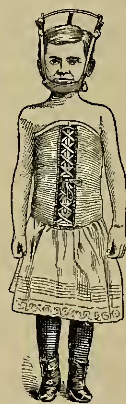

Fig. 543.—Plaster-of-Paris jacket and jury-mast applied (Sayre).

When the activity of the process abates, apply a fixation apparatus. In diseases at or near the vertebro-occipital articulation, as long as dyspnea persists, keep the patient supine with a small hard pillow under the nape of the neck (Hilton) and a sand-bag on each side of the head and neck. After several months mechanical support can be given by Furneaux Jordan's method. Jordan applies his support as follows: The patient lies on a flat, hard table, his arms are raised above his head, and traction is made upon the head by means of a pulley and a weight. Cotton pads are placed over the ears, the back of the neck and the clavicles, and are held in place by a broad flannel bandage applied as a figure-of-8 on the head, neck, and chest. The flannel bandage is overlaid with plaster-of-Paris bandages.[1] In disease of the cervical region below the axis, or of the dorsal region above the seventh vertebra, use Sayre's jury-mast (Fig. 543), or some other form of head support. Instead of the jury-mast a steel upright may be used to hold the head rigid. Sayre's appliance relieves the spine from the weight of the head and acts admirably. In most cases of dorsal and lumbar caries a steel, leather, or plaster jacket as a fixation apparatus must be employed. The best of all fixation apparatus

[1] See "Children's Deformities," by Walter Pye.

is Sayre's plaster-of-Paris jacket applied while the patient is suspended (Fig. 542) or, better, while the column is in hyperextension. The Sayre apparatus applied in this manner is used for the treatment of caries of the lumbar region and the lower half of the dorsal region, or a plaster jacket may be applied while the patient is lying prone in a hammock or stretched between two tables. Greater corrective pressure over the deformity is secured by this method than by suspension. When all subjective signs cease, substitute for the plaster-of-Paris jacket a felt or sole-leather jacket which laces down the front. Caries of the upper half of the dorsal region is often treated by a Sayre's jury-mast (Fig. 543); but if the jury-mast fails, it may be necessary to place the patient horizontally in "an open cuirass, fitted to the back from occiput to sacrum, and combined with pulley extension to the head and pelvis."[1]

During the course of caries of the spine have the patient eat fat-forming and nutritious food, insist on a plentiful supply of fresh air day and night, and administer tonics. Full antituberculous treatment is imperative (see page 230). Sea-air is very beneficial. When all active disease ceases and only angular curvature remains, use an apparatus to combine extension with mechanical support, the plaster jacket being generally employed.

Albee's Bone Transplantation Method of Treatment.—The ordinary ambulatory treatment of Pott's disease is seldom satisfactory. It is particularly unsatisfactory in the upper dorsal region. Ridlon and Jones emphasize this fact and declare that when the disease is situated in that region only prolonged recumbency prevents increase of the deformity. Albee reached the conclusion that the treatment should be one which secures bony union and hence perfect immobility. Perfect bony fixation means cure.

Albee was accustomed to see perfect cure in hip tuberculosis after ankylosing the joint, and in knee tuberculosis after erasion. He has secured a like result in vertebral caries by grafting into the spinous processes a large piece of bone cut from the patient's tibia. This graft usually becomes fixed to the spinous processes. It at least unites with the surrounding ligamentous structures and gives unyielding support which produces cure (see page 860). It is a highly useful method (Albee, in "New York Med. Jour.," March 9, 1912; in "Post-Graduate," Nov., 1912).

Spinal abscesses are treated as indicated on pages 245 and 246.

Paralysis in Pott's Disease.—Partial or complete motor and sensory paralysis may develop in the course of vertebral caries. It may be due to the pressure of tuberculous material or to pachymeningitis with thickening of the membrane. In only 2 per cent. of cases of paralysis is the paralysis due to the pressure of angled bone (Willard). The paralysis may come on gradually. There are weakness in walking or actual inability to walk, exaggerated reflexes, muscular rigidity, and impaired sensation in the legs, and loss of control of the bladder and rectum. Caries in the high dorsal region is more apt to result in paralysis than in any other region because of the small size of the canal. Pressure in the cervical region is highly dangerous.

Treatment.—We must remember that angulation is the rare cause, tuberculous masses the common cause. Treatment for paralysis due to tuberculous masses is the full open-air treatment of tuberculosis, with rest, fixation, and progressive straightening of the spine. The patient is kept in bed (see Treatment of Tuberculosis, page 230) on a Bradford frame and with his head overextended. If after one year the condition is not notably improved, do laminectomy and clear away tuberculous masses. If angulation is the cause of the paralysis, consider gradual correction, laminectomy, and Albee's bone transplantation. In several of the cases reported by Albee recovery from paralysis occurred soon after bone-grafting.

[1] Jordan Lloyd, in "Birmingham Med. Review," April, 1897.

Gradual Correction of Angular Deformity.—Pressure is made upon the hump with the hand, and while the hand is thus held the weight of the body is allowed to bear upon it above and below. Something is perhaps gained and then plaster of Paris is applied, somewhat later a little more gain is obtained, and so on. This method is safer and more satisfactory than forcible correction.

Forcible correction of angular deformity was advocated by Chipault and Calot in cases of Pott's disease without abscess. It was only used in angular deformity of the middle and lower part of the dorsal region and was not advised in the cervical, upper dorsal, or lumbar regions. The operation is not safe, and a number of deaths have been reported. Gabaert[1] pointed out certain disasters which may follow forcible correction; they are: death during anesthesia; rupture of an abscess; subsequent paralysis of the legs and bladder; disseminated tuberculosis, and shock, with convulsions and death. I do not believe in forcible correction and I do believe that the alleged dangers are real dangers, that the operation is unsafe, and that it should never be done.

Laminectomy is warmly advocated by some surgeons for paraplegia from spinal caries. This operation is rarely necessary, but in some few cases it is imperatively demanded. Many cases recover from paraplegia without operation. Operation for paraplegia has a very heavy mortality (25 per cent.), and many are not benefited at all by it. If degeneration of tracts in the cord has occurred, operation cannot help the paralysis. Nevertheless, in some cases laminectomy has certainly cured palsy and saved life. Menne has collected 132 cases of laminectomy. Of these 56 per cent. were cured or permanently improved and 18 per cent. were temporarily improved.

Laminectomy should not be undertaken until treatment by rest, fixation, and extension has been applied for at least one year. Laminectomy may become necessary in cervical caries to prevent asphyxia. The operation enables the surgeon to remove masses of inflammatory material which make pressure on the cord, and also to free the cord from pressure due to angulation. The dura should not be opened unless there is evidently trouble beneath it, in which case it is incised and any tuberculous area removed, the dura being subsequently sutured. Ménard removes the transverse processes of the diseased vertebræ and the heads and necks of the associated ribs in order to give the surgeon access to diseased vertebral bodies.

Spondylitis Deformans (*Bechterew's Disease*).—This is the name usually applied to osteo-arthritis of the spine (see page 642). In this disease osteophytic formation takes place at the vertebral borders, and the vertebræ become ankylosed. The vertebral bodies, as a rule, are most affected by the disease, but any portion of a vertebra may be attacked, and often the heads of the ribs are anchored to the spine by bone.

The disease may begin in infancy, childhood, youth, adult life, or old age.

Symptoms.—There are decided and persistent pain and tenderness of the spine, and occasionally evidence of pressure on the nerve-roots. Early in the case deformity is apt to occur, because at this period there is inflammatory softening.[2] The deformity is not angular, but is usually a total kyphosis, the column being bent forward from above and made into a single curve. Lateral curvature may occur. In many advanced cases and in some comparatively recent cases the spine becomes rigid and ankylosed, and when it does, there may be evidences of irritation of the posterior nerve-roots. In this condition there is rigidity of part or of the entire spine, other joints escaping. If the entire spine is involved, there is rigid cervicodorsal kyphosis, a condition which causes the neck to stick forward and the head to appear as if forcibly driven down between the shoulders. If the entire spine is in-

[1] "Ann. de la Soc. Belge," July 15, 1898.
[2] J. Jackson Clarke's book on "Orthopedic Surgery."

volved, the lumbar spine is rigid and the normal lumbar curve disappears. As a consequence the patient stands in an unnatural attitude, the hips and knees being partly flexed, and the legs and feet being in a condition of external rotation. In Bechterew's disease there are compression of the posterior nerve-roots, severe pain, muscular atrophy, and ascending degeneration of the cord. What Marie calls *spondylitis rhizomelique* is said by Osler to be a form of arthritis deformans. There is rigidity of the spine, shoulders, and hips, but no nervous lesions, as in Bechterew's disease.

Treatment.—Cure is impossible, but amelioration can be obtained.

The local and constitutional treatment is as for osteo-arthritis in any region (see page 642). If spinal curvature begins, a mechanical support must be applied or Albee's bone-grafting operation performed. Rugh operated on such a case with gratifying results ("Internat. Clinics," Vol. I, Twenty-third Series).

Injuries of spinal ligaments and muscles, which may complicate more serious injuries or may exist alone, are caused by wrenches, twists, and violent muscular efforts (as in lifting). Railway accidents may be responsible for these sprains and strains. The injury is called *railway spine* when it is caused by a railway accident.

Symptoms.—Injuries of the back, even without cord injury, are frequently linked with very deceptive nervous symptoms. Symptoms are often severe, but are usually temporary. In some few cases the symptoms are persistent. Secondary disease of the cord is extremely rare. Any region may be affected, but the lumbar is most usually injured, and the entire spine may suffer. The three marked symptoms are pain, tenderness, and stiffness of the back. At the time of injury and for a while after there is often marked shock, and hysterical excitement is occasionally observed. The cardinal symptoms may arise very soon, but may not become severe for a day or two. The pain is not acute when at rest, but becomes acute on movement.[1] The pain is felt in the back and sometimes darts into the extremities. The muscles of the back are rigid, the spasm being due to pain. The patient is very careful not to twist or bend the spine, because to do so increases pain. In a one-sided injury the rigidity is unilateral, and this symptom cannot be simulated. Often, but by no means always, the region of the back is swollen and the skin is discolored. The tenderness is not of the skin, but of the muscles. Firm pressure on a spot of real tenderness causes rapid pulse (*Mannkopf's sign*). The vertebral spines are regular and are not mobile. There is no distant paralysis or hyperesthesia unless the cord is damaged (though in some rare cases the bladder and the rectum are paralyzed when no cord lesion can be detected, and hyperesthesia may exist over the spines). Moullin tells us that the extremities feel weak because they are deprived of proper support on account of the immobility of the muscles of the back. For the same reason the action of the abdominal muscles is interfered with, and the power of micturition and of defecation is impaired (there are constipation and difficulty in emptying the bladder).

The **treatment** of recent injuries comprises rest, the application of an ice-bag, and leeching over the painful area. After a day or two hot fomentations, tincture of iodin, compression by adhesive strips, and inunctions of ichthyol and lanolin are used; and, later still, massage, douches, and frictions with a stimulating liniment are employed. Phenacetin helps to relieve pain, though in some cases opium is temporarily necessary.

Traumatic neurasthenia is apt to arise after the *immediate* effects of the accident subside. In this condition the patient grows tired easily and complains of pains and aches in the back and loins, interfering with or preventing

[1] Moullin on "Sprains."

work; paresthesia and numbness exist in the extremities; in many cases sexual intercourse is impossible because of premature ejaculation or of incapacity for erection. There are dyspepsia, eye-strain, insomnia, loss of memory, rapid and irregular pulse, cardiac palpitation, and mental depression or confusion. The reflexes are usually exaggerated, but they can be exhausted more easily than can the exaggerated reflexes of organic cord disease (because of irritable weakness). Some rigidity and tenderness exist in the back, and the skin over this region is often hyperesthetic. Attacks of retention of urine may occur. Hypochondriasis is not unusual.

Treatment of Traumatic Neurasthenia.—Employ rest, tonics, massage, douches, and frictions to the back. Secure sleep, and endeavor to bring about a gain in weight. If sexual incapacity or seminal emissions worry the patient, dilate the urethra with steel sounds.

Traumatic hysteria develops only in those predisposed by a neuropathic hereditary tendency; traumatic neurasthenia may arise in any one. In the first named disease the accident is only the *exciting* cause; in the second disorder it is *the* cause. Many cases of so-called "railway spine" are really examples of traumatic hysteria. Traumatic hysteria and neurasthenia may be associated. Neurasthenia is a condition of exhaustion associated with a number of chronic disorders; it forms a foundation on which hysteria is apt to build its structure. The structure of hysteria is made up of morbid impressionability, hyperesthesia of centers, lowered self-control, and sensitiveness of the peripheral nervous system. The accident plays a double part in producing traumatic hysteria—first, by its effect on the mind (psychical traumatism); second, by its effect on the body, which anchors the attention to one point. An area of pain or stiffness often serves as an autosuggestion which undergoes morbid magnification when viewed through the distorting medium of hysteria. Erichsen taught that the symptoms of what he named "railway spine" arose from inflammation of the cord and its membranes, a view now abandoned. A blow given to a hysterical person causes a feeling of numbness, and thus negative sensation from local shock may establish the idea of paralysis, or traumatism, acting as a suggestion, may inhibit motor representations and destroy the normal ideas of motion and feeling (Charcot and Pitre). Terror always causes a feeling of loss of power in the legs, and the terror of the accident may thus develop the idea of paraplegia. The site of a traumatism may localize symptoms; for instance, a blow upon the eye may cause amaurosis or blepharospasm. It is important to remember Charcot's saying that a hysteria long latent and unrecognized may be awakened into obvious activity by a blow or an accident. Pitre shows the same to be true of epilepsy. A not unusual lesion is hysterical traumatic monoplegia, not coming on at once after the accident, but usually some days afterward, and presenting flaccid muscles, the electrical reactions and reflexes remaining normal, but the muscular sense being lost (Pitre). The muscles usually waste. The skin of the paralyzed limb is anesthetic or analgesic. There may be anesthesia limited to a limb, hemianesthesia, or general anesthesia.[1] Hysterical paralysis is usually associated with the permanent *stigmata of hysteria*—concentric contraction of the visual field, pharyngeal anesthesia, convulsive seizures, and hysterogenic zones (Clarke and Pitre). The permanent stigmata may be latent. Hysterical phenomena lack regularity of evolution, and they may be produced, altered, or abolished by mental influences or by physical forces which produce no effect on organic disease. In most hysterical conditions the general health is not profoundly impaired.[2] In making a diagnosis of hysteria we must be most careful to

[1] J. Mitchell Clark, in "Brain."

[2] Read the works of Thorburn and Pitre.

exclude both malignant disease and imposture, because hysteria is a sort of diagnostic waste-basket into which we cast most things which we fail to understand. Babinski proposes that we should call phenomena hysterical only when they can be produced or can be cured by suggestion ("Brit. Med. Jour.," Jan. 23, 1909, p. 234). Brain tumor may cause hysterical symptoms.

Treatment is by moral means chiefly. Gain the confidence of the patient. Suggestion is of great value. In many cases separation from family and friends is necessary and isolation is desirable. The Weir Mitchell rest-cure is often the best plan of treatment, and all its details should be carried our faithfully.

Malingering.—Persons often pretend to suffer from maladies of the spinal cord or column as a result of accident when no diseases of those parts exist. Some get well upon the rendering of a favorable verdict by a jury (**litigation backs**). In any case always examine carefully, so as to be able to exclude malingering. Note the patient's behavior and motions when his attention is diverted from his disease. *Meningomyelitis* can be excluded if there be no spasm, paralysis, hyperesthesia, paresthesia, or anesthesia at a distance (A. Pearce Gould). If pain has lasted for months; if pressure downward upon the head or shoulders does not increase pain; if the vertebræ are movable and there is no angular displacement, exclude *caries*. Gould states that when there are wasted muscles, when moderate spine movement is painless, but effort in bringing the body erect causes pain in the erector spinæ region, the trouble is a *strain of the erector spinæ muscle*. If the muscle is not wasted and the pain is in bending forward rather than in straightening up, the *vertebral ligaments* are the seat of trouble. Unilateral spasm cannot be simulated. The administration of ether may dispose of a pretended paralysis, the patient moving the suspected extremity while drunk from the anesthetic.

Concussion of the Spinal Cord.—This term has no definite pathological meaning. It is probable that there is such a condition, but it is usually associated with laceration of capillaries and of cord substance.

The **symptoms** are shock, intense pallor, nausea, often vomiting, and sometimes syncope. With this condition special symptoms may be linked—as temporary paralysis, a girdle sensation, numbness and loss of power in the limbs, hiccup, torticollis, coarse tremors, pains in the back and limbs, areas of anesthesia and analgesia—depending on the portion of cord lacerated.

The **treatment** in concussion of the spinal cord is the same as that for sprains. Traumatic neurasthenia and hysteria or organic cord disease may follow this injury.

Contusion of the spinal cord may arise from a blow or a sprain, but it is usually due to extreme flexion of the spine. It causes hemorrhage into the gray matter of the cord (*hematomyelia*). The symptoms are motor and sensory palsy and diminished reflexes. Some cases recover, but others end in myelitis.

Wounds of the spinal cord are rare and are very dangerous. A knife is sometimes thrust in between the occiput and atlas. Wounds above the origin of the phrenic nerves cause almost instant death. Gunshot-wounds are the most usual form, the cord being damaged by the bullet and by bone-fragments.

In the American Civil War gunshot injuries of the cord were very rare ($\frac{1}{4}$ of 1 per cent. of all wounds), but at the present day in war they represent more than $\frac{1}{2}$ of 1 per cent. of all wounds, the increase in frequency being due to the increased penetrating power of the modern military bullet (Surgeon-General Robert M. O'Reilly, in "Keen's Surgery," vol. iv). The mortality is about 60 per cent.

A revolver bullet or a small-caliber bullet fired at long range may produce vertebral fracture without cord injury, and any bullet may fracture a process

of a vertebra without cord injury. If the laminæ are fractured the cord is almost sure to be injured. The cord may be concussed, lacerated, or cut across by bone or bullet, or compressed by bone or blood. The bullet may lodge or may perforate.

Treatment.—In a suspected wound of the cord perform exploratory laminectomy, arrest hemorrhage, and if the cord is divided, suture it. If a bullet is lodged, remove it.

Compression of the spinal cord may be due to blood or to inflammatory exudate, as well as to displaced bone (see page 844). *Compression from blood* may be due to *extramedullary* hemorrhage or to *intramedullary* hemorrhage. *Extramedullary* hemorrhage causes sudden pain in the back, the pain radiating from compressed nerve-roots; hyperesthesia and paresthesia in the area of the radiated pain; spasm of muscles supplied by the compressed nerves, sometimes of muscles whose nervous supply is below the lesion; tremors; convulsions; retention of urine; paralytic symptoms following the signs of irritation, but no absolute paralysis (Mills). A girdle sensation is usual. *Intramedullary* hemorrhage causes pain, a girdle sensation, abolition of reflexes, and paralysis. Spasms, rigidity, and paralysis come on early. Bedsores may form, and retention of urine and incontinence of feces may be observed. Paralysis from hemorrhage is rapidly progressive from below upward (*crawling paralysis*). Compression from extramedullary hemorrhage may be recovered from without operation, and in some cases recovery is rapid.

Treatment.—If paralysis from spinal bleeding extends rapidly and life is endangered through the probable involvement of a vital center, perform a laminectomy, remove the clot, and arrest hemorrhage. It is wise always to open the dura and inspect the cord. Extramedullary hemorrhage may be arrested by sutures or by packing. Intramedullary hemorrhage may be arrested by suture-ligatures or by packing. If an extramedullary clot is extensive it is proper to make a second laminectomy near the lower end of the spinal column in order to permit the surgeon to wash it out thoroughly. The dura must be sutured and drainage is to be employed. If there is paraplegia, complete anesthesia of the paralyzed parts, and entire abolition of the deep reflexes, operation is probably useless, but it is justifiable to try it because of a possibility that the cord is not completely divided. In some cases with persistent paraplegia the operation should be undertaken. If operation is not undertaken, have the patient lie upon his side, apply a spinal ice-bag, and give morphin hypodermatically. If hemorrhage continues in the cord and if the patient be plethoric, perform venesection. To promote absorption of the clot and exudate give a combination of carbonate and acetate of ammonium, order pilocarpin, and employ spinal galvanism and hot douches. Iodid of potassium may be given.

Fractures and dislocations of the spine are very rare. The spinal regions most liable to injury are the atlo-axial, the cervicodorsal, and the dorsolumbar (Treves). A vertebra may be fractured alone, but dislocation without fracture, except in the upper cervical region, very rarely occurs. These two lesions, dislocation and fracture, are so often associated that the term *fracture-dislocation* is used by many surgeons to include them both. The causes of fracture and dislocation are direct force (seldom) and indirect violence (commonly). In fracture by direct force the laminæ and spinous processes are most apt to suffer. In most cases the fragments are not greatly displaced. A fracture by indirect force may result from a fall on the shoulders, from a weight falling on the shoulders, or from a fall on the buttocks. Forced flexion or overextension is the commonest cause. In fractures from indirect force the cord generally suffers. In some cases the displacement of the vertebræ lacerates the cord, the vertebræ return into place, and no deformity is

detectable. Fracture-dislocation from direct force may occur at any part of the column, and in this accident the posterior vertebral segments are driven together, and the cord, as a rule, escapes injury. Fracture-dislocations from indirect force most commonly happen in the dorsolumbar region, but are met with in the cervical and dorsal regions. In the cervical region reduction can usually be secured, but in the lumbar region reduction is impossible.

Symptoms.—In fracture-dislocation great displacement is unusual, but some is almost always recognizable (irregularity of the spines or angular deformity). There are pain (which is increased by motion), tenderness, ecchymosis, and motor and sensory paralysis. Priapism, cystitis, and retention of urine often occur. Horsley has pointed out that in many cases paralysis passes away only to recur subsequently, the recurrence being due to

Fig. 544.—Fracture of third lumbar vertebra.

edema of the cord. In some cases of spinal injury there is *temporary paralysis* due to *shock*. *Persistent paralysis* may be due to laceration of the cord, division of the cord, or compression of the cord by bone, blood-clot (Fig. 545), or products of inflammation. The extent of paralysis depends on the seat of the cord injury. We must always try and decide if the spinal cord is completely divided or hopelessly crushed (Fig. 546). When the symptoms are not immediate in onset; when all the muscles below the seat of injury are not completely paralyzed; when there is some retention of sensation; when reflexes are present and muscular rigidity exists, we may be sure that the cord is not completely divided. When the cord is completely divided the symptoms are immediate, there are absolute flaccid motor paralysis and complete sensory paralysis (loss of appreciation of pain, touch, and temperature). The

line of anesthesia is definite and suddenly terminates (Walton). The bladder and rectum are paralyzed and there may be priapism. All the reflexes, superficial and deep, except, perhaps, the plantar have disappeared. There is pain, there are no muscular spasms, there is vasomotor paralysis with sweating of the paralyzed parts, and the symptoms persist and do not vary (J. J. Thomas, in "Boston City Hospital Med. and Surg. Reports"). There is usually tympanites (Walton). If this latter symptom-group is due to shock, it will usually be temporary, but occasionally, even when so caused, it persists some considerable time. It is also probable that concussion of the cord may in some cases simulate complete

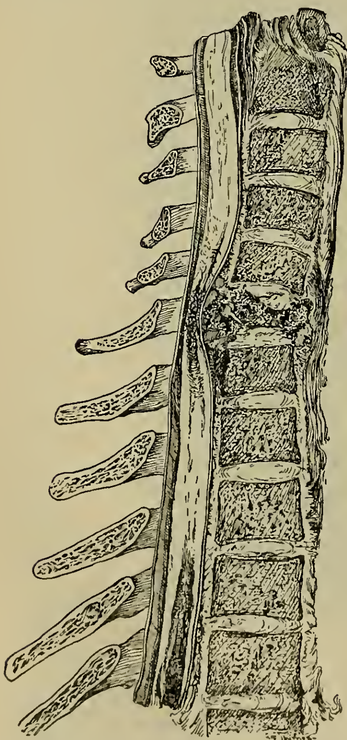

Fig. 545.—Fracture of the cervical spine, cord compressed by bone and blood. Hemorrhage into the cord at the seat of the lesion and below the lesion (Warren Museum). (From Scudder's "Treatment of Fractures." Drawn by Byrnes.)

Fig. 546.—Spine sawed. Fracture of the spinous processes of the seventh cervical and first and second dorsal vertebræ. Fracture of the bodies of the fifth, sixth, and seventh cervical vertebræ with displacement *backward* of the upper fragment. Total crush of the cord. The section passes a little to one side of the cord, which is seen in place, and the staining of the cord by hemorrhage into its substance shows plainly through the membranes even in photograph. The spinous processes of the second and third dorsal vertebræ were found fractured at the operation, and were removed (Thomas).

division. As Walton says, no symptoms *prove* a hopeless crush of the cord: it is the persistence of the symptoms which does prove it ("Jour. Nervous and Mental Diseases," Jan., 1902); I would add, the *unchanging persistence* of the symptoms proves it.

A. J. McCosh ("Jour. Amer. Med. Assoc.," Aug. 31 and Sept. 7, 1901) points out that definite pressure is indicated by marked symptoms and absence of reflexes. When there is not definite pressure the symptoms are irregular; there is incomplete palsy, or muscles of the same group show different degrees of paralysis; anesthesia is partial; signs of irritation are not distinct, and there are patches of hyperesthesia and zones of paresthesia. If in doubt at the end of twelve hours, perform an exploratory operation.

Fig. 547.—Fracture of the odontoid process of the second vertebra and dislocation between the first and second vertebra a number of years after injury. (From *X*-ray Dep't. of Jefferson Hospital.)

The **prognosis** depends on the amount of damage done to the cord. Fracture-dislocations in the cervical region produce obvious deformity, stiffness of the neck and irregularity of the spines, and a displaced vertebra may occasionally be detected by a finger in the pharynx. Crepitus can rarely be detected unless a spinous process is fractured. The Röntgen rays aid diagnosis immensely. The seat of cord injury may be determined by a study of the palsy and other symptoms.

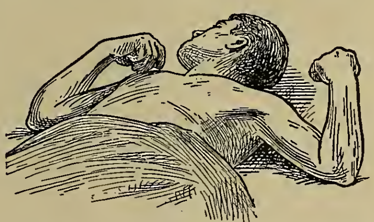

Fig. 548.—Lesion of spine between fifth and sixth cervical vertebræ. Note position of arms, due to paralysis of subscapularis. Brachialis anticus, supinator longus, and deltoid muscles intact. Elbow flexed, shoulders abducted and rotated outward (after Thorburn).

Fracture-dislocation of the atlas or axis usually causes instant death. When the displacement is only trivial, the patient may actually recover, but will probably die of secondary cord disease. Dr. N. J. Blackwood of the U. S. Navy records a case of fracture of the atlas and axis and forward dislocation of the occiput on the spinal column, life having been maintained for thirty-four hours and forty minutes by artificial respiration, during which time laminectomy was performed on the third cervical vertebra ("Annals of Surgery," May, 1908). Lofton has recorded a case of recovery after dislocation of the anterior arch of the atlas on to the odontoid process ("New York Med. Jour.," April 18, 1908). Fig. 547 exhibits a case which recovered after fracture of the odontoid and dislocation between the first and second vertebræ. In

injury of the third cervical vertebra the phrenic nerve is involved, the diaphragm is paralyzed, and death soon occurs. In fracture-dislocation of the fifth cervical vertebra the subscapularis muscles are paralyzed, but the biceps, brachialis anticus, supinator longus, and deltoid muscles escape, and the patient assumes a characteristic attitude (Fig. 548). In Jones's case of fracture of the fifth cervical vertebra no operation was performed, but the patient partly recovered and became able to walk, but with a spastic gait ("Lancet," Nov. 28, 1903). If the sixth cervical vertebra is dislocated there is palsy of the muscles of the hand. In injuries below the sixth cervical vertebra no muscle of the arm, forearm, or hand is paralyzed at first, although after some days paralysis may develop. Damage to the cord above the sixth cervical vertebra produces anesthesia of the body below the injury and of the entire upper extremity except the shoulder. In injury just above the upper level of the seventh cervical there are body anesthesia and anesthesia of the outer surfaces of the arms and ulnar margins of the forearms and hands. In any cervical injury there are body anesthesia and diaphragmatic respiration, and in cases without paralysis of the arms there is sure to be pain. Injuries of the dorsal spine can be accurately located. There is paralysis of motion and sensation up to, or almost up to, the seat of injury. The arms are not paralyzed. Very great pain in the legs occurs if the lumbar enlargement is involved. In injury of the twelfth dorsal or upper lumbar vertebræ there are paralysis of the bladder and rectum, incomplete anesthesia, and partial motor paralysis of the limbs.

Treatment of Fracture-dislocations.—When dislocation of the body of the vertebra obviously exists the surgeon may attempt reduction by extension and rotation. The maneuver is very dangerous in the cervical region, and, as deaths have happened, some eminent surgeons advise against reduction when the injury affects that region. Walton's plan for a unilateral cervical dislocation is as follows: Give the patient ether and hold him erect and sitting on a chair. The surgeon stands behind the patient and holds the head with both hands. The first motion is a slight degree of rotation to carry the dislocated process forward and "unlock" it. The head is then rocked toward the sound side and somewhat backward and finally the process is replaced by rotation. No force is used (Clopton, in "Interstate Med. Jour.," Jan., 1908. Quoted in "General Surgery," by John B. Murphy, 1909). After reducing a fracture-dislocation of the cervical region, place the patient in bed, elevate the head of the bed a few inches, and immobilize the neck and head. In fracture-dislocation of the dorsal or lumbar region the traditional plan is to straighten the spine, gently if possible, and to put the patient upon his back upon a water-bed or upon air-cushions. Empty the bladder every six hours with a soft catheter, which is kept strictly aseptic. Take every precaution to prevent bed-sores. Some surgeons advocate reduction of the deformity by extension and counterextension, and the application of a firmly fitting but removable jacket with the suspension collar (as used in Pott's disease). If this plan is employed, the head of the bed is raised and the collar is fastened to it. Every day extension is made gently—from the shoulders in dorsolumbar fracture and from the chin and occiput in cervical fractures. Extension may be maintained permanently until cure. Surgeons have come rather slowly to a belief in laminectomy. One deterrent factor has been the high mortality: Lloyd collected the records of 159 operations and found that 59 patients died almost at once and 39 died later. In Lloyd's collection of 185 cases there were but 24 recoveries and 40 improvements. In 82 immediate operations only 5 recovered. In 103 late operations there were 19 recoveries (John B. Murphy, in "Surg., Gynecol., and Obstet.," April, 1907). Some employ purely expectant treatment in vertebral fractures. My own

feeling is that when simply a spinous process or some other part is fractured, and there are no cord symptoms, we may treat the patient expectantly, following Burrell's advice, and fixing the patient in bed on a Bradford frame and having him carefully nursed and watched. Reduction by extension and counterextension is dangerous and unjustifiable if there is marked kyphosis and if cord symptoms exist. I agree with Burrell that it should only be done if operation is refused, or if there are no cord symptoms and no marked kyphosis ("Annals of Surgery," Oct., 1905). If it is attempted it must be done slowly and as gently as possible because it may cause grave or even irreparable damage to the cord. I fear to delay, and, with Burrell, Lloyd, Walton, and others, operate when the patient recovers from shock, if there seems to be even a gleam of hope that operation may help him. To wait when pressure exists means that during every hour of delay the pressure is damaging the cord. Another reason for operating is that we cannot know the condition of the cord without direct inspection. The operation to be performed is laminectomy. As before stated, this is to be done even if we suspect division or hopeless crush of the cord. In some cases, it is true, we may commit the error of operating when there is only concussion, but such a mistake is less grave than to fail to operate when there is bone-pressure or hemorrhage. An objection filed by the neurologist against laminectomy is that portions of cord above and below the level of the fracture may be damaged (see Fig. 545), but, as Lloyd says, this fact does not forbid operation, but renders it necessary to make a wider exploration than has been the custom. In many cases after prompt laminectomy we get some considerable improvement, and this improvement may be sufficient to enable a man to earn a living. It is true that statistics would indicate that late operations have been more successful than early ones, but these figures must be analyzed in the light of the knowledge that many of the fatalities after early operation would have occurred if no operation had been done, and some improvements after late operation would have occurred to as great or a greater degree after early operation. The prognosis of any operation, early or late, is never gratifying, and Thorburn feels no confidence in obtaining improvement except in injuries of the laminæ, hemorrhage, or injuries of the cauda equina, as he says laminectomy in the cervical region is followed by death, and laminectomy in the dorsal region, though not commonly fatal, is seldom followed by recovery of function. Our statistics of early laminectomy will show fewer deaths and fewer useless operations if we do not operate till shock abates. As Lloyd ("Phila. Med. Jour.," Feb. 5, 1902) says: "It is therefore evident that if we operate immediately after the injury we will have failures that should not be charged against the operation itself, and, if possible, we should wait before operating until the question can be settled whether the patient will overcome the shock or will succumb directly to the effects of the injury." All surgeons operate for compound fracture, for hemorrhage, and for cases with marked bone pressure. If early operation were not performed and if pachymeningitis arises, operation is called for.

My own convictions are that if symptoms are significant we should explore as soon as shock has passed away, even if we think it probable that the cord has been divided; and if it is found divided, it should be sutured. If in any case we are in doubt twelve hours after the injury as to whether or not pressure exists, we should explore. If soon after the accident we think pressure by bone exists, we should operate. If the case is improving, we should not operate even if there are pressure signs, unless there is a chance that pressure is due to bone, in which case we should operate. As McCosh says, pressure by blood or inflammatory exudate may pass away; pressure by bone cannot. Even long after an injury laminectomy may be productive of some benefit.

The rather radical views set forth above regarding the advisability of

operating even if the symptoms point to complete division of the cord arose largely from a knowledge of the well-known case operated upon by Stewart for total division of the cord. In a case of gunshot-wound of the dorsal spine treated at the Pennsylvania Hospital by Francis T. Stewart, and reported by Francis T. Stewart and Richard H. Harte ("Phila. Med. Jour.," June 7, 1902), an exploratory incision made three hours after injury showed that the spinal cord was completely divided. There was a fracture of the laminæ of the seventh dorsal vertebra. The spines and laminæ of the seventh and eighth dorsal vertebræ were removed. The bullet-hole was recognizable in the membranes, and the bullet and some bone-fragments were removed. When the dura was opened, the ends of the completely divided dorsal cord were found to be $\frac{3}{4}$ inch apart. Stewart freshened these ends and brought them together with two sutures of chromicized catgut. In this case a considerable degree of restoration of function took place. At the time of the operation, three hours after the injury, there were complete paralysis and absence of reflexes below the seat of injury; but sixteen months later the patient was able voluntarily to flex the toes, flex and extend the legs, flex and extend the thighs, and, while sitting, lift an extended leg from the floor. The movements of the lower extremity became more forcible when reinforced by contracting the muscles of the upper extremity while making them. The patient could stand with one hand resting on the back of a chair, and could get herself from her bed to her chair by sliding. The bowels were under perfect control, and there was no incontinence of urine when she was awake, although there was occasionally some when she was asleep. There were occasional cramp-like pains in the lower limbs. The sense of touch, temperature, pain, and position were perfect all over the previously paralyzed parts. Below the knee the localization of sensation was not so accurate. There was a slight amount of muscular rigidity; and on each side, an ankle and patella clonus, which was easily exhausted. When the sole of the foot was tickled, the big toe flexed, the thigh abducted, and there was slight contraction of the anterior tibial, the hamstring, and the tensor vaginæ femoris muscles. There were no reactions of degeneration and no trophic changes. There had never been any bed-sores. George Ryerson Fowler ("Annals of Surgery," Oct., 1905) operated on a gunshot-wound of the dorsal spine eleven days after the injury. He removed the laminæ of the tenth, eleventh, and twelfth dorsal vertebræ and found the cord divided, the bullet lying between the severed ends. A piece of dura $\frac{1}{8}$ inch wide was intact. The bullet and blood-clot were removed. The cord was sutured by three sutures of chromicized gut, which included the dura, and more sutures were taken through the dura only. The ends of the cord were easily approximated. The patient recovered from the operation. Twenty-six months later voluntary motion was found to be practically lost in the area below the injury, although when supported by the hands he could stand and when in a frame could move a little by a swinging movement. He is able to tell when his bowels or bladder are about to move, and, if furnished promptly with a utensil, does not soil himself. When asleep, he passes urine involuntarily. Both legs exhibit spastic rigidity, but there are no reactions of degeneration. Patella reflex on each side exaggerated. Ankle clonus is found on one side, but not on other. There is complete anesthesia of the affected area, except in a region 5 inches in length on the outer side of the right thigh. Touch is appreciated, but not correctly localized. In connection with the foregoing important cases we would note that Dr. Estes, of Bethlehem, has also operated upon a case of complete division of the spinal cord, in which suturing was apparently followed by some restoration of function.

In the light of these positive reports we must ask ourselves if we have not been wrong in the view that the spinal cord cannot regenerate. If there

is even a chance that we have been wrong, we must reverse our former conservative treatment and follow a radical plan. The 3 cases strongly suggest the possibility of some regeneration, but do not prove it. The cord may have appeared to be completely divided and yet minute undivided bundles may have escaped recognition. Again, as Fowler suggests, there may be a nerve anastomosis through uninjured portion of the dura or between adjacent nerve-trunks which arise above and below the lesion. At my request Dr. Samuel Lloyd, of New York, kindly wrote me a personal communication setting forth his views on this important subject. They are as follows: "The question of the regeneration of the spinal cord after traumatism of the spine deserves careful consideration in all cases that are operated upon. Up to the present time, however, although a number of operators have reported improvement following suture of the spinal cord in these cases, a careful analysis does not substantiate the fact that that improvement is due to an actual regeneration. It is a recognized fact on the part of all who have had experience with the surgery of the spinal cord that in almost every instance a certain amount of improvement is noted during the first few months. This is probably due to the fact that at the time of the injury minute hemorrhages occur into the adjoining segments, and that pressure is also increased in those portions of the cord by the inflammatory exudate and edema. Within a short time after the injury these conditions improve, and there seems to be an improvement in function; but in every case of spinal suture yet reported the amount of improvement may be explained by these facts. In no instance has there been a complete recovery of function, but in every one there has remained more or less permanent disability. This, however, should not discourage attempts at spinal suture, and in every case operated upon the dura should be opened and the condition of the cord examined. In those cases where a complete destruction has occurred and where the extent of it is not over $\frac{3}{4}$ inch, it may be possible to cut out the lacerated portions and coaptate the surfaces by a series of sutures placed in the dura. In all these cases the patient should be put up in a plaster retaining bandage in extreme extension, even the head being thrown back so as to relax as much as possible the tension on the line of suture. The operator should be very sure, however, that there are no undestroyed fibers traversing the lacerated area, for the destruction of these in case regeneration did not occur would increase the amount of paralysis." With the views of Lloyd I am in entire agreement, and now I always follow this plan, bearing in mind that it is often impossible to tell whether the spinal cord is completely divided or seriously damaged without examining it, and it can be examined only by exploratory operation; therefore, if the serious symptoms already indicated exist after shock has passed away, exploratory operation should be performed; if pressure exists, it should be removed; and if the spinal cord is found to be completely divided, it should be sutured. It is well to remember that Abbe's experiments have shown that there may be great difficulty in bringing the divided ends of the cord into apposition. In order to effect this it may be necessary to resect a vertebra.

Operations on the Spine.—Operation for Spina Bifida.—A. W. Mayo Robson[1] maintains that operation is not demanded when the sac is of small size and is well protected by sound integument; that operation is improper when a large portion of the column is fissured, or when paraplegia or hydrocephalus exists; that operation is advisable only in meningocele, in cases in which the integument is thin and translucent, in cases in which the cord is flattened out or the nerves are fused. Robson has closed the osseous defect by transplanting periosteum.

[1] "Annals of Surgery," vol. xxii, No. 1.

Surround the sac by elliptical incisions. Find the neck of the sac, and if it contains no visible nerves, ligate it and cut off the protrusion. Push the stump into the canal. Freshen the bone-margins and spring a piece of celluloid beneath them to close the gap (Park). Suture over the stump with small sutures of catgut.[1]

Treves's Operation for Vertebral Caries.—(See page 695.)

Laminectomy.—The patient lies prone and a sand-pillow is placed under the lower ribs. Make a vertical incision over and down to the vertebral spines, the middle of the incision corresponding to the seat of injury or disease. The sides of the spinous processes and the laminæ are cleared. The periosteum is incised in the angle between the laminæ and spines, and is lifted away from the arches. It is my custom to bore through a lamina on each side of a spinous process by means of Hudson's burrs. When this has been done the spinous process and lamina are easily bitten through and removed. The usual method of operating is as follows: The spinous processes are cut off close to their bases by means of bone-cutting forceps, the laminæ are removed on each side with the same instrument or the rongeur, and the dura is exposed. In some cases of fracture fragments will be found on exposing the vertebra, or a blood-clot will be seen between the dura and the bone; in other cases the dura must be opened by scissors vertically in the middle line while it is grasped by mouse-toothed forceps. After reaching and removing the compressing cause, or after failing to find or remove it, it is best not to close the dura completely, because, if we do so, cord pressure may result from hemorrhage. The dural wound is left open or is partly closed. I used to insert a drain of rubber tissue, but have given it up. Horsley shows that it is not necessary, and if we refrain from draining we lessen the tendency to headache, temporary pyrexia, and rapid pulse, which frequently follow laminectomy. The superficial parts are stitched with silkworm-gut and dressings are applied.

Albee's Method of Bone-grafting for Pott's Disease of the Spine.—In 1891 Hadra, of Galveston, advocated the treatment of Pott's disease of the spine by wiring the spinous processes of the diseased vertebræ to adjacent vertebræ for the purpose of securing fixation. Chipault, in 1895, and Calot, in 1896, did this after forcible correction of angular deformity. Lange buried steel wires on each side of the spine and anchored each one at each end by silver wire (J. T. Rugh, in "Internat. Clinics," Vol. I, Twenty-third Series). The object of these operations was to do away with the necessity for an external supporting jacket or brace. The objection to them was the introduction of a foreign material, and the fact that strain caused that material to cut through the tissues and permit relaxation.

In 1911 both Hibbs and Albee, working independently, reported methods for producing fusion of the arches of the vertebræ.

Hibbs ("New York Med. Jour.," May 27, 1911, and "Annals of Surgery," May, 1912) takes strips of the periosteum from the spines and laminæ, transposes the spinous processes, and sutures the periosteum and the supraspinous ligament over these processes. The periosteum is depended upon to produce new bone, which fuses the parts together. This operation, if successful, lessens kyphosis and produces fusion of spines and laminæ. Albee, doubting the reliability of the periosteum as a bone producer, practises bone-grafting. The patient is placed prone. An incision is made to expose the spines of the diseased vertebræ and also one or two vertebræ above and one or two below. Some make a straight incision. Rugh makes a curved incision at one side of the spine and turns back a flap. Each spine is split vertically by a chisel and each split portion is broken and pushed over to the same side. The interspinous liga-

[1] A full consideration of the various plans of operating will be found in an article by Marcy, in "Annals of Surgery," March, 1895.

ments are cut so as to correspond to the split in the spines. We thus obtain a wedge-shaped incision through bone and ligament.

The length of the cut is measured on a probe. The wound is packed temporarily. The leg is flexed upon the thigh. An incision is made over the anterior surface of the tibia. A wedge-shaped graft of bone is cut by means of a surgical engine, a Gigli saw, or a chisel and mallet. The graft is covered with periosteum on one side and contains some medullary tissue on the other. It is $\frac{1}{3}$ inch thick at its base. This graft is fitted to the unbroken sides of the spinous processes. If the kyphosis is marked, numerous cross-cuts are made with a saw into the thin edge. Thus the graft will be made flexible. No attempt is made to forcibly correct the deformity. Here and there the periosteum is incised to favor the emergence of osteoblasts. The interspinous ligaments are sutured over the graft by sutures of kangaroo tendon. The incision is closed. The patient is put on a Bradford frame or plaster of Paris is applied. The patient remains recumbent for from six to twelve weeks, then he is allowed to sit up and soon after to walk, of course wearing a brace or plaster.

The brace or jacket is removed in five or six months. The results of this operation are excellent. The fate of the bone-graft is a matter of dispute. Some hold that it really lives. Others hold that it is simply a scaffold for new bone. One thing is certain—it strongly stimulates the production of new bone from the raw surfaces of the split spinous processes. New bone comes, and new bone, however formed, constitutes the permanent splint (Albee, in the "Post-Graduate," Nov., 1912, and in "N. Y. Med. Jour.," March 9, 1912; J. Torrance Rugh, in "Monthly Cyclopedia and Medical Bulletin," Feb., 1913, and in "International Clinics," Vol. I, Twenty-third Series).

Puncture of the spinal meninges, or lumbar puncture, was devised by Quincke, and has been carefully tested by many surgeons. It is the operation for withdrawing cerebrospinal fluid from the subarachnoid space of the cord. It is employed as a means of diminishing cerebral pressure in hydrocephalus, cerebral tumor, uremia, and tuberculous meningitis, but in these cases it has proved of little or only of temporary therapeutic value. It may be of some service in cerebrospinal meningitis. The condition of a patient with a fracture of the base of the skull is sometimes temporarily improved by the operation. Pain is often temporarily relieved. In the performance of a brain operation the brain may bulge so that the dura cannot be sutured. Lumbar puncture makes suturing possible. Puncture is the preliminary step of spinal anesthesia. In some cases the examination of the fluid has been of great diagnostic value. The fluid is not only subjected to a naked-eye study, it is also studied microscopically and bacteriologically. If the fluid from the puncture gives no positive finding, the operation should be repeated (Lorgo). When a diagnostic tap is made we must know the appearance, nature, and pressure of the fluid normally.

Normally the fluid is clear, transparent, alkaline, and under a pressure of from 40 to 60 mm. of mercury (Dana) its specific gravity is from 1.006 to 1.008, and from 5 to 10 c.c. will flow out at a tap. It contains a very few endothelial cells and leukocytes. In cases of increased tension it flows out more forcibly, rapidly, and profusely (brain tumor, hydrocephalus, meningitis, and some infectious conditions). When there is meningeal inflammation the specific gravity is increased. In apoplexy and other hemorrhages beneath the cerebral arachnoid, in fracture of the base of the skull, and in hemorrhage beneath the arachnoid of the cord, the fluid contains blood. Laceration of the brain tissue without subarachnoid or ventricular hemorrhage does not make the fluid bloody. The fluid is turbid in purulent meningitis of the cord or brain, may contain many polymorphonuclear leukocytes, and also bacteria. Lumbar puncture is of great diagnostic use in the cerebral hemorrhage of the newborn and in some fractures of the base of the skull.

The *chemical* study of the fluid is sometimes of value.

In intracranial tumor, purulent meningitis, subarachnoid hemorrhage of the brain or cord, and apoplexy albumin is increased. The normal fluid contains a carbohydrate substance resembling glucose. This is absent in meningitis and is increased in saccharine diabetes.

In uremia the chlorids are diminished.

Cytodiagnosis (a microscopical study of the cells of the fluid) may furnish useful information; numerous polymorphonuclear leukocytes are found in meningitis. Lymphocytosis suggests a tuberculous lesion rather than an acute meningeal inflammation. Lymphocytosis occurs also in syphilis of the brain and cord, locomotor ataxia, paresis, and uremia.

Bacteriologic study by cover-glass preparations or cultures may give important information. In over 75 per cent. of cases of tuberculous meningitis of the brain membranes the fluid contains bacilli. Stadelmann has reported 37 cases in which tubercle bacilli were found in the fluid.[1] In tuberculous meningitis the fluid may or may not contain tubercle bacilli. In cerebrospinal meningitis the cerebrospinal fluid contains the meningococcus. In this disease diagnostic puncture is unnecessary if the nasal mucus contains the Diplococcus intracellularis. The operation of lumbar puncture is simple, and if done with proper precautions is harmless. The back should be carefully sterilized and thorough asepsis must be preserved in every detail. The patient may lie on the right side with the left knee well drawn up, may lie prone, with a pillow under the belly, or may sit in a chair, with the body bent forward. The site of the intended puncture may be frozen with ethyl chlorid, but no general anesthetic is required. A Pravaz syringe is employed. The needle, which should be 3 inches in length, is guarded by the surgeon's index-finger and the point is inserted $\frac{1}{2}$ inch to the right of the median line and between the third and fourth lumbar vertebræ. It is pointed upward and a little inward under a spinous process. It enters the canal in the middle line. In a child the needle enters the canal at a depth of from 2 to 3 cm.; in an adult, at a depth of from 4 to 6 cm. The fluid is permitted to fall drop after drop into a sterile test-tube. In some cases only a few drops of fluid can be obtained; in other cases many cubic centimeters may be removed. It is not wise to draw for diagnostic purposes over 5 c.c. from a child and 10 c.c. from an adult. If we evacuate too much cerebrospinal fluid, the ventricles are emptied and compression of the cerebellum may arise. The flow should be spontaneous and suction ought not to be used. Sometimes nausea, vertigo, and severe headache follow the operation, and sudden deaths have been reported. For a number of hours after tapping the patient should remain recumbent.

The Mingazzini-Foerster Operation in Tabes.—Mingazzini suggested intradural division of the posterior sacrolumbar nerve-roots for unbearable pain in the lower extremities due to tabes.

Foerster follows a like method in treating gastric crises. He divides the posterior dorsal roots from the sixth to the ninth. Some of these operations have been notably successful. Others have failed. In at least one case the condition was aggravated (Doerr, in the "Wien. med. Woch.," No. 45, 1911). For the pains and crises of tabes some surgeons advise extradural division of the posterior roots (Gulcke). The posterior roots may be divided for intractable neuralgia and for athetosis. The roots selected depend upon the seat of pain or the region of athetosis.

Intradural Root Anastomosis in Cases of Vesical Paralysis.—Kilvington ("Brit. Med. Jour.," 1907, vol. i) suggested intraspinal anastomosis of nerve-roots. He found by experiments on dogs that the last lumbar root, when joined to the roots of the second and third sacral nerves, gives contraction to a palsied

[1] "Berliner klinische Wochenschrift," July 8, 1895.

bladder. Bird, at the suggestion of Kilvington, did the operation on a human being, but it was a failure. Frazier, in a case of Mills's, anastomosed the root of the last lumbar to the roots of the third and fourth sacral nerves. There was decided improvement (Frazier and Mills, "Jour. Am. Med. Assoc.," Dec. 21, 1912).

Horsley's Operation for Chronic Spinal Meningitis.—Sir Victor Horsley ("Brit. Med. Jour.," Feb. 27, 1909) states that during the past ten years he has operated on a number of cases for what he calls chronic spinal meningitis. Such cases are commonly confused with tumor, are much more frequent than tumors, and are often cured or greatly improved by operation. The first published case of this sort was reported by Spiller, Musser, and Martin ("Univ. of Penna. Med. Bulletin," March, 1903). Martin performed laminectomy, found a "circumscribed meningitis," and cured the patient. In these cases a fluid accumulation is found and this fluid is stagnating and under pressure. The cord passes into a condition of sclerogliosis. The symptoms are pain, advancing loss of power in the legs, perhaps slight kyphosis, and eventually progressive and fatal paraplegia (compression paraplegia).

The pain in these cases involves an extensive area, not as in extramedullary tumor a small area supplied by one or two nerve-roots, and there may be hyperesthesia over an entire extremity, which does not occur in extramedullary tumor (Horsley, Loc. cit.). Horsley has never seen absolute abolition of tactile sense. The operation consists in laminectomy, opening the theca, washing it out with mercurial solution (1 : 500 followed by 1 : 2000), and closing without drainage. Bailey and Elsberg ("Jour. Am. Med. Assoc.," March 9, 1912) suggest the term *spinal decompression* for laminectomy and opening of the dura when no lesion is located or found. They believe that in such cases as Horsley describes the laminectomy and opening of the dura do the good. A number of other intradural conditions may perhaps be benefited by the operation.

XXVI. SURGERY OF THE RESPIRATORY ORGANS

Asphyxia.—In drowning, strangulation, suffocation, and hanging the mode of death is by the same process, that is, by asphyxia or apnea. "Asphyxia," though the commonly used designation, is an unfortunate term, and apnea is the more correct one. By asphyxia we mean the non-oxygenation or the incomplete oxygenation of the blood, and yet even in this condition death is not immediate, for the heart may continue to beat for some little time after all breathing has ceased. A man may be apparently dead from asphyxia and yet be capable of resuscitation. In general, it may be said that asphyxia produces lividity, a struggle like a convulsion to obtain breath, and finally, in many cases, genuine convulsions. In the very beginning of non-oxygenation the senses may be remarkably acute, but consciousness is soon lost. The veins stand out and the pulse becomes weaker and weaker. The individual may bleed from the nose, from the rectum and other mucous membranes, and there may be involuntary passage of urine. For a short time the chest heaves, making respiratory attempts, and after a short time the heart stops beating.

Asphyxia is a common mode of death. It is the mode of death occasioned by a foreign substance in the air-passages, by paralysis or by tetanic fixation of the respiratory muscles, by great pressure upon the chest or abdomen, by acute traumatic pneumothorax, by a clot in the pulmonary artery which cuts off the blood-supply of the lungs, by hanging, throttling, drowning, absence of sufficient oxygen from the gases breathed, presence of quantities of irrespirable gases (CO, CO_2), or the presence of irritant gases (Cl, SO_2) which cause spasm of the glottis.

The terms *smothering*, *stifling*, and *suffocation* mean prevention of entry of air into the lungs in sufficient quantity to properly aërate the blood.

Treatment in General.—Of course, each form requires some particular method of care. In general, it may be said that the surgeon should at once endeavor to determine the cause of the asphyxia and should particularly ascertain if it came on gradually or suddenly. As a rule, a gradual asphyxia is due to some intrathoracic lesion. If the asphyxia were sudden the surgeon must examine the neck and chest externally to see if there is any sign of injury. Then the mouth is opened, the tongue pulled forward, and the glottis felt by the finger to see that no foreign material is blocking the air-passages. The patient will do best in a free draft of fresh air, and it may be possible to excite respiratory activity by dashing hot water and then cold water on the face and chest and making a number of these alternate applications. The application of electricity to the phrenic nerve may do good (the anode at the root of the neck and the cathode over the epigastric region). If there is cardiac dilatation, bleeding is urgently indicated. When the patient is breathing, inhalations of oxygen do good. If there is laryngeal obstruction, tracheotomy or intubation should be done. In most cases of threatened asphyxiation artificial respiration is necessary. There are several different methods.

Artificial respiration is resorted to in case of suspension of breathing from any cause; among the more frequent causes are the inhalation of smoke or poisonous gases, drowning, profound anesthesia, opium-poisoning, and electric shock.

There are several methods of giving artificial respiration. One method may have an advantage over another in a certain type of case, as will hereafter be described.

Before resorting to any method the clothing about the neck, chest, and abdomen must be free and loose; the mouth unobstructed by foreign bodies, as false teeth, etc., the throat clear of mucus, etc.

If edema of the glottis, malignancy of the tongue, or an immovable foreign body should obstruct the air-passages, tracheotomy should be performed before attempting artificial respiration.

When giving artificial respiration the operator should not desist because respirations are not established in a few minutes, but, on the contrary, should persist (even using relays of men if necessary) for an hour or more. Many cases of drowning, opium-poisoning, asphyxia from smoke, etc., have been resuscitated after an almost incredible period of time, during which time artificial respiration was carried on.

During the manipulations of artificial respiration it should be remembered that the patient must be cared for as in shock: the body kept warm, frictions applied by the hands or rough towels, and massage over the heart be practised. Enemas of coffee by rectum and stimulating hypodermatic injections are important. The author prefers an enema of 5 oz. of hot coffee with 1 oz. of brandy and a hypodermatic injection of atropin sulph., gr. $\frac{1}{100}$, or strychnin, gr. $\frac{1}{20}$. One of the oldest methods of artificial respiration and the one most applicable in children is *mouth-to-mouth inflation*. In this method the operator holds the victim's tongue forward with a suture or with a piece of string tied around the tongue; with the other hand he closes the nostrils, and then, after taking a deep inspiration, blows directly into the patient's mouth. The air is then expelled from the patient's lungs by direct pressure on the walls of the thorax. This procedure is repeated 16 times a minute. Instead of the direct mouth-to-mouth inflation a soft-rubber catheter may be passed through the mouth into the trachea and the patient's lungs be expanded by the operator blowing through the catheter.

Artificial respiration must not be stopped when the patient has taken one or

two breaths, but should be continued until the respiratory movements are regular and normal. The patient must be carefully watched for fear of secondary apnea.

Sylvester's method is a popular one, and is probably the best in many cases in severe electric shock, but if there is any fluid in the lungs or air-passages (as in cases of drowning) another method may be preferred.

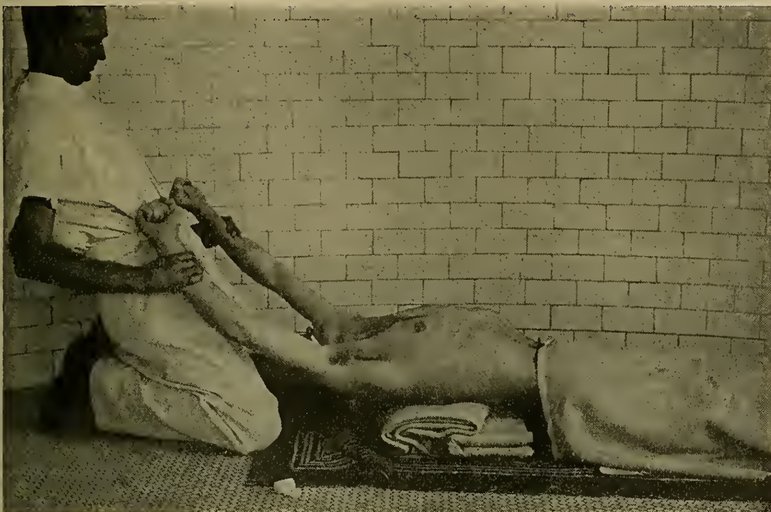

Fig. 549.—Sylvester's method. Inspiration.

To make artificial respiration by this method the patient is placed on his back with a folded coat or blanket under his shoulders. The tongue is pulled forward and held by forceps, a suture, or, in an emergency, may be tied with a

Fig. 550.—Sylvester's method. Expiration.

string, or even a necktie can be used. The operator, kneeling at the head of the patient, grasps the forearms just below the elbows and circumducts the arms outward and upward, meanwhile making traction until the arms are perpendicular to the body (Fig. 549). By this movement the chest is expanded and in-

spiration is caused. The arms are now brought slowly to the sides of the chest and firm pressure is made for two or three seconds, thus forcing the air from the lungs and causing expiration (Fig. 550). This procedure should be repeated about 15 or 16 times a minute.

This method is best suited to those overcome by gas, smoke, or apnea other than that due to drowning.

Howard's Method.—This method is now used by the United States Life Saving service in cases of drowning. The procedure as laid down by Dr. Howard is as follows:

"Rule 1: To expel water from the stomach and lungs, strip the patient to the waist, and, if the jaws are clinched, separate them and keep them apart by placing between the teeth a cork or a small piece of wood. Place the patient face downward, the pit of the stomach being raised above the level of the mouth by a roll of clothing placed beneath it. Throw your weight forcibly two or three times upon the patient's back over the roll of clothing so as to press all fluids in the stomach out of the mouth."

Fig. 551.—Howard's method of artificial respiration.

"Rule 2: To perform artificial respiration quickly turn the patient upon his back, placing the roll of clothing beneath it so as to make the breast bone the highest point of the body. Kneel beside or astride of the patient's hips. Grasp the front part of the chest on either side of the pit of the stomach, resting the fingers along the spaces between the short ribs (Fig. 551). Brace your elbows against your sides, and steadily grasping and pressing forward and upward, throw your whole weight upon the chest, gradually increasing the pressure while you count 'one, two, three.' Then suddenly let go with a final push, which springs you back to your first position. Rest erect upon your knees while you count 'one, two'; then make pressure as before, repeating the entire motions at first about 4 or 5 times a minute, gradually increasing them to about 10 or 12 times. Use the same regularity as in blowing bellows and as seen in natural breathing, which you are imitating. If another person is present let him, with one hand, by means of a dry piece of gauze, hold the tip of the tongue out of one corner of the mouth, and with the other hand grasp both wrists and pin them to the ground above the patient's head."

Schäfer's Method or the Prone Method.—In this method, instead of lying on his back as in the Howard method, the patient lies on his stomach, his face being turned to one side. The arms are placed above the head. A roll of

blankets or clothing are placed under the chest. The operator now kneels astride of the patient and grasps the thorax with both hands, the fingers running parallel with the ribs. Brace your elbows against your sides and press firmly inward and upward, throwing your whole weight against the chest. Release your pressure after two or three seconds, count "one, two," and again make pressure as before. This sequence should be repeated about 15 times a minute.

The advantage of this method is that fluid in the air-passages will gravitate out through the mouth and the tongue falls forward without being held.

Marshall Hall's method is more easily applied on the operating table than any other method of artificial respiration. On the other hand, it is not as efficient and is only justifiable when the patient's normal respirations are resumed after three or four applications of pressure. The patient lies on his back, and the operator, with a hand on either side of the thorax near the costal region, makes pressure upward and inward. This pressure is continued for two or three seconds, then suspended for the same length of time, and then pressure again made. This procedure is repeated about 15 times a minute.

Laborde's method is not as efficacious as the foregoing, but has its uses in cases in which, because of injury to the chest, shoulders, or arms, Sylvester's or Schäfer's method or their modifications cannot be employed.

Laborde's method rests on the assumption that "systematic and rhythmic traction" upon the tongue produces respiratory reflexes and causes contractions of the diaphragm, hence establishing respirations.

The tongue is grasped by tongue-forceps or a piece of gauze held between the forefinger and thumb, and is pulled well out of the mouth with considerable traction. It is held for two or three seconds and then relaxed. This procedure is repeated about 15 times a minute.

When a certain amount of resistance is felt, it is a sign that respiratory function is being restored. Noisy respiration first occurs, termed inspiratory hiccup.

When the condition of the chest will allow, that is, if there are no fractured ribs, empyema, etc., Laborde's method and Marshall Hall's method may be combined.

It can be readily realized that Laborde's method cannot be used when there is disease or injury of the tongue.

Intratracheal Insufflation.—This consists in forcing air by external pressure through a tube which passes through the mouth and larynx into the trachea. The air, under the influence of the same force which drove it in, emerges between the tube and tracheal wall. "The air-stream has to be interrupted several times a minute for only about two seconds at a time" (S. J. Meltzer, in "Keen's Surgery," vol. vi). (See Insufflation Anesthesia, p. 1199.)

Artificial Respiration by the Pulmotor.—The pulmotor is a most ingenious apparatus. It is for two purposes: (1) To give artificial respiration; (2) to administer oxygen.

Both the administration of oxygen and the production of artificial respiration are accomplished by means of oxygen which is under pressure. This fact makes the instrument especially valuable in cases of asphyxiation from illuminating gas or other poisonous vapors. The apparatus should be a part of the equipment of every modern hospital (for work on the ambulance, in the accident ward, and in the operating room), every gas and electric company, every mine, should be accessible at resorts where bathers congregate in any large number, and should be on the ground at every city fire.

The apparatus is contained in a narrow wooden case which can be carried by one person. The weight of the case with the apparatus is less than 50

pounds. A diagram of the apparatus (Fig. 552) is here given which shows its mechanism: C is a cylinder containing $11\frac{1}{2}$ cubic feet of oxygen, which will keep the apparatus in operation and create artificial respiration for forty minutes; V is a valve which opens and closes the oxygen tank and which is the sole governor of the apparatus.

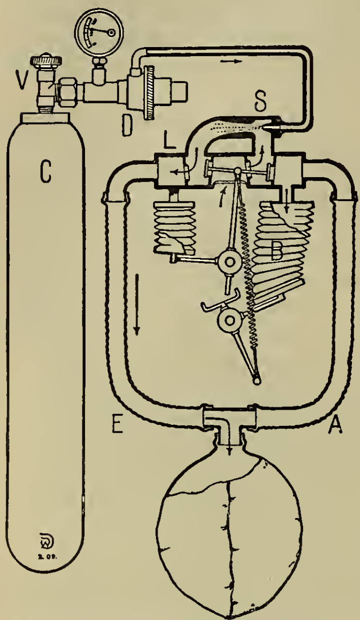

Fig. 552.—Diagrammatic illustration showing the action of the pulmotor. (See text for explanation of letters.)

The mask is fitted on the patient's head as in Fig. 553. The oxygen is then turned on by the valve V. The oxygen passes through the reducing valve D to the injector S, which has the property of drawing in a large volume of air with a certain force of suction, and propelling that air forward with equal force through the flexible tube in front of the injector. This suction and delivery injector therefore serves as a motor, automatically filling the lungs by pressure and emptying them by suction. The suction is accomplished by the leather accordion bellows B, which effects without cessation the automatic reversal of the apparatus from suction to delivery and vice versâ. During inflation the same pressure obtains in the bellows as in the lungs, but as soon as the latter are filled the bellows becomes inflated, and in moving forward throws over the valve in the reversing chamber L, which becomes reversed into position for suction. This operation is now reversed, and as soon as the lungs have been emptied the bellows contracts and automatically reverses the valve into position for inflation.

Fig. 553.—Application of mask of pulmotor, the tongue being held forward by forceps, and oxygen prevented from entering esophagus by pressure with right hand.

The apparatus adapts itself to any pulmonary capacity. The rhythm will be slow when the lungs are capacious and faster when they are of less capacity.

It causes all the movements of respiration without any assistance being required from the hands other than to keep the windpipe of the patient open and the gullet closed in order that air will not be forced into the stomach. This latter maneuver is accomplished by placing the hand on the windpipe, as in Fig. 553, and making pressure sufficient to close the esophagus. The tongue must, of course, be held forward, as in Fig. 553.

The apparatus is devised so that no residual air from the system can find its way into the lungs again. In this way no air contaminated with poisonous or asphyxiating gas is breathed.

After respiration has been established, the lever, which is seen in Fig. 552, is thrown from pulmotor to inhalation, and oxygen is then given as shown in Fig. 554.

In addition to this regular sized pulmotor, there is an infant pulmotor which is especially adapted for use in maternity hospitals and by obstetricians. Both

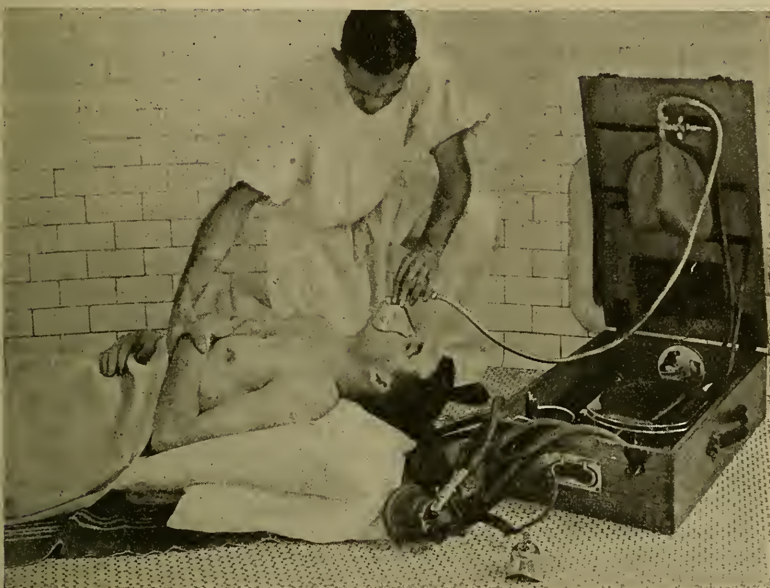

Fig. 554.—Administration of oxygen after respirations have been established.

the adult and the infant apparatus have a lever with which the operator can regulate expiration and inspiration at will, instead of using the automatic bellows.

If the mask fits, the pulmotor works admirably. If it does not fit, it fails. The mask fits some faces and not others. The great need of the instrument is a certainly adjustable mask.

Drowning is asphyxia brought about by having the mouth and nose submerged in fluid, air being thus excluded from the lungs. It is not only water that may be responsible for drowning. An individual may be drowned in mud or in a cesspool.

Phenomena of Drowning.—As asphyxia begins the victim struggles frightfully and clutches at anything that seems to be within reach. He usually sinks and rises an uncertain number of times. The old rule of three times has no particular force. It may be that the victim sinks and rises oftener, it may be that he does so less frequently. He may not rise at all. During this awful struggle air and water are inhaled, and, as a rule, some of the water is cast

out by vomiting and violent cough. During drowning water is certain to be drawn into the bronchial tubes and air-cells. While this struggle is going on the blood becomes less and less oxygenated, exhaustion deepens; finally the patient sinks to rise no more, some air is forced from the lungs causing bubbles on the surface of the stream, the ears ring, the muscles are convulsed, the mind wanders, merciful insensibility arrives, and death follows. During the mental wandering the memory may take clear and extensive or irregular and incoherent journeys through the events of years or a lifetime, but this does not always happen.

The duration of the death struggle is uncertain: it may be very brief, it may last a considerable time. The weaker a person is, the sooner it is over. It is probable that death occurs in two minutes after the final sinking. In spite of some specially trained divers being able to remain in water as long or even longer than this, "we may conclude, from all data, that fatal asphyxia is probable at the end of two full minutes' submersion of the head" (Draper's "Legal Medicine").

Treatment.—Because it is probable that a person is dead after two minutes' continuous immersion is not a sufficient reason for refusing to attempt resuscitation when it is alleged that the body has been immersed for longer than that period.

As Draper says, "the evidence as to time may be incorrect, and there are probably exceptional people who would not drown in two minutes. Resuscitation has been successful after five minutes and 1 case is recorded of recovery after twenty-five minutes" (Draper's "Legal Medicine"). The *ordinary emergency treatment* should be conducted out of doors. The mouth is emptied by turning the body on the face, with the head on a lower level than the body, and holding it so for a few seconds. While this is being done the mouth is opened and the tongue is drawn out. The body is turned upon the back, the head and shoulders being slightly elevated. The clothing is rapidly removed, and, while artificial respiration is being made (see page 866), hot bottles and hot blankets are being placed around the body and legs, and the mouth and nostrils are kept free of froth. If the individual makes an effort to breathe, help each respiration along. Give hypodermatic injections of brandy and strychnin.

Artificial respiration is continued until the patient breathes naturally and all cyanosis has passed away. As soon as he can swallow he should be given hot coffee and brandy. If minute follows minute and the patient does not attempt to breathe, we must still continue our efforts. Artificial respiration should not be abandoned for a full hour. Even after he begins to breathe he must be carefully watched for some time, as secondary respiratory failure is not uncommon.

On a battleship and upon the beach of a large seaside resort, where every preparation has been made to treat such accidents, more can be done than is described above. Artificial respiration can be made by the pulmotor or by the insufflation apparatus of Meltzer and Auer (see page 867). Adrenalin may be injected centripetally, as advised by Crile (see page 468). Hot enemata may be given and galvanism may be applied to the phrenic nerve.

After resuscitation there is danger of exhaustion and of bronchopneumonia.

Hanging.—A physician is occasionally called to a case of attempted suicide by hanging. In these cases there is no fracture and no dislocation of cervical vertebræ, as may occur in legal execution by the drop. The victim is dead or almost dead because of obstruction to the pulmonary air-way, the pressure upon the great vessels of the neck, and perhaps also upon the pneumogastric nerves.

Treatment.—The subject, after being cut down, is treated much like a case of drowning. Resuscitation is always difficult, no matter how soon the victim is cut down. It is impossible if asphyxiation is far advanced.

The neck and chest are bared, cold water may be applied to the head or face, as it sometimes will incite respiration. Artificial respiration is begun at once, external heat is applied, a hot enema containing brandy and hypodermatic injections of brandy are given. When there is distinct lividity, bleed from a vein of the leg (to do so from a vein of the arm might interfere with artificial respiration). Galvanism of the phrenic nerve is advisable. Even when breathing begins there is for some time the gravest danger of relapse and death.

Throttling.—When the assailant grasps the opponent's throat with the hands and squeezes the wind-pipe or larynx and forces it against the vertebræ the victim is said to be throttled. The ordinary fighter makes the attack from in front. The garroter seizes the throat from behind. Death from throttling is death from asphyxia plus an influence from the pressure upon the great vessels.

Treatment.—As for hanging.

Smoke Asphyxia.[1]—One of the first duties required of an intern in a hospital of a large city is ambulance service, and in performing such duty he is not infrequently called upon to attend fires. In fact, any physician may be called upon in such an emergency, and while on the fire ground may meet cases of asphyxiation by smoke. The clinical aspect and the treatment of such cases is not taught in the classroom. Literature on the subject is scanty. It is for these reasons that the author has deemed it expedient to insert a few words regarding it.

There are several factors which govern the character of smoke cases. In the first place, there are many different kinds of smoke. All smoke is hard to bear, but some kinds are worse than others. Some smoke is merely irrespirable, while other smoke is not only irrespirable, but is highly poisonous. Smoke from lumber, varnish, furniture, paper, rags, and wet hay is difficult to tolerate, whereas smoke from pitch, tar, and oils is not so pungent. Smoke impregnated with the fumes of ammonia, sulphur dioxid, chlorin, or pepper and other spices is frightfully irritant. Smoke containing nitric acid is highly irritant, and is apt to produce edema of the glottis and lungs. The hotter the smoke, the more irrespirable it is.

Again, the individual idiosyncrasy or susceptibility of the person plays an important part. It is remarkable how firemen can accustom themselves to remaining in a smoke-ladened atmosphere. The older members of a fire department can tolerate smoke much longer than those recently appointed. Firemen learn that the best air is near the floor or near the nozzle of the hose. There is a current of air along the floor, as the smoke naturally tends to rise, and the water carries through the hose a certain amount of air.

For clinical purposes, smoke asphyxia may be divided into three stages: the first stage is that in which the victim is conscious; the second is when consciousness is lost, but respirations are still present; the third stage, when respirations have ceased.

The first symptoms which occur are a choking sensation, severe throbbing in the head, dizziness, nausea, and muscular weakness. If at this time one is able to reach a window or able to leave the building and get fresh air he will probably recover quickly. His eyes are red and watery. He coughs and tries to vomit, and although his face may be hot and sweaty, yet his hands will be cold and clammy. His pulse is slow but bounding. Headache is intense and the eyes burn violently.

A patient in this condition should be rapidly removed to a spot where the air is free from smoke. He should be laid on a blanket. All constricting clothing should be loosened and he ought to be fanned. If he gags or attempts to vomit, but cannot do so, he may be given a drink of an effervescing salt, such

[1] The author, in "Therapeutic Gazette," March, 1903.

Fig. 557.—Fire carry. Step three.

as a Seidlitz powder or a dessertspoonful of effervescent sodium phosphate in a tumbler of water. Firemen have great faith in weiss beer. It usually makes them belch and vomit and thus relieves them of much of the mucus and the

gases in their lungs and in their stomach. In this manner it acts as does an emetic dose of ipecac in the first stage of bronchitis. A drink which is often given, but which is most injurious, is whisky. The fireman who is a whisky drinker stands smoke poorly, and to take whisky after having been overcome with smoke only adds to the headache and nausea. Usually after vomiting has been induced and after he has had fresh air the fireman is able to return again to his work. If he does not rapidly recuperate or should he be overcome a second time, he should not be allowed to return to the smoky atmosphere. If a man who has been overcome by smoke has a chill he must be sent to a hospital. His usefulness is at an end for that fire. When a man becomes unconscious his comrades carry him to the street. Pictures of a very quick and satisfactory fire carry are given in Figs. 555–557. It is unusual for a man to leave a smoky building conscious and to lose consciousness after reaching the fresh air unless the smoke was impregnated with illuminating gas, which condition is discussed on page 874.

When an unconscious man is carried from a smoky building he must be taken to a spot where the air is free from smoke, his clothing must be loosened, and his body kept warm with blankets. His hands and face should be rubbed with a coarse towel, and oxygen (which should be carried on all ambulances and on all patrol wagons) should be administered. If the circulation or respiration is weak, he should be given a hypodermatic injection of strychnin or atropin, and when he is able to swallow he can be given a stimulant by mouth (as Hoffmann's anodyne or aromatic spirits of ammonia), or if he is trying to vomit he may be given weiss beer, effervescent sodium phosphate, or Seidlitz powder. He should not be given anything by mouth until he is entirely conscious and able to swallow. I mention this emphatically because I have often seen attempts made to pour whisky or some other stimulant down the throat of an unconscious fireman. The danger of such a procedure is obvious. As soon as practical he should be removed to the nearest hospital. The man should be taken to the *nearest* hospital unless the receiving ward of that hospital is overcrowded. He should then be taken to the next nearest hospital.

The third stage of asphyxiation by smoke is that in which respirations have been suspended. The lips are cyanotic, the skin is cold and clammy, the pupils are fixed, and usually dilated. The conjunctival reflex may be gone. The mouth may be open or, on the other hand, the teeth may be tightly clenched. The pulse is weak and fluttering, even imperceptible. There is frequently bleeding from the nose and mouth and involuntray evacuations of urine and feces may occur. A man in this state should never be placed in an ambulance to be taken to the hospital until respirations have been re-established. I have seen stupid and assertive policemen on many occasions insist on putting such cases in ambulances. He should be quickly laid on his back, all mucus cleared from his throat and mouth, all constricting clothing loosened, torn, or cut away. Artificial respiration is started at once. The pulmotor described on page 867 is most useful under such circumstances. If Sylvester's method is used, oxygen may be administered with a tube through the nostrils. The body must be covered with blankets and the man must be stimulated with strychnin, atropin, camphor, etc. When respirations have been established he may then be removed to the nearest hospital. As a rule, the man should be kept in a hospital at least twelve to twenty-four hours and may then be allowed to go home if there is no complication or sequel. In severe smoke cases there is a tympanitic percussion note extending well above each collar-bone and due, I believe, to blocking of bronchial tubes by spasm. It lasts often for several hours and then fades away.

In cases of edema of the glottis from the inhalation of irritant vapor, tracheotomy should be performed and artificial respiration given, oxygen pass-

ing in through the tracheotomy tube. It is imperative that the first-aid kits of all ambulances should contain a tracheotomy set. I have been compelled to do a tracheotomy with a penknife upon a fireman lying on the pavement.

A chill or a series of chills not infrequently follows smoke asphyxiation, and a man who has or has had a chill must always be sent to a hospital. If the smoke has been impregnated with ammonia, a piece of gauze or a handkerchief should be saturated with vinegar and held over the face so that the vapor may be inhaled. On the other hand, a few whiffs of diluted ammonia should be given after the inhalation of fumes from acids. The eyes should be carefully treated. Ice-compresses are most grateful. Pieces of lint or gauze are placed on ice and are transferred, when cold, to the eyes. They are changed at frequent intervals. The eyes must be washed with a saturated solution of boric acid at frequent intervals. Even after the acute symptoms have subsided it may be necessary to wear blue glasses for several days and to use an astringent eye-wash twice a day.

To relieve headache an ice-bag can be applied to the head and bromid should be administered by mouth. Bromid also relieves the severe nervousness which often ensues. Occasionally bronchitis or even bronchopneumonia may occur. Even after mild smoke cases there is usually a cough for several days, the sputum being streaked with black, carbonaceous material.

Inhalation of the vapor of nitric acid is apt to cause edema of the lungs and glottis and death. The acute edema may not come on for some hours after the inhalation. The *treatment* of edema of the lungs consists in venesection, hypodermatic injection of camphorated oil, the administration of alcohol and digitalis, and counterirritation of the chest. The treatment of edema of the glottis is set forth on page 873.

Illuminating Gas-poisoning.—Poisoning by illuminating gas is becoming more common. The statistics for the city of Philadelphia during 1912 showed that 152 cases died from illuminating gas-poisoning. Of these 77 were suicides and 75 were accidental. The number of cases has increased since the substitution of the so-called water-gas for coal-gas. The coal-gas formerly used was not nearly so dangerous. Coal-gas contains a small amount (about 7 per cent.) of carbon monoxid. In comparatively recent years, however, in order to reduce the cost and simplify the manufacture the new water-gas has been used. This is developed by forcing steam through hot coals or coke. To this water-gas hydrocarbons are added (methane, ethane, etc.). The amount of carbon monoxid in water-gas is about 38 per cent.

Jones ("Amer. Jour. Med. Sci.," 1909, vol. cxxxvii) gives as further reasons for the marked increase in poisoning by illuminating gas: first, concentration of population in cities; second, increased susceptibility to emotional states and insanity.

Suicide from illuminating gas is growing in frequency, due to the means being at hand, the known painless nature of the death, and also to the fact that the sale of toxic drugs to laymen is now forbidden.

Carbon monoxid has a marked affinity for hemoglobin. It completely destroys the oxygen-carrying power of the red blood-cells and thus deprives the tissues of oxygen. It enters the system solely through the lungs. An atmosphere becomes dangerous when it contains .05 per cent. of carbon monoxid (Gruber, cited by Edsall, in Osler's "System of Medicine"; Haldane, "An Investigation of Mine Air," 1895). It is not proved whether carbon monoxid has any direct action of its own, or whether it acts solely by robbing the blood of its oxygen. Edsall ("Amer. Jour. Med. Sci.," 1907, and Osler's "System of Medicine") says it is highly probable that both conditions occur. McCombs ("Amer. Jour. Med. Sci.," 1912, vol. cxliv) says that carbon monoxid has a direct toxic action on a human being.

Suicide cases make up approximately one-half of all the fatalities from illuminating gas in Philadelphia and in Massachusetts (McCombs, "Amer. Jour. Med. Sci.," 1912, vol. cxliv). Cases of accidental poisoning are due either to a leak from a gas-pipe or failure to close a gas-jet. Pettenkofer (cited by Edsall, in Osler's "System of Medicine") has shown that the leak may not be in the building itself, but the gas, having escaped from a broken main, may travel through the ground for some distance and finally enter a house. This is especially liable to occur in the winter when the heating of the building causes active motion of the atmosphere, thus drawing gas into the house by aspiration. Numbers of the employees of the large gas companies are overcome while working in the ditches in the city, yet among all such cases that have occurred in the city of Philadelphia there has been but one fatality. This is due to the careful instruction to the men by the physicians connected with the gas company. The men are not only instructed, but they also carry a first-aid kit and are competent to give immediate treatment.

Illuminating gas-poisoning has been divided into the acute and chronic forms. There is little evidence, however, to support the theory of chronic gas-poisoning. McCombs (Loc. cit.) has examined the blood of men who are constantly in contact with carbon monoxid, some of whom have been frequently overcome by it. He has found the average blood-count shows polycythemia. He has not noted any cases of muscular weakness, irregularity of the heart, bradycardia, lack of concentration, poor memory, cardiac dilatation, splenic enlargement, or pleural effusion. The acute cases are, of course, well known.

The symptoms of an acute case are ushered in by a sensation of vertigo or dizziness, headache, and muscular weakness. They are often accompanied or even preceded by a throbbing sensation in the head and throbbing of the vessels of the neck. McCombs (Ibid.) states that at first the pulse is slow, from stimulation of the pneumogastric. I have probably never seen a case in so early a stage, as every case I have examined has had a rapid and weak pulse.

During the early stage there is occasionally cerebral excitement. The pupils are dilated and the respirations are increased, both in depth and in frequency. There is no irritation of the mucous membranes. The victim has an odor of gas emanating from him. Unconsciousness now ensues. In some cases, however (as in the case of firemen working in smoke impregnated with illuminating gas), the irritant and suffocative qualities of smoke may overshadow all early symptoms of illuminating gas, and the victim may drop as suddenly as though he had been shot.

The foregoing symptoms have been called by McCombs the first stage of gas-poisoning. He then states that the second stage begins with syncope and ends with apnea. In the second stage, therefore, the patient is unconscious, but respirations are still in progress.

The respirations may be rapid and stertorous or may be of the Cheyne-Stokes type. The face is cyanosed. There is often frothing at the mouth. The froth may contain blood. The blood-pressure falls, but the temperature is usually elevated. There may be general tetaniform convulsions. The pulse is rapid and weak. The temperature varies from 99° to 103° F. Occasionally the temperature may rise rapidly, reaching 105° to 110° F., these cases usually terminating fatally. A great rise of temperature is usually coincident with the development of edema of the lungs. The high temperature is not due to the edema, but is probably due to the overwhelming toxemia. The toxemia is purely hemolytic in origin. The tongue is swollen and is cherry red, and the same peculiar cherry-red color makes its appearance on the skin of the neck, trunk, and buttocks. The blood, if drawn, is bright cherry-red in color and will show by the spectroscope the presence of carbon monoxid.

Edsall ("Amer. Jour. Med. Sci.," 1907) believes that, with the exception of the spectroscope, the best test for carbon monoxid in the blood is the Hoppe-Seyler test. The blood containing carbon monoxid, if treated with twice its volume of a solution of sodium hydrate, yields a beautiful red color when spread on a porcelain plate, while blood not containing carbon monoxid is changed into a dirty, brownish mass.

Katagama's test consists in adding to 10 c.c. of blood, diluted with water, 2 c.c. of ammonium sulphate solution and 0.2 c.c. of 30 per cent. acetic acid. Carbon monoxid blood gives a bright red precipitate, while normal blood gives a greenish precipitate. These tests should be used in cases of coma of uncertain origin.

Pettenkofer insists upon the importance of searching for gas-poisoning as the cause of the trouble, when various persons in the same house have a tendency to wake with headache or nausea.

In the third stage there is coma with apnea. The pulse is more rapid and is weaker. It is often impossible to count the rate. The skin is usually cyanosed, is cold and dry, and occasionally there appear on the extremities the back blebs. Blebs usually occur in chains and are most apt to appear in cases in which the coma persists for twelve hours or longer. The blebs contain clear serum and have frequently been mistaken for burns from the application of hot-water bags. There flexes are abolished. There is paralysis of the sphincters. Coma may last for days and yet be followed by a recovery.

Gilman Thompson ("N. Y. Med. Record," July 9, 1904) considers it a bad sign if leukocytosis, which is usually present, is of high degree. Reported cases, however, do not seem to substantiate this belief. The leukocytosis varies from 10,000 to 22,000. Thompson, moreover, reports an increase in the number of red blood-cells. The same observation is made by McCombs, but is denied by Glenn Jones.

Glenn Jones ("Amer. Jour. Med. Sci.," 1909, vol. cxxxvii) found the red cells reduced in number. The specific gravity and the coagulability of the blood are increased.

The pathology of gas-poisoning consists principally of the characteristic cherry-red spots on the surface of the body, the cherry-red color of the blood, and the same color of many or all of the organs. There is usually intense hyperemia of, and occasionally small free hemorrhages into, all the organs. Nephritis is usually present and is apt to be of the acute hemorrhagic type. There may be small scattered hemorrhages throughout the brain and cysts may form as the result of softening. Cardiac dilatation, fatty degeneration of the heart, and splenic enlargement have been described by Koren in cases of supposed chronic gas-poisoning.

The sequelæ of gas-poisoning are principally nervous manifestations. In the milder class of cases nervousness, insomnia, and headache are usually present for several days; in the more severe cases, intention tremors, loss of sexual power, delirium, neuritis, transient hemiplegia, confusional insanity, leptomeningitis, and encephalomyelitis have been reported. Prolonged fever and glycosuria have also been found.

There may be acute congestion of the lungs, edema, emphysema, or bronchopneumonia. McCombs states that all of the sequelæ usually clear up within six months or less, and that cases with sequelæ constitute less than 2 per cent. of all cases, and are usually confined to those persons who have absorbed large amounts of the carbon monoxid. Sequelæ are, of course, more apt to occur in those of advanced years and feeble condition than in those who are young and vigorous.

The prognosis should be based upon the duration of the exposure, the age of the victim, the degree of coma, the condition of the blood, and the character

of the pulse and respiration. Usually a short exposure to illuminating gas means a case amenable to treatment and which will promptly recover. Longer exposure, or exposure of the aged and feeble, means a far worse prognosis.

Edsall cites 39 cases treated in the Episcopal Hospital of Philadelphia, of which 34 recovered. Of the 5 fatalities, several were due to sequelæ. If the onset of the symptoms are rapid, if edema develops, or if pronounced hemolytic changes are present, the prognosis is unfavorable. The persistence of coma is highly unfavorable, and Jones states that all cases that develop cutaneous blebs end fatally.

The treatment of poisoning by illuminating gas must be prompt and heroic. In the milder cases, in which there is neither coma nor apnea, the patient must be removed to an atmosphere free from the poison and must be given oxygen freely. The object of all treatment is to give oxygen in sufficient quantities to displace the carbon monoxid from the blood. Nausea and the feeling of fulness in the stomach can be relieved by the administration of effervescent sodium phosphate, Seidlitz powder, or a bottle of weiss beer. These procedures will usually cause vomiting and give relief. The patient should be kept quiet, an ice-bag being applied to the head to relieve the headache. Doses of bromid of potash will give comfort. Hoffmann's anodyne and aromatic spirits of ammonia act as useful stimulants and carminatives. Caffein, digitalis, strychnin, and camphor should be given if necessary. They will hardly be necessary, however, unless the victim is in the second stage or the stage of unconsciousness. When the patient is unconscious, venesection should be performed, followed by transfusion, or by the intravenous injection of salt solution.

The patient must be kept quiet, as many victims have died from sudden exertion. Venesection without the injection of salt solution or without transfusion is usually condemned, but Halsted reported 2 cases in which he thought it did good. Transfusion of defibrinated blood was practised in the 70's and 80's and successful cases were reported. Reinfusion of blood was attempted by Halsted in 1884, at which time he reported a successful case: 512 c.c. of blood were withdrawn from the radial artery, defibrinated and strained, and 280 c.c. were reinfused into the artery. In 1907 Crile and Lenhart reported their studies of transfusion, which procedure has supplanted all former methods of treatment.

Of course, in the third stage, that of coma with apnea, artificial respiration must be made, and for this purpose the pulmotor is most valuable, as it not only gives artificial respiration, but at the same time administers large quantities of oxygen under pressure.

Massage is an important feature of treatment. It increases circulation in the extremities. Transfusion, of course, requires the presence of a skilled surgeon, whereas intravenous injection of saline solution is not nearly so difficult a procedure. It is most important that artificial respiration should not be abandoned for a number of hours, as cases have been reported in which artificial respiration was finally successful after a period of six hours. In conditions which lead one to suspect that chronic poisoning may be present, the cause should be sought and, if found, removed, and the case be treated symptomatically. The general public should be instructed as to the danger of acute gas-poisoning.

Diseases and Injuries of the Nose and Antrum

Foreign bodies in the nose (see Poulet on "Foreign Bodies in Surgery") are usually introduced through the anterior nares, but in rare instances during swallowing they enter by way of the posterior nares, a sudden expiration being the cause of the entry. During vomiting foreign bodies may enter the posterior nares. Small particles are often expelled spontaneously; larger

pieces collect mucus and epithelium and become fixed. Some materials swell after lodgment. Others become encrusted with lime salts. Seeds may sprout. In very rare cases insects enter and lodge. Cases are on record of leeches, taken in with drinking-water, passing into the nasal fossæ from the pharynx. In the tropics flies may deposit larvæ within the anterior nares and they develop with great rapidity. A foreign body is usually near the floor and may be between the vomer and turbinate bones. It may shift after lodgment.

Treatment.—In many cases general anesthesia is required. Illuminate the nostril, and, if the foreign body can be seen, insert a hook back of it and effect its removal by means of forceps. Some foreign bodies require to be pushed back into the nasopharynx. Occasionally expulsion may be effected by inserting a rubber tube into the unblocked nostril and telling the patient to blow forcibly through the tube. In serious cases a specialist should be summoned to remove a portion of the turbinated bone or to perform whatever operation he thinks best.

Inflammation and Abscess of the Antrum of Highmore (the Maxillary Antrum).—The source of this disease may be inflammation within the nose or periostitis around the roots of the teeth. In some cases the natural opening into the meatus is patent; in other cases it is partly or completely blocked. Caries and necrosis may arise. The **symptoms** are pain, edematous swelling of the face, and thinning of the bone so that it may crepitate under pressure. When pus has formed, if the antral opening is patent, certain positions of the head will cause a purulent flow from the nose, and if a speculum is inserted pus may be seen as it flows into the nose. The opening of the maxillary antrum into the nasal channel is at the summit of the antrum; hence the antrum drains when the head is inverted. The ethmoidal cells and frontal sinus drain best when the patient is upright. Wipe the interior of the nose and place the patient with his head between his knees. If the nostril fills with pus, it comes from the antrum (Cobb). In severe cases the jaw expands, the eye protrudes, and great tenderness of the alveolus exists. Percussion exhibits a dull note. In making a diagnosis it is well to take the patient into a dark room, insert an electric light into the mouth and note the diminution of light transmission on the diseased side as contrasted with the sound side. Transillumination may be easily practised by the use of a cautery electrode, protected by a small glass vial. Any cautery battery may be employed (plan suggested by Ohls). Exploratory puncture will settle a doubtful diagnosis. This may be by way of the lower meatus, the canine fossa, or the alveolar process.[1]

Treatment.—Before pus forms order the use of hot fomentations and remove any diseased teeth. When pus has formed, evacuate it at once. Before performing a severe operation try the effect of opening into the antrum from the nose, by means of Krause's trocar, followed by insufflation of iodoform. If this procedure fails, other means may be employed. If the disease arises from a carious tooth, pull the tooth and push a trocar through its socket into the antrum. If the teeth are sound, bore a hole with a large gimlet or with a bone-drill above the root of the second bicuspid tooth and 1 inch above the edge of the gum. A counteropening should be made into the inferior nasal meatus. A drainage-tube is pulled from the first opening into the nose and is allowed to protrude from the nostril. Irrigate daily with normal salt solution. In three or four days discontinue through-and-through drainage, but prevent the first opening closing until the discharge ceases to be purulent. In severe cases make a free incision through the canine fossa by means of a chisel.

Distention and Abscess of the Frontal Sinus.—The usual cause is an injury which may long antedate the symptoms. This injury causes or leads

[1] Cobb, in "Boston Med. and Surg. Jour.," May 7, 1896.

to blocking of the infundibulum; secretion accumulates and distends the sinus, and in some cases pus forms. In many cases the fluid slowly accumulates, and it may require years to produce marked symptoms. In other cases infection takes place early or existed from the start, and the symptoms are positive and violent. If the outlet into the nose is not permanently blocked, the fluid may discharge itself from time to time. In the chronic cases there is seldom much pain. The chief sign is a swelling of the inner or upper part of the orbit, which swelling progressively increases and finally displaces the eye. If at any time acute symptoms supervene, there will be pulsatile pain, discoloration, and tenderness.

Treatment.—In some cases it is possible to pass a trocar upward from the nose into the sinus, and so drain and irrigate. In most cases an incision should be made through the soft parts, and the sinus be opened by a trephine or chisel. After the sinus has been opened it must be curetted. The opening into the meatus should be restored and enlarged, and a drainage-tube must be passed from the forehead incision into the nostril. I usually prefer to open the sinus by making an osteoplastic flap in the anterior wall.

Diseases and Injuries of the Larynx and Trachea

Edema of the Larynx (*Edema of the Glottis*).—The **causes** of edema of the larynx are: acute laryngitis; chronic diseases, such as tuberculosis, malignant disease, or syphilis; inflammatory disorders, such as diphtheria and erysipelas; acute infectious diseases; Bright's disease; aneurysm; whooping-cough; pneumonia; quinsy; wounds of the larynx; wounds of the neck; scalds and burns of the larynx, and the inhalation of irritating vapors, such as those of ammonia, nitic acid, or sulphur.

The **symptoms** are sudden and rapidly increasing dyspnea, respiratory stridor, huskiness of the voice, and finally aphonia. The swollen epiglottis may be felt with the finger and may be seen with the help of a mirror.

Treatment.—In cases in which edema of the larynx is not excessively acute, introduce a gag between the teeth, hold the mouth open, take a knife wrapped to within $\frac{1}{4}$ inch of its point, make multiple punctures into the epiglottis, and favor bleeding by the inhalation of steam. In severe cases perform intubation or tracheotomy.

Wounds and Injuries of the Larynx.—The larynx may be injured internally by foreign bodies, and externally by blows and cuts. A condition often met with is *cut throat*, the result usually of a suicidal attempt on the part of the patient or a homicidal effort on the part of an assailant. The cut of the suicide is usually in front; as a rule, it misses the great vessels, but divides the cricothyroid or thyrohyoid membrane. The epiglottis may be incised, or even be cut off. If a large vessel is cut, death rapidly occurs. The immediate dangers of cut throat are hemorrhage, suffocation by blood in the wind-pipe and bronchi, or by displacement of parts, and entrance of air into veins. The secondary dangers are bronchopneumonia, infection and sepsis, exhaustion, and secondary hemorrhage. The remote dangers are stricture and fistula (Keetley).

Treatment.—In wounds of the throat arrest hemorrhage, remove clots from the larynx and trachea, bring about reaction, asepticize the parts as well as possible, suture the deeper structures with silver wire, catgut, or kangaroo-tendon, and the superficial parts with silkworm-gut, dress antiseptically, and place a bandage around the head and chest so as to pull the chin toward the sternum. If laryngeal breathing is much interfered with, perform tracheotomy. Feed the patient through a tube until union is well advanced. The old method of leaving the wound open is to be condemned. When sutures are

used, primary union may be obtained. This fact was proved by Henry Morris.

Scalds of the Glottis.—(See section on Burns and Scalds.)

Foreign Bodies in the Air-passages.—The lodgment of foreign bodies in the air-passages is a frequent accident. A multitude of different things have been reported as having lodged in the air-passages. Small solid bodies are usually expelled by coughing. Liquids and solids rarely pass beyond the larynx (except in laryngeal disease or palsy, wounds of the floor of the mouth, cut throat, and in people unconscious or very drunk). In vomiting during or after the administration of an anesthetic or in the vomiting of drunkards the vomited matter may find its way into the larynx or lungs. There is great danger of this accident in an operation upon a patient with intestinal obstruction who has stercoraceous vomiting. In most instances of foreign bodies lodged in the air-passages it will be found that the object was being held in the mouth when a sudden deep inspiration was taken (often during laughter).

The **symptoms** are *immediate,* due to obstruction by the body and by spasm; and *secondary,* due to the situation of the body and the changes it undergoes or induces.

Lodgment in the pharynx causes violent dyspnea. The body can be seen or felt.

Lodgment in the Larynx.—A foreign body may lodge in the superior opening of the larynx, in the rima, or in the ventricle. In a severe case the patient fights madly for air; his face becomes livid and cyanotic; his veins stand out prominently; speech is impossible, though he may make noises and utter harsh cries; violent coughing begins, and then vomiting; he tries to force a finger down his throat and clutches at his neck; sweat pours from him; he feels a sense of impending dissolution, and he falls unconscious, with incontinence of feces and urine.[1] In a less severe case violent dyspnea gradually departs and the patient lies exhausted; but dyspnea and cough are liable to recur suddenly at any time because of spasm, and they may be induced by a change of position. These attacks of fierce spasmodic cough are not at first linked with expectoration, but after inflammation begins there is a profuse and often bloody expectoration. Inflammation follows more rapidly the lodgment of a sharp or irregular body than it does that of a round or smooth one. Inflammation is apt to produce edema of the glottis, bronchopneumonia, or ulceration and necrosis of the larynx. Any sort of foreign body in the larynx may at any moment produce spasmodic dyspnea, and is always very liable to cause edema of the glottis. The body if bony or metallic can be detected by the x-rays. A body may remain lodged in the ventricle for a long time without producing symptoms.

Lodgment in the Trachea.—The immediate symptoms of a foreign body in the trachea depend on the shape and weight of the body, and whether it becomes fixed in the mucous membrane or moves to and fro with the air-current. A smooth, heavy body falls to the tracheal bifurcation, and, if it does not enter a bronchus, moves with every breath, and by its movement causes violent laryngeal spasm, cough, and whooping inspiration without aphonia. The patient is often conscious of the movements of the foreign body, and the surgeon may detect them by the stethoscope. The foreign body may be found by the Röntgen rays. A foreign body in the trachea is liable to cause death by suffocation, or it may ascend so as to be caught in the larynx, or may even be expelled. Irregular or sharp bodies lodge in the mucous membrane, produce inflammation, frequent cough and expectoration, and finally lead to ulceration. Bodies which swell from heat and moisture tend to lodge and to become fixed (seeds may sprout).

[1] See Moullin's graphic description in his "Treatise on Surgery."

Lodgment in a Bronchus.—Foreign bodies in the bronchi seriously endanger life. They usually lodge in the right bronchus. The right bronchus is more nearly the direct continuation of the trachea than the left bronchus. When a small area of lung is obstructed the obstructed side shows diminished respiratory movement and murmur with occasional whistling sounds and large moist râles; the percussion-note is at first normal and later dull. When an

Fig. 558.—Author's case of pin in bronchus removed by low tracheotomy.

entire lobe is obstructed all respiratory sounds are absent over it, and over the unobstructed lung respiration is exaggerated; the percussion-note over the obstructed area is at first resonant, but becomes dull. The x-rays will enable the surgeon to detect many foreign bodies in a bronchus. Lodgment in a bronchus may cause bronchopneumonia, abscess, hemorrhage, and even gangrene. In some cases the body has been expelled spontaneously. In rare instances

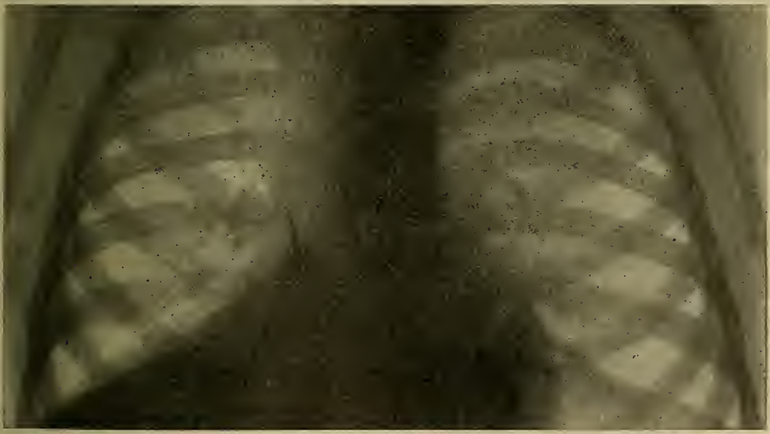

Fig. 559.—Gibbon's case of tack in the right bronchus removed by low tracheotomy, child six years old.

people have lived for years with lodged foreign bodies. If death does not soon follow the lodgment of a foreign body, an abscess is very apt to form.

Treatment.—If a foreign body lodges in the pharynx, try to pull it forward; if this fails, it may be wise to push it back into the esophagus. In lodgment in the larynx or below, if the symptoms are very urgent, at once perform quick laryngotomy or tracheotomy. If the symptoms are

not so urgent, get a complete history of the accident and find out the nature of the foreign body. Be sure that a foreign body is really retained in the respiratory tract, and then try to determine what its situation may be. A person sometimes imagines a body is lodged when it has been expelled or even when it was never in the larynx, trachea, or bronchus at all, but was swallowed. Often a laryngologist can remove a foreign body from the larynx by means of forceps, a mirror and lamp being used for illumination. The fauces and upper portion of the larynx should have cocain applied to them to lessen pain and spasm. If the surgeon fails in extraction by forceps, and laryngotomy has been performed, continue the search through the opening in the cricothyroid membrane; if laryngotomy has not been performed, let the larynx be opened by *thyrotomy* (a vertical incision between the alæ of the thyroid cartilage, and the separation of these alæ to permit of exploration). After a thyrotomy suture the perichondrium with catgut. If the foreign body is in the trachea, perform ordinary tracheotomy; if it is in a bronchus, perform low tracheotomy. Tracheotomy prevents suffocation from laryngeal spasm or edema of the glottis. It may be possible to remove the body in the bronchus through the incision of a low tracheotomy, and this ought to be tried. By this method I succeeded in 5 cases, removing a pin, a bone, a bean, a tack, and a broken tracheotomy tube from the right bronchus. The foreign body may be expelled through the tracheotomy wound; if it is not expelled, search the trachea and bronchi with Gross's forceps, with probes, with hooks, or with the finger. If the foreign body cannot be found, put the patient to bed and maintain a moist atmosphere in the room. As a rule, when the foreign body is not found, insert a tube. If the foreign body be extracted, do not insert a tube (unless edema of the glottis exists or is likely to come on), do not suture the wound, but cover it with moist gauze and let it heal by granulation. Morphin and sedative cough-mixtures are given. Gross says that even when a foreign body has long been retained an operation should be performed if the air-passages are not seriously diseased. What shall be done when a foreign body is lodged in a bronchus and we are unable to extract it through a tracheotomy wound or by tracheobronchoscopy? Truc said if "the patient is in danger of death" cut through the chest-wall and attempt to remove the body. He said this with a full knowledge of the difficulty of locating the body. This difficulty has been partly overcome by the *x*-rays, and it seems now more certainly our duty to operate than it was a short time ago. Nasiloff proposed to reach the obstruction by the posterior route after rib resection. Curtis attempted this, and though the patient died, his operation proves that the method is feasible. An operation by the posterior route should be performed at once if low tracheotomy fails. The danger of pulmonary collapse will be abolished by the use of a suitable apparatus to prevent it (see pages 895 and 904).

Tracheobronchoscopy.—Killian, of Freiburg, devised a bronchoscope for introduction through a tracheotomy wound. I have used the endoscope in this manner. Later Killian devised a straight instrument which could be used through the mouth and larynx, tracheotomy being unnecessary. During its introduction the head was held far back.

Brüning, of Freiburg, improved the instrument. His tube is long enough to reach between the vocal cords to the divisions of the bronchi. In 1907 Killian was able to collect 164 cases of foreign bodies removed by this direct method.

Dr. Chevalier Jackson, of Pittsburgh, has devised a tracheobronchoscope through which he has succeeded in removing foreign bodies from the trachea and from a bronchus. In 10 cases of foreign body in the bronchus he removed the offender in 7. In 7 cases of foreign body in the trachea he was successful in each case, but 2 of the cases required tracheotomy. Whenever there is dyspnea he always prepares to do tracheotomy ("Annals of Surgery," March,

1908). In Jackson's trained hands the instrument is most useful, but an untrained man with it would be like an untrained man with a cystoscope. When used by a fully trained man the instrument prevents many cutting operations and saves many lives (see page 885).

Operations On the Larynx and Trachea

Tracheotomy.—In a formal operation give ether or chloroform, but in an urgent emergency this cannot be done. The patient may be placed supine with a sand-pillow under the neck and with the head thrown over the end of the table. If a child, Liston used to wrap it up to the neck in a sheet to prevent movements of the limbs, would seat himself on a chair, place the child upon the nurse's lap, and take its head between his knees. The head must be exactly in the middle line and extended (in an adult this gives $2\frac{3}{4}$ inches of trachea above the manubrium; in a child of ten, $2\frac{1}{4}$ inches; in a child of six, about 2 inches). The operator stands to the right side when the patient is supine. If bleeding is profuse when the surgeon is ready to open the trachea, place the patient in the Trendelenburg position with the neck extended. The trachea may be opened above or below the isthmus of the thyroid gland. The isthmus in an adult

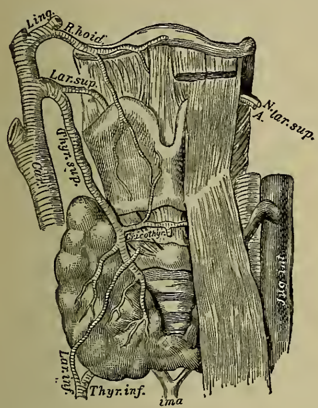

Fig. 560.—Blood-supply of the larynx and trachea (Esmarch and Kowalzig).

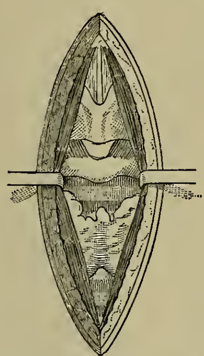

Fig. 561.—Parts exposed in tracheotomy (Esmarch and Kowalzig).

usually lies over the second and third rings (Figs. 560 and 561). The isthmus in a child usually lies over the first ring or even over the space between the cricoid cartilage and the first ring. The high operation is always chosen except in cases in which it is desired to search for a foreign body in a bronchus.

High tracheotomy is preferred because in this region the muscles are distinctly separated (Fig. 561), the main vessels of the neck and the inferior thyroid vessels are not encountered, the anterior jugular veins are small and have very few transverse branches, and the trachea is near the surface (Treves). The surgeon accurately locates the cricoid and thyroid cartilages. An incision is begun at the upper border of the cricoid cartilage, and is carried down precisely in the middle line for about $1\frac{1}{2}$ inches. Treves advises the operator to steady the skin of the neck with the fingers of the left hand and to cut with the unsupported right hand (if the hand be supported, the respirations will interfere with the operation). The skin, the superficial fascia, and the anterior layer of the cervical fascia are incised, the sternohyoid and sternothyroid muscles are separated, and the fascia over the trachea is divided. This fascia is attached above to the cricoid cartilage, and it divides below into two layers to invest the thyroid body and its isthmus. If veins are in the line of the incision, they are

pushed aside, but it is not necessary to take the time to apply double ligatures. Even if bleeding is profuse, as soon as the trachea is opened and air enters freely into the lungs, venous congestion is relieved and bleeding is apt to cease. If hemorrhage be violent and the veins are not at once caught by forceps, it may be well to place the patient in the Trendelenburg position before incising the windpipe, in order to prevent the entrance of blood into the lungs. Before opening the trachea the isthmus of the thyroid gland is pushed downward; if it cannot be pushed down sufficiently, a transverse incision is made through the fascia at the upper border of the cricoid cartilage, and the fascia and the isthmus with it are lifted off the trachea (Bose's method). A tenaculum is inserted into the cricoid cartilage in order to steady the tube. The back of the knife is turned toward the sternum, a finger being held upon the blade to prevent too deep a cut being made. The knife is plunged, as if it were a trocar, into the midline of the trachea above the isthmus, and two or three rings are divided from below upward. The hook is not removed until the operation is completed. If a foreign body is present, an attempt is made to remove it; if success attends the effort, no tube need be worn; but if the body is not found, a tube must be used. In croup or diphtheria remove membrane (by means of a feather and a solution composed of bicarbonate of sodium 2 oz., glycerin 1 oz., water 10 oz.—Parker) and insert a tube. The edge of the cut is grasped with the dissecting forceps, the mucous membrane being included in the bite; the head is placed erect, the tube is introduced, and the tenaculum is removed. Secure the tube by tapes, and suture the wound below the tube. Remove the tube at the first moment consistent with safety. After tracheotomy put a screen around the bed; have the air kept moist by steam; remove the inner tube and clean it every few hours at first; clean the outer tube whenever required. In croup or diphtheria put the patient in a croup tent and keep the air moist by a steam atomizer or a croup kettle. Remove and clean the inner tube every two hours. Clean the larynx and trachea from time to time by means of a feather and Parker's solution.

Quick laryngotomy must never be attempted upon a child under thirteen years of age, because of the small size of the cricothyroid space before this age (Treves). In view of the difficulty of introducing a tube and of wearing it so near the vocal cords, laryngotomy should not be performed for croup, diphtheria, or for any condition in which a tube must be long worn. The operation is performed as follows: Make an incision $1\frac{1}{4}$ inches in length in the middle line, from above the lower edge of the thyroid to below the lower border of the cricoid cartilage. Divide the skin, superficial fascia, and deep fascia, separate the cricothyroid and sternothyroid muscles, divide the deep layer of fascia, and cut the cricothyroid membrane transversely just above the cricoid cartilage. The tube must be shorter than the ordinary tracheotomy tube. An operation which opens vertically the cricothyroid membrane, the cricoid cartilage, and the upper rings of the trachea is called *laryngotracheotomy*.

Intubation of the Larynx (*O'Dwyer's Operation*).—Bouchot conceived the idea of intubation; O'Dwyer perfected it and made it a genuine scientific proceding. The instruments required for the performance of this operation are a mouth-gag, an instrument to hold the tube and introduce it, and an instrument for extracting the tube. The collar of the tube has a perforation through which a piece of silk is fastened to draw out the tube. The child is wrapped in a sheet to secure the limbs, is seated in a nurse's lap, and its head is held by an assistant. The jaws are opened and held apart by the self-retaining mouth-gag. The surgeon sits in front of the patient, wraps a piece of rubber plaster about the index-finger of his left hand, and passes the finger into the child's mouth until its tip touches the epiglottis. He introduces the holder and tube (observing if the silk is free) along the surface of the tongue until the

obturator touches the epiglottis; raises the epiglottis with the left index-finger, and passes the tube into the larynx; places the left index-finger against the tube, and withdraws the holder with the right hand. The silken thread is tied to the ear, and the nurse is directed to employ the thread to remove the obturator if it becomes obstructed or is coughed up. The tube is removed in two or three days; if breathing is easy, it is not reintroduced; but if dyspnea recurs, it is replaced for two or three days more. If, in introducing the tube, a mass of false membrane is pushed before it into the trachea, breathing ceases, and, if the mass is not at once coughed up, tracheotomy must be performed. Feed these patients on semisolids rather than upon liquids (mush, soft eggs, and cornstarch); and if trouble occurs in swallowing these articles, feed by the rectum or by means of a nasal or an oral tube. In opium-poisoning, in asphyxia, in acute traumatic pneumothorax, and in cerebral injuries, intubation may be associated with the use of Fell's apparatus (see page 896).

Fig. 562.—Direct laryngoscopy for the introduction of a tube for intratracheal insufflation anesthesia. The patient's head is on the table, with the forehead pushed strongly down backward, so that the vertex is under the chin, the head in extreme extension, and the hyoid bone thrown upward (Chevalier Jackson).

Chevalier Jackson's Tracheobronchoscopy (Dr. Chevalier Jackson did me the honor and the favor to write for me the following description of his operation).—"Direct inspection of the trachea and bronchi by means of a suitably illuminated tube passed through the mouth is now well established as a procedure of great value for the removal of foreign bodies and for diagnosis and direct local treatment of disease. In the earlier days of bronchoscopy a tracheotomy was done for the insertion of the bronchoscope, but this is now quite unnecessary, because perfection of instrumentarium and technic have rendered it very easy for those who have acquired the knack to insert the bronchoscope through the mouth and larynx. The first step in bronchoscopy is the exposure of the larynx by direct laryngoscopy.

"*Direct laryngoscopy* is so called in contradistinction to the ordinary methods of examination of the reflected image in a throat mirror. The latter pro-

cedure is invaluable for diagnosis, but for operative work the anteroposterior reversal of the image involves extreme difficulties. By direct laryngoscopy the larynx is exposed to direct view for operative work, removal of specimens of tissue, and for insertion of tubes for intratracheal insufflation anesthesia (Fig. 562). For laryngeal operative work direct laryngoscopy is usually done under local anesthesia in the sitting position in adults; and without anesthesia, general or local, in children. General anesthesia is particularly dangerous in any condition of the larynx associated with even a slight degree of dyspnea. The patient is usually in the sitting position for direct laryngoscopy in adults with local anesthesia (Fig 563), recumbent for direct laryngoscopy in children, and usually recumbent for bronchoscopy regardless of anesthesia,

Fig. 563.—Direct laryngoscopy with the patient in the sitting position, for diagnosis and for endolaryngeal operation, and removal of specimens of tissue. For endobronchial diagnosis and local medication the bronchoscope may be passed in this position, but for foreign-body work in larynx or bronchus the recumbent position is better, in order to have the aid, instead of the opposition, of gravity (Chevalier Jackson).

though occasionally diagnostic bronchoscopies are done in the sitting position in adults. The technic of direct laryngoscopy and bronchoscopy is easily understood from Fig. 564, which represents the procedure in the recumbent position. The patient's head is fully extended by forcing the occiput down backward toward the shoulders, which throws the anterior part of the neck high up, elevating the hyoid bone and its attached structures. In doing this the *head must be raised*, never lowered. For this reason the schema is drawn with the head on the table, because the head should never be below the level of the table. For bronchoscopy the head and neck should be out in the air beyond the table and supported by an assistant, so that the head may be freely movable as needed. For instance, it must be moved to the right for

the bronchoscope to enter the left bronchus, and vice versâ to enter the right bronchus; and it must be slightly lowered to enter the middle lobe bronchus of the right side, raised to enter the posterior branch bronchi. For direct laryngoscopy only, however, the head should be on the table, and for the insertion of intratracheal insufflation tubes should be precisely as shown at A in Fig. 564. With the head properly placed, the next point of importance is to expose the larynx to direct view. To pass the speculum posterior to the tongue and to identify the epiglottis are easy. Now comes the most important movement in all peroral endoscopic procedures. The beak of the direct laryngoscope is passed posterior to the epiglottis for about 1 cm., when a strong lifting motion is given by the *beak* of the instrument, as if to lift the epiglottis out anteriorly through the neck in the direction of the dart. The upper teeth must not be used as a fulcrum. With the vocal cords in full view, the bronchoscope is inserted, with the handle horizontal, into the laryngoscope. The eye is now transferred from the laryngoscope to the bronchoscope. When the vocal cords separate at the next inspiration the bronchoscope is quickly passed through the glottis into the trachea, as shown at B. The bite-block is now inserted to prevent the patient damaging the thin-walled bronchoscope. The slide is then removed, as shown at C, leaving the bronchoscope in the trachea, as shown at D. The bronchial tree is exceedingly elastic and flexible, and may be explored by following the lumen by sight. Secretions may be removed by the sponge-holder (Fig. 565, C) uncontaminated by the secretions from the mouth for diagnosis or vaccine therapy. Suspected tissue may be carefully removed for examination by means of biting forceps (Fig. 565, E). Foreign bodies may be extracted from the trachea or bronchi with suitable forceps (Fig. 565, D). Compressive stenosis by the thymus gland, mediastinal tumors,

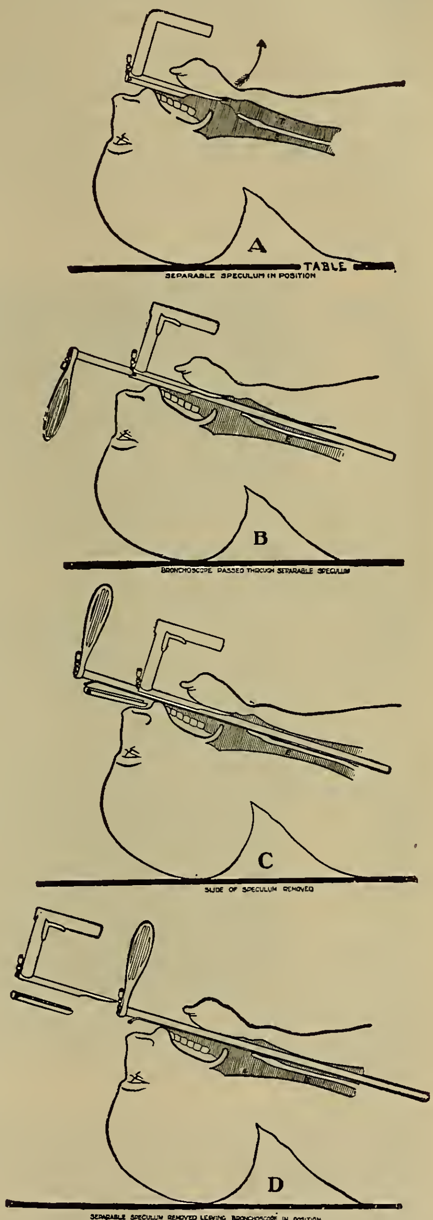

Fig. 564.—Schema showing the technic of direct laryngoscopy and bronchoscopy. The upper illustration (A) shows also the position of the patient and the direction of the force to be exerted on the direct laryngoscope in exposing the larynx for the insertion of intratracheal insufflation tubes for anesthesia (Chevalier Jackson).

and adenopathic masses may be diagnosticated. Deviation or compression of the trachea by goiter can be determined, and valuable aid can be rendered the surgeon by an accurate localization of the stenosis in all cases associated with dyspnea. No dyspneic case should ever be generally anesthetized without a preliminary examination of the larynx and trachea.

"*Esophagoscopy.*—For the passage of the esophagoscope no anesthetic, general or local, is really necessary, and none should be given in children, because cocain is dangerous in the very young, and general anesthesia assumes a graver risk especially in foreign-body cases in children because of the compression of the trachea by the bulk of the bube plus the bulk of the foreign

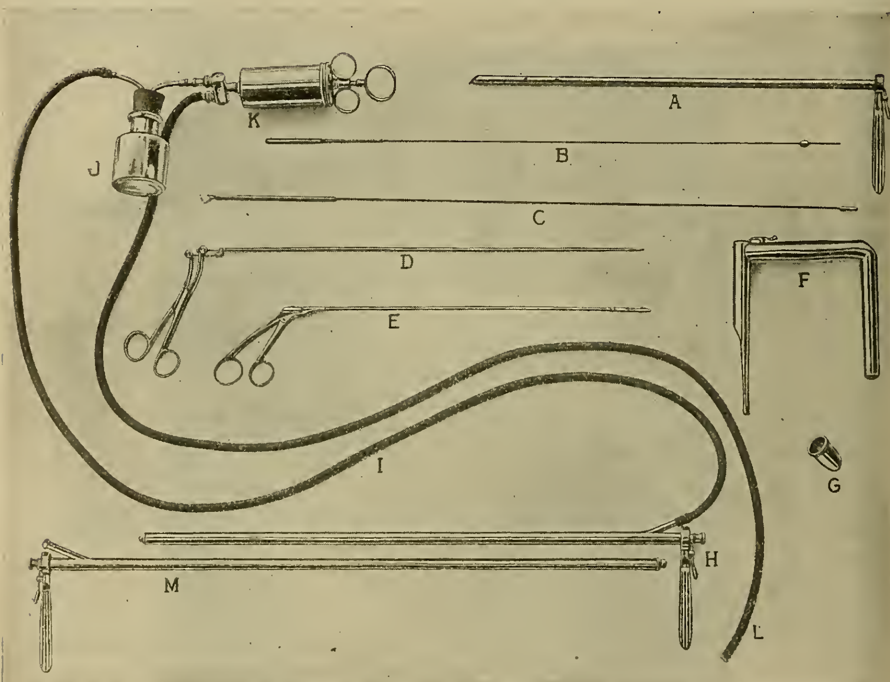

Fig. 565.—Jackson's instruments for direct laryngoscopy, bronchoscopy, and esophagoscopy: A, Bronchoscope; B, olive bougie for esophagoscopic bouginage; C, sponge-holder for sponging the field and obtaining specimens of secretion; D, forceps for removing foreign bodies; E, forceps for removing tissue; F, laryngeal speculum, called also slide speculum and direct laryngoscope; G, bite-block; H, esophagoscope with tubing (I) leading to aspirator (J, K) for removal of secretions. The tubing (L) is connected with the positive pressure side of the syringe (K) for use when needed to blow out obstructions, such as clots of pus, food, etc., that have been aspirated into the drainage canal of the esophagoscope. At M is shown a gastroscope.

body, especially if the latter is overriden or displaced. Respiratory arrest is likely to follow and the respiration can rarely be started except by bronchoscopic insufflation. In adults the lower pharynx and mouth of the esophagus may be anesthetized with an 8 per cent. solution of cocain. There is no need of anesthetizing the esophagus below the orifice, because it is quite insensitive there. Until the knack is acquired, the operator will find it difficult to pass the esophagoscope without deep general anesthesia, which should be by ether, never chloroform. The patient is placed in the Boyce position, previously described, the bite-block being held by the index of the assistant's right hand. The esophagoscope is inserted at the right side of the patient's tongue (Fig. 566) and the pyriform sinus sought immediately to the right of the right arytenoid.

Once the tube mouth is in the sinus, very gentle pressure is used, and the lumen of the mouth of the esophagus is watched for and followed at the moment of inspiration. Absolutely no force should be used, and no attempt to advance the tube should be made except at the moments when the patient takes a deep breath, which he must be encouraged to do. It is the spasm of the inferior constrictor at the cricoid level that gives the trouble. Once this is passed, the lumen of the cervical esophagus is easily explored, and the thoracic esophagus opens widely at each recurrence of the inspiratory negative intrathoracic pressure. Passing the hiatus esophageus requires a moment for the relaxation of spasm and the tube must be directed slightly upward (recumbent patient) to the left. Esophagoscopy is useful for the detection of acute and

Fig. 566.—Introduction of the esophagoscope under guidance of the eye. The tube-mouth is just entering the pyriform sinus. The assistant is holding the head in extreme extension and elevated. The nurse at the left is manipulating the aspirator for the removal of secretions without interruption of the operator's work (Chevalier Jackson).

chronic esophagitis, ulceration, diverticulum, dilatation, paralysis, and various stenotic diseases, such as cicatricial stenosis following the ulceration of syphilis, typhoid fever, corrosive poisoning by bichlorid of mercury, caustic alkalis, acids, etc. Cicatricial stenoses are dilated under guidance of the eye with olives, divulsers, and silkworm bougies left *in situ* for a few hours. Obstinate cases may require endoscopic esophagotomy. Stenosis may be due to neoplastic involvement of the esophageal wall when the growth will be visible endoscopically, or the stenosis may be compressive, when the esophageal walls will be seen to be covered with normal mucosa, but the lumen is obliterated by the compression, the place of the lumen being occupied by a slit-like crevice, the long axis of which is often curved and is almost always at right angles to

the direction of pressure. Specimens of endo-esophageal growths may be removed for examination, and it is reasonable to hope that when patients shall be esophagoscoped early for any abnormal sensation in the esophagus the surgeon will have a fair chance to resect the intrathoracic esophagus. Spastic stenosis of the esophagus, especially hiatal and abdominal esophagismus (so-called cardiospasm), is not only easily diagnosticated esophagoscopically, but esophagoscopic divulsion of the abdominal esophagus will cure almost all cases. The esophagoscopic removal of foreign bodies is possible in all cases, no matter how large the foreign body. The mortality is practically nil in careful hands."

Diseases and Injuries of the Chest, Pleura, and Lungs

Traumatic Asphyxia (*Pressure Stasis; The Ecchymotic Mask*).—This is a condition that occasionally arises when the trunk is subjected to sudden and violent compression (caught under an elevator, caught under a heavy box, cave in of earth, crushed in the rush of a panic, etc.). The compression may be upon the chest, the abdomen, or both; and in the majority of cases it has been very temporary. The discoloration arises immediately, and is manifested over the head and neck down to and sometimes below the clavicle. The hue is a violet lividity. There are a great many spots in the skin in which the color is much deeper, which have been supposed to be hemorrhages, and similar spots exist on the labial, buccal, glossal, palatine, and pharyngeal mucous membranes. Subconjunctival hemorrhage is the rule. There may be bleeding from the nose, mouth, and ears. There is brief or prolonged unconsciousness, circulatory and respiratory depression, sometimes cough and bleeding from the lungs. There has never been a reported instance of intracerebral hemorrhage. There are (rarely) convulsions, there is no paralysis and no delirium. The lividity may clear up in a few hours. The spots seldom fade for days. The spots do not fade at all from pressure, the livid area fades but slightly.

If death occurs, it results from associated injuries. The condition in the cases without severe associated injuries has soon disappeared, and entire recovery has followed. The view generally taught is that traumatic asphyxia is the result of compression of the abdominal veins, causing distention of the superior cava and its tributary veins, this region of the body showing the effect more than the limbs, because of the comparative feebleness of the valves (Villemin). The blood is forced back along the veins and into the capillaries, and capillary paresis ensues. One thing is sure, and that is, that the condition is particularly apt to arise if the patient struggles violently to free himself from the compression; and many observers have held the opinion that actual vascular ruptures take place. There are certainly some cases, however, in which there is simply great venous and capillary distention in the skin without rupture, because pieces of skin have been excised and microscopical examination has indicated that there had been no blood effused. The selection of the face and neck as the regions of discoloration is due, perhaps, to absence or incompetence of valves in the jugular and facial veins. The fluid state of the blood which has been noted occurs in all forms of asphyxia. (See Winslow, "Medical News," Feb. 4, 1906; Birge, "Cleveland Medical Journal," Sept., 1905; Beach and Cobb, in "Annals of Surgery," April, 1904; Villemin, "Bull. et mém. de la Soc. Chir. de Paris," No. 9, 1906.) Despard ("Annals of Surgery," June, 1909) has reported 1 case and collected 17 from recent literature. Ettinger in 1907 collected 36 cases and added 1 of his own ("Wien. klin. Wochen.," 1907, vol. xx). I have seen 2 cases.

Pleuritic effusion may arise from the lodgment of foreign bodies, from injury by fragments of a broken rib, from tumors, and from inflammation of the

lung, but most usually is due to pleuritis. The commonest cause of primary pleuritis is tuberculosis. Inflammatory effusion is nearly always unilateral (except in tuberculous pleuritis; but even in this form it is often one-sided in origin).

The **signs** of pleuritic effusion are: dulness on percussion over the area of effusion, this dulness, when the patient is erect, being at the lower part of the chest and ascending higher posteriorly than anteriorly (alteration of position alters the situation of the dulness); the intercostal spaces are widened, the intercostal depressions are obliterated, the intercostal muscles are rigid, and their rigidity lessens the mobility of the ribs (Przewalski). No breath-sounds can be detected in the area of percussion flatness when the collection of fluid is large, but in small effusions deeply situated the breath-sounds are often audible; the percussion-note above the liquid is hyperresonant or tympanitic, and is often associated, at the edge of the liquid, with a friction-sound; posteriorly, high up and near the spine, there are bronchial respiration and bronchophony. In cases of pleurisy with effusion pain almost or quite disappears with the advent of effusion, dyspnea comes on, and the patient lies upon the diseased side. Cough always exists if there is pleuritic effusion, and fever is usually present. In serous effusions the diagnosis may be confirmed by the aseptic introduction of a clean aspirating-needle. Ramond has pointed out that in serofibrinous pleurisy the iliocostal and longus dorsi muscles are always noticeably enlarged on the side of the effusion ("Bull. de la Soc. Méd. des hôp.," 1910, vol. xxvii).

The **treatment** in this stage is to discontinue arterial sedatives and to stimulate if the circulation calls for it. The exudation is removed by the administration of salines, compound jalap powder, or elaterium. If these means fail, if the effusion is excessive, or if it is producing severe dyspnea, at once aspirate. Aspiration should be performed for an effusion which fills the whole chest, which produces great dyspnea, or which has lasted for three weeks. In tuberculous pleuritis early aspiration is not advisable, but aspiration should be performed if the fluid becomes purulent, if the effusion displaces the heart considerably, and if it adds notably to the dyspnea. If a non-tuberculous effusion becomes purulent, the proper procedure is incision, resection of a portion of a rib, and drainage.

Empyema is a collection of pus in the pleural cavity displacing and compressing the lung. It may begin suddenly, but rarely does so. Among the causes of empyema are those of serous effusion. Empyema is due to infection of the pleura, and in every case a bacteriological study should be made of the pus to discover the causative bacterium. The pneumococcus is the causative micro-organism in many of the cases which follow pneumonia. Pneumococci live but a short time, and in empyema due to pneumococci these micro-organisms may not be discoverable when the pus is evacuated. In most cases of empyema streptococci or staphylococci can be found in the pus. These micro-organisms may appear in an empyema induced originally by pneumococci (Stephen Paget). In empyema developing during or after typhoid fever typhoid bacilli may be discovered. In putrid empyema various bacteria are found. Bouchard thinks acute empyema has a special organism. Bacilli of tuberculosis are present for a time at least in tuberculous empyema, but may disappear, and are particularly apt to after mixed infection with pyogenic bacteria. In adults many cases, in children few cases, are secondary to tuberculosis. Empyema may be due to a wound or contusion, an attack of pneumonia, tuberculous pleuritis, phthisis, influenza, pyogenic infection of a serous effusion, caries of a rib, specific fevers, especially typhoid, peritonitis, abscess of the liver, suppurating hydatid cyst of the liver, subphrenic abscess, malignant disease of the pleura, gangrene of the lung, and pneumothorax.

Pneumonia is the common cause in children. In them we find streptococci in only 15 per cent. of the cases, and sterile fluid in 20 per cent. In 65 per cent. of the cases we find pneumococci. In adults the pus is often thin and very putrid. In children the pus is nearly always thick. Pneumococcic pus is fairly thick, contains some clots, and is white or greenish white.

Acute Empyema.—The *signs* are, in reality, those of pleuritis with effusion —viz., dulness on percussion, absent breath-sounds over the purulent matter, bulging of the intercostal spaces, and sometimes edema of the skin of the chest. The *symptoms* of acute empyema are dyspnea, pallor, cough, sweats, chills, and usually irregular fever, but fever may be absent. There is marked leukocytosis. The fingers may become clubbed. An empyema may pulsate, particularly an empyema of the left side. The cause of *pulsating empyema* has been much debated. The most probable explanation is that of W. J. Calvert ("Am. Jour. Med. Sciences," Nov., 1905). He says the requirements for such a condition are: "A firmly fixed, pulsating organ; distention of the pleural sac with fluid or air or solid material; and a collapsed condition of the lung." In all probability the thoracic aorta is the "fixed pulsating organ." The left parietal pleura is in close relation with the aorta, and most pulsating empyemas are left sided. The right parietal pleural may be "pushed against the aorta." If a lung contains air, it is elastic and compressible to a degree that enables it to absorb the aortic impulse; if it is collapsed and solid it cannot, and aortic pulsations are transmitted to fluid in the pleural cavity and the thoracic wall pulsates. A neglected empyema may break into the lung, esophagus, or pericardium, through an intercostal space, or may point in the lumbar region. When an empyema is pointing externally, the condition is called *empyema necessitatus.* A *total empyema* is a condition involving the entire pleural sac. In a *partial* or *localized empyema* the purulent matter is encapsulated. A *closed empyema* is one in which no opening has been made by the surgeon and no opening has formed spontaneously. In a closed empyema the pus is rarely putrid; in an *open empyema* the pus is often putrid. After an empyema ruptures spontaneously it rarely heals without surgical interference, a *pleural fistula,* as a rule, persisting. A *subphrenic abscess* may follow an empyema. When an empyema ruptures into a bronchus, pneumothorax arises, as a rule. Empyema may cause death by compression of the heart and lung, pulmonary embolism, pericarditis, peritonitis, cerebral embolism, cerebral abscess, septicemia, exhaustion, or rupture into a bronchus. Empyema is particularly fatal in childhood. In empyema of the early months of life nearly all the victims die. In those under one year of age 50 per cent. of the affected will die (Holt). In older children 30 per cent. die.

A small empyema due to pneumococci occasionally, though very rarely, undergoes spontaneous cure, the pus being absorbed (Stephen Paget).

A small empyema is occasionally cured by encapsulation by fibrous tissue.

Under exceptional circumstances even a large empyema may be cured by breaking externally or into a bronchus.

Empyema is so rarely cured spontaneously that it does not do to trust to Nature at all, and practically almost all cases die without surgical treatment.

Double empyema is a rare and extremely fatal condition.

Chronic empyema may follow acute empyema, or the condition may be chronic from the beginning. It is more common in adults than in children. In chronic empyema the lung is compressed, shrunken, does not expand and is strongly adherent, and the pleura is very thick. In some cases the pleura is over an inch thick. This thickening is brought about by the deposition of layer after layer of fibrin. In not a few cases a chronic empyema succeeds an acute one. Sometimes chronic empyema is maintained because a drainage-tube has slipped into the pleural cavity and remains lodged.

Treatment of Empyema.—The treatment is purely surgical, and the earlier it is applied the better. To delay allows the pleura to thicken and permits adhesions to form, conditions which prevent lung expansion and retard or even prevent cure. The results of operation for chronic empyema are better in children that are not very young than in adults. In acute empyema the prognosis is better in small collections than in large; in recent than in advanced cases; in pneumococcus empyema than in empyema due to other organisms. The surgical methods for various stages of empyema comprise aspiration, incision, rib-resection, the operation of Schede, the operation of Estlander, and the operation of Fowler (see pages 908 to 912 inclusive).

I do not believe in any of the appliances to drain with a small tube and maintain negative pressure in the chest to favor lung expansion. The Thiersch method consists in introducing a trocar into the cavity, passing a Nélaton catheter through the trocar, and removing the trocar. The external end of the catheter is attached to an easily collapsible rubber tube, the other end of which is in a bottle of water. The catheter is fixed to the side by rubber tissue and rubber plaster. "The theory is, that when the patient expires, the pus runs out through the tube, and on inspiration the collapsible walls of the tube are sucked together and prevent the entrance of air, and cause negative pressure in the chest, favoring expansion of the lung" (Lund, "Jour. Am. Med. Assoc.," August 26, 1911). In any method of suction so far devised the tube is so small that it blocks up, and though the drainage-tube may at first make an air-tight joint with the chest, it always loosens sooner or later and leaks air.

In acute empyema general practitioners are very apt to *aspirate*, and yet aspiration is almost never curative. It may cure a pneumococcus empyema in a child and an encysted empyema, but even in these it will usually fail. Aspiration is not to be considered a method of curative treatment. It is to be regarded as the surgical treatment only in a tuberculous empyema in a young person with rapidly progressing phthisis, because in such a case incision will probably prove fatal (Lockwood). It is a very useful diagnostic expedient, and enables the surgeon to prove the existence of pus, and the pus which is obtained can be examined bacteriologically. In a very large effusion it is wise to aspirate and withdraw part of the effusion a short time before operating. This enables the patient to take an anesthetic with greater safety and obviates the danger attending the rapid evacuation of a large amount of pus.

In a recent empyema, *incision* and *drainage* or *rib resection* and *drainage* will often cure the case, and yet many of the results are unsatisfactory. In some cases the discharge ceases and yet pulmonary function is not completely restored. In other cases a pleural fistula persists. If a profuse discharge is maintained, amyloid disease may arise. An acute empyema is to be drained by intercostal incision or by resection of a rib (see page 908). A chronic closed empyema is drained in the same manner, and if the lung will not fully expand and remains stationary for one year, Schede's or Estlander's operation is required. An open chronic empyema, in which the lung will not expand, requires the operation of Schede, Estlander, or Fowler (see pages 910 and 911). The results are best in children almost in the teens. Extensive decortication is sometimes impossible, and then Ransohoff's operation may be done. He calls it *discission of the pulmonary pleura* (see page 912). When there is an external opening which persists and which joins a long, narrow cavity, the condition is spoken of as *pleural fistula*, and pleural fistula is often produced by the prolonged use of a drainage-tube and sometimes by caries of a rib. Even if there is no opening on the cutaneous surface, there may be one into a bronchus. A pleural fistula may sometimes be cured by dilatation of the sinus. If this fails, and it usually does, it is the custom to resect one or more ribs.

Before resorting to operative treatment in chronic empyema we may try, in

some open cases at least, the injection of bismuth paste. We owe this method to Dr. Emil Beck. This plan will sometimes succeed. Ochsner has strongly commended it ("Annals of Surgery," July, 1909). The injection is made by a glass syringe and the material should fill but not stretch the cavity. After injecting the paste the external opening of the fistula is plugged with gauze. The treatment is begun with solution No. 1 (1 part of subnitrate of bismuth devoid of arsenic and 2 parts of yellow vaselin).

This is used every second day until pus has practically disappeared. Then solution No. 2 (30 parts of bismuth, 60 parts of yellow vaselin, and 10 parts of paraffin) is substituted for it. The injections are made often enough to keep the sinus and pocket full. They are made at first every day, then every other day, and so on until, finally, every eighth or tenth day is often enough. If poisoning should arise from these injections Beck advises the injection of olive oil at a temperature of 110° F. to dissolve the paste and favor its evacuation. McKelvey Bell recommends a paste which is more stimulating than Beck's. He takes 1 oz. of subnitrate of bismuth and 2 oz. of white petrolatum, dissolves over a hot-water bath, and stirs until cool. Then, while stirring, he adds 72 gr. of iodoform (5 per cent.). This must be kept in a dark place to prevent decomposition of the iodoform ("New York Med. Jour.," May 4, 1912). (See page 623.)

Non-traumatic Pneumothorax.—By the term "pneumothorax" is meant the presence of air in the pleural cavity. As a rule, besides air there is serous fluid or pus. It may be due to the rupture of an empyema into a bronchus; to the rupture into the pleural sac of a tuberculous area, an area of gangrene, an abscess of the lung, an air-cell in a state of emphysema, or of pulmonary tissue softened because of hemorrhagic infarction. The condition is by no means uncommon in phthisis. In 473 autopsies held in the Henry Phipps Institute of Philadelphia upon persons dying of pulmonary tuberculosis there were 41 cases of pneumothorax, or in 8.6 per cent. of the autopsies this lesion was found (J. M. Cruice, "Med. Record," Sept. 23, 1911). In 60 per cent. of the cases the lesion is on the left side. It is inaugurated by cough, straining at stool, vomiting, or lifting. It is more frequent in men than in women and is most common between the ages of thirty and forty. The immediate effect of the entrance of air into the pleural sac is to compress the lung, the degree of compression being in proportion to the amount of air present. In severe cases the lung is squeezed against the vertebral column, and the heart and diaphragm are displaced. In a right-sided case the liver may be displaced. In some cases, when the admission of air does not continue, the amount set free in the pleural sac is absorbed. In most cases pyopneumothorax (empyema) follows.

The **symptoms** usually arise suddenly (in three-fourths of the cases), and consist of distressing dyspnea, pain in the chest, lividity, and rapidity and weakness of the pulse. In some cases of phthisis the symptoms are gradual and not very severe. There may be pain and dyspnea or only dyspnea. In the latter case, if dyspnea existed before, the accident may be unrecognized. It has been pointed out that occasionally in phthisis pneumothorax seems actually to benefit the tuberculous area in the lung. There is nothing characteristic in the attitude. The patient usually lies on the opposite side, but may lie on the side of the trouble or on the back. He may sit erect or semi-erect. He may place himself in a knee-chest position. The physical signs of pneumothorax are as follows: The affected side of the chest is often bulged, movements are lessened or absent, and the heart is displaced, especially if the condition affects the left side. Palpation discovers that vocal fremitus is lessened or absent. On auscultation it is found that the breath-sounds are very feeble or absent in 70 per cent. of cases. Occasionally they are amphoric, bronchovesicular, or cavernous. The voice may be transmitted as a metallic sound (this is present in about half the cases), râles may sound metallic, and

on coughing there may be metallic tinkling. The percussion-note is hyper-resonant or tympanitic in 95 per cent. of cases. Very seldom it is normal. In some rare cases the percussion-note is dull. When fluid gathers, there is a positively dull note on percussion over the fluid.

Treatment.—Osler says the treatment should be the same as that for pleurisy with effusion. In many cases it is wise to perform paracentesis without suction to remove air and serous effusion. If pus forms, a rib should be resected and a tube inserted (see Empyema). In pneumothorax occurring during chronic phthisis operation is of service. In cases with rapidly progressive phthisis it is practically useless.

If the opening into a bronchus or air-cell remains patent, aspiration will not get rid of air; the air will enter into the pleura as rapidly as the aspirator removes it. Incision has dangers of its own: the diaphragm is flapping during respiration and may be injured (Fowler), and when the pleura is opened there is a great alteration produced in the air-pressure in the chest, and the patient may "drown in his own secretions." After incision irrigation is not justifiable, because the fluid may enter a bronchus and produce suffocation (Fowler).

West's rules[1] are those I follow. West says early incision is dangerous. In an early stage use paracentesis without suction. This will often relieve the patient. If paracentesis does relieve him, wait a while and perhaps repeat the operation if the symptoms again become severe. If paracentesis does not relieve, incise, resect a portion of a rib, and drain. If pus forms, an incision must be made and a portion of a rib be resected to afford exit to the fluid.

Fowler pointed out that if the lung is bound down by adhesions, incision is dangerous but justifiable. Operation at the proper time often prevents the lung being bound down by adhesions.

Acute Traumatic Pneumothorax.—This is produced by the sudden admission of a quantity of air into the pleural cavity as a result of a wound of the chest wall. A small quantity of air, or the gradual introduction of considerable air, does not, as a rule, produce very serious symptoms. The sudden admission of a quantity of air causes very dangerous symptoms and even death. A quantity of air may be admitted rather suddenly as a result of an accident or during the performance of a surgical operation which opens the pleura. It sometimes arises during the removal of tumors from the chest wall, during operations upon the lung, and during empyema operations. As a rule, when pulmonary adhesions exist, dangerous symptoms do not arise, even when the pleura is widely opened, and adhesions exist in 25 per cent. of empyema cases seen by the surgeon.[2]

It was formerly taught whenever the pleura is opened there is a strong tendency to the development of pneumothorax, but West has shown that the surfaces of the pleura often cohere with a force superior to pulmonary elasticity, and in such cases pneumothorax does not arise.

In surgical operations in which it is necessary to open the pleura widely (as in operation for sarcoma of the chest wall) the surgeon endeavors to prevent acute pneumothorax, which may prove fatal. This may be done by operating in the Sauerbruch negative pressure chamber (see page 905) or by applying positive pressure (see page 905).

Symptoms.—When the pleura is opened during an operation or by an injury, the symptoms may be trivial and transitory, may be tolerably severe, may be extremely grave, and the patient may quickly die (Quénu and Longuet). Rudolph Matas[3] sets forth the symptoms as presented by the French observers.

[1] "British Medical Journal," Nov. 27, 1897.
[2] Rudolph Matas, "Annals of Surgery," April, 1899.
[3] Ibid.

The mild symptoms are weak, slow pulse and irregular, noisy respiration.

The severe symptoms are slow pulse, slow and irregular respiration, and dyspnea, continuing after the anesthetic has been withdrawn.

The grave symptoms are cyanosis; collapse; small, weak pulse; shallow and noisy respiration; and spells of syncope. Death may occur suddenly from inhibition, or later from mechanical asphyxia (Matas).

Treatment.—Various plans have been adopted: suturing the opening in the pleura; plugging the opening; pulling the diaphragm into the wound in the chest wall and suturing it; and grasping the lung and suturing it to the wound. Whenever the pleura is to be widely opened, operate in a Sauerbruch chamber or use a positive pressure apparatus, and when the operation is complete, suture the lung to the margin of the opening in the pleura with a continuous catgut suture. The apparatus for insufflation anesthesia accomplishes the object. Parham, Keen, and the author followed this plan, using the Fell-O'Dwyer emergency apparatus, and the lung was kept from collapsing.[1] This apparatus is shown in Fig. 567.

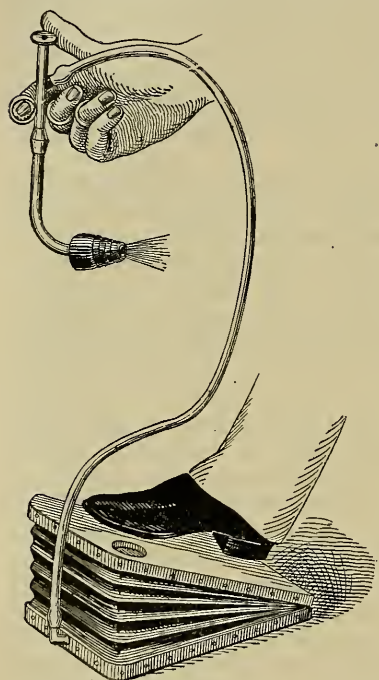

Fig. 567.—The Fell-O Dwyer apparatus. This illustration shows an early model; since then the bellows has been improved by the addition of a strong wooden frame, which holds it steadily, and is provided with a long arm that acts as a powerful foot-piece for compressing the machine with the least amount of muscular effort.

O'Dwyer's tube is introduced into the glottis as is the tube in intubation, and is attached to a bellows, the lung is inflated, respiration is maintained by the use of the bellows, and collapse, with all its dangers, is avoided. The modern positive pressure apparatus or the apparatus for insufflation anesthesia is better (see page 905). So is the pulmotor (see page 867).

Contusions and Wounds of the Chest.—Contusions.—A contusion may be trivial and limited to the superficial parts of the chest wall; it may involve the muscles; it may be associated with fracture of the ribs or sternum or with visceral injury.

Symptoms.—In an ordinary contusion without visceral injury there are considerable pain, discoloration, and often much swelling. The patient prefers to lie upon the back and the respiration is abdominal. After a severe blow upon the chest there is great shock and may even be instant death. The condition of shock so produced is called *concussion of the chest.* After a severe blow upon the chest a limited area of inflammation may arise in the pleura (*traumatic pleuritis*). Severe visceral injury is announced by positive symptoms. A *contusion of the lung* causes extravasation of blood and leads to pain, cough, expectoration of bloody mucus, dyspnea, and possibly distinct hemophthisis. Over the contused region the percussion-note is dull and on auscultation crepitus is audible. It may be mistaken for phthisis, but complete and early recovery soon dispels this fear. *Traumatic pneumonia* always follows. This usually involves a limited area of lung tissue, but genuine croupous pneu-

[1] F. W. Parham's paper on "Thoracic Resection for Tumors Growing from the Bony Walls of the Chest." Read before the Southern Surgical and Gynecological Association, November, 1898.

monia may arise after injury of the chest even when no rib was broken. The physical signs and symptoms are not evident until two or three days after the accident (Sir Thomas Oliver, in "Brit. Med. Jour.," April 30, 1910). Traumatic pneumonia may be caused by other things than external violence, viz., inhalation of illuminating gas, of dust, or of a foreign body.

In **rupture of the lung** the physical signs are dependent on the extent and situation of damage. A minute rupture would not produce definite physical signs. If the lung is ruptured and the pulmonary pleura is not, there will not be pneumothorax, but there may be cellular emphysema first becoming evident at the root of the neck. If the pleura is torn as well as the lung, there will be pneumothorax and hemothorax, the amount of hemorrhage depending upon the situation and extent of the injury.

Robt. G. Le Conte ("Annals of Surgery," March, 1908) points out five ways in which rupture may be caused: (1) *Bruising* (simply causes subpleural ecchymosis); (2) *bursting* (violent force—a lung unable to empty itself of air is broken as an inflated paper bag is broken by a sharp blow); the question as to whether the glottis must be closed for such an injury to occur is not settled; (3) *penetration* by a green-stick fracture of a rib; (4) *compression* of the lung against some resistant structure; (5) *tearing* (when the lung has previously been adherent to the wall of the chest).

These five causes might be sententiously designated as bruising, bursting, puncturing, squeezing, and tearing.

The *symptoms* are shock, dyspnea, cough with or without bloody expectoration, rapid and irregular pulse, cyanosis, emphysema (appearing first over the region of injury if a broken rib penetrated the lung, and first at the root of the neck is the lung is ruptured, but the pleura is not), and in some cases pneumothorax and hemothorax (Le Conte, Ibid.).

Rupture of the diaphragm causes pain, dyspnea, and often vomiting. The stomach or intestine may pass into the pleural sac. If this happens, there will be a tympanitic percussion-note over the displaced viscus and symptoms will vary with the viscus involved. Such a diaphragmatic hernia may become strangulated (see page 1152). In a case in the Jefferson Medical College Hospital, in which the stomach passed into the left pleural sac, there were persistent vomiting, violent pain in the chest and upper abdomen, great thirst, and displacement of the apex-beat. The condition may be confused with pulmonary rupture causing pneumothorax, but in rupture of the diaphragm persistent nausea and vomiting are prominent features; whereas, in pulmonary rupture, if they exist at all, they are early and temporary; further, in rupture of the diaphragm the tympanitic percussion-note is not found over the pleural apex, but in pulmonary rupture with pneumothorax a tympanitic note is found all over the entire pleural cavity (Le Conte, Ibid.).

Treatment of Contusions of the Chest.—A contusion of the chest wall is treated as directed in the section on Contusions (see page 259), and the chest is strapped with adhesive plaster, as in the treatment of fractured ribs. In concussion of the chest the treatment for shock is applied. It may be necessary to employ artificial respiration for a time. If a diaphragmatic hernia is diagnosticated, the abdomen should be opened, the displaced viscera restored to their proper abode, and the diaphragm sutured. The diaphragm may also be reached by resecting several ribs and opening the pleural sac. In contusion of the lung cold is applied to the chest early in the case, and any inflammation which arises is treated according to general rules. In rupture of the lung the case may be treated expectantly, but dangerous and continued bleeding or pneumothorax may render surgical interference necessary. For pneumothorax paracentesis without suction is employed. If this fails, it may be repeated. If it fails again, resect a portion of a rib and put in a tube. If bleeding is danger-

ously profuse resect a portion of a rib and insert a drainage-tube into the pleural cavity.

Wounds of the Chest.—Non-penetrating wounds are not particularly grave, and are treated according to general principles, the chest being immobilized. Penetrating wounds are extremely grave, as viscera are apt to be injured. In such a wound an intercostal artery may be severed or the internal mammary artery may be divided. An intercostal artery is rarely divided unless a rib is broken. The surgeon should always examine carefully in order to determine whether an intercostal artery or the internal mammary artery has been divided, and, in doing so, should bear in mind the admonition of Matas—that is, the bleeding from these vessels may be internal, the blood collecting in the pleural sac. The pericardium or heart may be injured (see page 404). A wound of the pleura is usually, but not always, associated with a wound of the lung. If the lung is injured, there are usually great shock, pain in the chest, dyspnea, and cough. In a large wound, damage to the lung will be indicated if air is sucked into the wound during inspiration and expelled during expiration, and if blood is forced out of the wound by coughing. The lung may be visible or may protrude (*protrusion of the lung*). In a small wound it is often difficult and sometimes impossible to determine whether the lung has been injured. Pneumothorax with pulmonary collapse proves it has. Severe hemothorax strongly suggests it. Spitting blood does not prove it. In some severe cases there is no hemoptysis; in some slight bruises the amount of blood coughed up is large. Emphysema about the wound does not prove lung injury. An incised wound of the lung is apt to produce rapid death from hemorrhage, especially if the wound is at the root of the lung. A pistol-bullet or a sporting-rifle bullet may not be productive of great primary hemorrhage; but infection will probably follow, and secondary hemorrhage will be apt to occur. The modern military-rifle ball passes through, rarely lodges, is aseptic, and often produces astonishingly little trouble. A pistol-bullet and an old-time rifle-bullet may lodge or may perforate.

Treatment.—Bring about reaction as previously directed (see page 262).

An incised wound of the chest, if large, should be carefully inspected. If the wound is small, cut down layer by layer until the depths of the wound are reached. Disinfect the wound and arrest hemorrhage. If the pleura is not open, proceed according to general rules. If the pleura is found to have been opened, suture it with catgut, close the superficial wound, dress with gauze, and immobilize the chest wall.

The above proceeding should be carried out whether it is or is not believed that the lung has been damaged, provided there is no pneumothorax and no violent hemorrhage. What course shall be pursued if the lung has been injured by a stab? If hemorrhage does not threaten life and there is no pneumothorax, the patient is kept at rest and observed. If pneumothorax occurs, the pleural sac must be drained by means of a tube, because clots must be evacuated and infection should be anticipated. If hemorrhage into the pleural sac persists, active measures become necessary. The use of ice-bags and drugs is but waste of time. Some surgeons believe that the mere closure of the external wound leads to arrest of hemorrhage, blood accumulating and making pressure. It is true that hemorrhage often ceases after suturing or plugging a wound and strapping the chest, but it is not probable that it ceases because of these measures. Blood in the pleura usually remains unclotted for several or many days. Further, as Le Conte[1] shows, as the blood is forced against the root of the lung the right heart is engorged, the blood-pressure is raised, and the bleeding continues.

Bleeding from the lung can often be arrested by inserting the end of a drain-

[1] "Annals of Surgery," April, 1899.

age-tube into the pleural sac. In cases in which a drainage-tube is inserted into the pleural cavity and free drainage established the pleura is immediately filled with air, and the muscles of respiration are kept from acting on the lung. The lung contracts by its own elastic tissue, as well as by the pressure exerted by the pneumothorax, and at the same time the presence of the air favors clotting in the severed vessels.[1] Baudet maintains that all grave wounds of the lung should be operated upon. If the insertion of a tube fails, or if the bleeding is rapid and obviously seriously threatens life, several ribs must be rapidly resected and the bleeding part explored. In some cases the bleeding may be arrested by ligation, in some cases by packing a small wound with gauze, in some cases by the suture-ligature. Two cases of lung suture have been recorded by Philadelphia colleagues (Jopson, in "Annals of Surgery," 1906, vol. xliii; Kelly, in "Annals of Surgery," 1910, vol. li). In a violent secondary hemorrhage following a gunshot-wound of the lung I packed the entire pleural cavity with sterile gauze to obtain a base of support, and arrested the bleeding by carrying iodoform gauze directly against the oozing surface.[2] The man recovered. I did the same thing on a Chinaman suffering from a gunshot-wound of the lung. The hemorrhage was arrested and he lived three weeks, dying finally from pericarditis. After directly arresting hemorrhage from the lung, turn clots out of the pleural sac and insert a drainage-tube. In a perforating wound inflicted by a bullet, reaction must be brought about, the wound dressed antiseptically, the chest strapped, and the patient kept quiet. If pneumothorax occurs, the pleura should be drained with a tube. If hemorrhage occurs, it should be met as directed above. In a wound in which the bullet has lodged, an examination should be made to see if the bullet is under the skin, and if it is, it is removed after the patient has reacted. It should always be borne in mind that a pistol-bullet may be deflected by a rib or may pass from the front to the back part of the chest by making a burrow under the skin (*a contour wound*). If a bullet is lodged, no attempt should be made to remove it unless an operation must be done for bleeding, unless the bullet causes trouble, or unless it is felt under the skin. Under no circumstances conduct a long search for a bullet. If emphysema of the chest walls is moderate, strapping or a bandage will control it; if it is great, make multiple punctures and then apply pressure. In protrusion of a portion of the lung try to restore the protrusion; but if restoration is impossible or if gangrene seems likely to occur, ligate the base of the protrusion with silk and cut away the mass.

Moller ("Archiv. f. klin, Chirurgie," 1909–10, vol. lvi) collected 26 cases of gunshot-wounds, which were operated upon, and 11 died (42 per cent.). In 20 suturing was done, with 7 deaths. In 2 the wound was sutured to the pleural opening, with 1 death. In 2 lung resection was followed by death. One, in which pleural packing was used, recovered. He collected 10 stab-wounds: 7 were sutured, with 1 death. In 3 the pleura was packed and all recovered.

Wounds of the Chest Involving the Diaphragm.—In such a case abdominal viscera may pass through the wound in the diaphragm and appear in the wound of the chest. If there is no indication of a wound of the abdominal viscera some surgeons would suture the wound of the diaphragm by way of the thorax. If there are indications of injury of abdominal viscera the abdomen must be opened. Personally, I prefer to open the abdomen in every chest wound implicating the diaphragm, even when symptoms of injury to abdominal viscera are not as yet manifest.

Occluding Pulmonary Embolism.—By this term we mean an embolism which completely blocks the pulmonary artery or some of its chief branches. Such cases occasionally follow a surgical operation. They are more frequent

[1] Le Conte, in "Annals of Surgery," April, 1899.
[2] The author, in "Annals of Surgery," Jan., 1898.

than used to be thought. The clot is derived from a vein. The calamity is most apt to occur between the second and fourth weeks after an operation (Bartlett and Thompson, in "Annals of Surgery," May, 1908). Pulmonary embolism may arise from fractures, inflamed hemorrhoids, or inflamed veins anywhere, and during or after pneumonia, erysipelas, typhoid fever, and any acute infection. In malignant endocarditis and mitral stenosis small emboli are common. If the pulmonary artery is completely blocked death occurs at once. If one branch only is blocked the patient may recover if the heart is sound and strong. If the artery proper is partly blocked the patient has a period of suffering and dyspnea before death, but death is sure to occur from subsequent complete blocking.

Bartlett and Thompson (Ibid.) report 22 cases of occlusive pulmonary embolism, 20 of which were fatal. The greatest cause in a surgical operation seems to be varicose veins, especially about an abdominal or pelvic tumor. I am convinced that most sudden deaths in infected cases are due to pulmonary embolism.

The **symptoms** of a mild case of embolism are rapid pulse, dyspnea, after some hours dulness of the base and impaired breath sounds, and, perhaps later, spitting of blood. In a real occluding embolism there are sudden collapse, cyanosis or pallor with livid lips, the pulse at the wrist is absent or very rapid, and irregular. There are pain in the chest, intense dyspnea, dilated pupils, and early unconsciousness. The right side of the heart distends greatly and the second sound is accentuated in the pulmonary area.

Schumacher in discussing these cases says there are three classes of them: Those in which almost immediate death occurs; those in which death occurs in a few minutes, and those which last much longer. In the latter cases a main branch becomes blocked and total obstruction is gradual (Willy Meyer, in "Annals of Surgery," August, 1913). Only the latter cases are suitable for operation. The surgeon must bear in mind the danger of embolism and endeavor to prevent it in operations by handling and exposing viscera as little as possible, by applying ligatures above all clots in veins and all varicosities, and removing the affected structures. Quénu proposed to lessen the danger of postoperative thrombosis by administering citric acid before operation. This agent lessens the coagulability of the blood. Tuffier fears this remedy, believing that it makes an existing thrombus more apt to break up and form emboli ("Presse Médicale," April 20, 1910).

Treatment.—In small, non-occluding emboli, in which condition the only symptoms are dyspnea, pain, rapidity of pulse, and, after some hours, dulness at the base and impaired breath sounds, give stimulants, dry cup the chest, and administer morphin if there is no cyanosis. In a very severe case death is rapid and there is nothing to do medically.

Trendelenburg, of Leipzig, suggests surgical treatment (German Congress of Surgery, 1908). He points out that death is not always sudden (in 7 cases out of 9 the victim lived from ten minutes to one hour), and advises opening of the pulmonary artery and removal of the embolus. The first patient operated on died before the completion of the operation. "Since then it was done, twelve times in all, at the Leipzig clinic, without one permanent recovery" (Willy Meyer in "Annals of Surgery," August, 1913). One patient lived four days; 1 died on the table; 1 died in fifteen hours from cardiac failure; 1 lived for thirty-seven hours and died of reactionary bleeding from the internal mammary artery. Kruger did one operation for embolism. The early result was apparently successful, but the patient died of infection on the eighteenth day ("Zentral. für Chir.," May 22, 1909). In Sauerbruch's clinic at Zurich the operation has been performed four times without a recovery (Willy Meyer, Loc. cit.).

Trendelenburg thinks that the surgeon has about fifteen minutes in which to

work. The operation is done under differential pressure. The pleura is opened, then the pericardium. A rubber tube is passed through the transverse sinus of the pericardium and the aorta and pulmonary artery are constricted. This constriction must be released within forty-five seconds. The artery is opened, the clot removed, the arterial wound clamped, and the elastic constriction released. The arterial wound is then sutured.

Abscess of the lung may follow ordinary pneumonia. It is more apt to follow aspiration-pneumonia. It is usually caused by streptococci or staphylococci, but it may result from pneumococci or colon bacilli. These germs may reach the pulmonary tissue by direct entrance from adjacent organs, by way of the blood, or by way of the bronchi and alveoli. Osler[1] tells us that pulmonary abscess may result from the aspiration of septic particles after "wounds of the neck, operations upon the throat," and suppurative lesions of the nose, larynx, or ear. Aspiration-pneumonia may develop when there is difficulty in swallowing from any cause, when there is profound exhaustion, and when there is palsy or incoördination of any of the muscles of deglutition. Cancer of the esophagus may be a cause; so may perforation of the lung by an abscess, wound of the lung, impaction of a foreign body in the lung, suppuration about a focus of tuberculosis or a metastatic abscess. A pulmonary abscess may be of trivial size or it may be very large, involving an entire lobe. There may be one abscess, several, or many. When suppuration results from aspiration-pneumonia or blood-infection, there are usually multiple abscesses.

Symptoms.—The expectoration is not frequent, but is profuse, and during a paroxysm mouthfuls are coughed up in rapid succession. The expectorated matter is sour or very offensive in odor and contains fragments or shreds of pulmonary tissue, which can be identified as such by the microscope. The patient lies upon the diseased side in order to keep the pus from running into the bronchi and causing cough. When the cavity fills and pus reaches the bronchi, violent cough and expectoration begin, continue until the cavity is partly or entirely emptied, and then subside, perhaps for several hours. If the abscess-cavity is large and full of pus, an area of dulness on percussion can be mapped out. When the pus is coughed out and the air enters, physical signs of a cavity are clear. The *x*-rays often show the situation of such a cavity.

The course of abscess of the lung is usually acute. There are fever of the hectic type, rapid loss of weight, weakness and rapidity of circulation, dyspnea, pallor, sleeplessness, and great weakness. Gangrene may arise; empyema or pyopneumothorax may develop; very rarely the abscess breaks through the chest wall; recovery may follow spontaneous evacuation or drainage by coughing up pus; death may result from exhaustion or secondary septic lesions. If operation is performed, from 70 to 80 per cent. of the patients will recover.

The treatment is purely surgical (*pneumotomy*). Make an incision over the cavity. Resect a portion of one or more ribs. Expose the pleura. If the two layers of the pleura are not adherent, suture them together and either wait two days, or surround the area to be incised by a coffer-dam of gauze and then operate. If they are adherent, always proceed at once. Search for the abscess with an aspirating needle. When the cavity is found, open into it with the actual cautery and insert a drainage-tube (see page 912). The direct mortality is about 20 per cent.

Gangrene of the Lung.—This term means the putrefaction of a devitalized portion of pulmonary tissue. The tissue is devitalized by the action of pyogenic micro-organisms. Gangrene may follow abscess, bronchitis, or pneu-

[1] "Practice of Medicine."

monia, or may be due to diabetes, to embolism of a branch of the pulmonary artery, bronchiectasis, tuberculosis, malignant disease, wounds, or the lodgment of foreign bodies. Gangrene may be circumscribed or diffused. There may be one cavity, small or large, or multiple cavities may form. The gangrenous area putrefies, softens, and the softened matter may be expectorated, a gangrenous cavity being formed. In the rare cases which undergo spontaneous cure the cavity is, after a time, surrounded by fibrous tissue and obliterated by granulations. The mortality from operation is about 30 per cent.

Symptoms.—Expectoration occurs only now and then, but at each seizure a great quantity of matter is brought up and this matter is horribly offensive. Occasionally there is no expectoration. The patient, as in lung abscess, lies upon the diseased side. The expectorated matter is mucopurulent, contains particles or shreds of pulmonary tissue, bacteria, and altered blood. The fetor of the pus is much greater than is the fetor of the pus of an abscess. The breath is very foul. Physical signs may indicate either consolidation or a cavity. There are hectic fever, great exhaustion, deathly pallor, and diarrhea. Pulmonary hemorrhage is not unusual, and complications spoken of in the article upon Abscess may occur (see page 901). Recovery sometimes ensues, the cavity closing by granulation. Death may take place in a few days. Often the patient lives for weeks, being sometimes better and sometimes worse, dying finally from exhaustion or from the effects of a complication.

The **treatment** is to operate as for pulmonary abscess.

Surgical Treatment of Pulmonary Tuberculosis.—For a number of years past surgical thought has been actively directed toward placing on a scientific footing operations for pulmonary phthisis. The matter is still in a transition stage, and operations at present have a very limited field of application, although Sonnenberg and others have reported cures. Baglivi, in 1643, endeavored to tap and inject tuberculous cavities. Hastings and Stuckè did the same thing in the eighteenth century. Mosler, a number of years ago, attempted to treat cavities by introducing a trocar into the cavity and injecting permanganate of potassium solution through the cannula. Patients were not benefited by this procedure. The plan was revived by Pepper in 1874. The results are bad and the operation is dangerous. Hillier tried injection of corrosive sublimate into the lung parenchyma, but the effect of the injections was disastrous. Vidal advocates counterirritation by the actual cautery and maintains that congestion improves nutrition. When the strength of the patient is well preserved and the pulmonary lesion is circumscribed and slowly progressive, it may, in some few cases, be justifiable to perform an operation, open the cavity, and treat it directly (*pneumotomy*). That pneumotomy might be performed successfully was suggested to surgeons by observing that some patients recovered after sword-thrusts into the lung. Fowler said it is not justifiable to operate if the disease has come "to a standstill." The same surgeon stated that the only accessible region is bounded above by the clavicle, to the inner side by the manubrium, to the outer side by the lesser pectoral muscle, and below by the second rib.[1] This operation does not cure any one, but it may cause distinct improvement when there is hectic from an ill-drained cavity containing the products of a mixed infection. In an advanced case there is usually more than one cavity, and if there is, the operation is contra-indicated. Before attempting it, be sure the case is advanced and not incipient and that the cavity is single. Locate the cavity by auscultation, percussion, and the x-rays. (See Willard, "Jour. Amer. Med. Assoc.," Sept. 20, 1902.) Tuffiier collected 45 cases and only 1 was a success.

[1] See the very full and thoughtful article by George Ryerson Fowler on "The Surgery of Intrathoracic Tuberculosis," "Annals of Surgery," Nov., 1896.

Mauclaise[1] says that pneumotomy is justifiable only in circumscribed tuberculous cavities without peripheral infiltration and in pulmonary abscesses. Bronchiectatic cavities are usually multiple; they are exceedingly difficult to locate, and treatment by pneumotomy should not be attempted. In the teatment of pulmonary tuberculosis resection of the diseased area was proposed by Ruggi (*pneumectomy*). Tuffier successfully performed this operation. Surgeons, as a rule, do not believe in pneumectomy. Reclus[2] voices the general opinion when he says the operation is not required if the area of disease is very limited, as such a condition is frequently curable by medicinal means, and it does no good if the area of disease is extensive.

Only two methods of surgical treatment seem to have won a distinct place: one is the artificial production of pneumothorax; the other, some form of plastic operation upon the thorax to collapse and immobilize the lung.

Artificial Pneumothorax.—It has long been known that pneumothorax might benefit a tuberculous lung. Carson, of Edinburgh, in 1843 tried to create artificial pneumothorax by making a puncture in the visceral pleura to allow the passage of air into the pleural sac. Farlanini suggested the introduction of a gas into the pleural sac and reported a successful case in 1894. In 1898 Murphy began the use of nitrogen. There are now on record about 400 cases (Mary E. Lapham, in "Am. Jour. Med. Sciences," April, 1912). The method should only be used in unilateral cases which are not far advanced. It is used when the patient continues to grow worse in spite of medical treatment. The method is useless if there are adhesions, and is contra-indicated if diabetes exists or if there is uncompensated valvular disease of the heart (Lapham, Ibid.). Adhesions forbid because they prevent pulmonary collapse. It is maintained that the operation occludes the lymph-channels, lessens the absorption of toxins (shown by the abatement of fever), prevents bleeding, compresses the lung, arrests its mobility, approximates the walls of cavities, squeezes masses of bacteria out of the tubes, favors the development of fibrous tissue, and leads to healing of cavities.

Certainly it seems that the once widely condemned therapeutic pneumothorax is of real value in proper cases. Nitrogen is the best gas to use. It is non-irritant and remains long in the pleural cavity. Our aim is to keep the lung compressed for one year. The nitrogen is introduced by means of a special apparatus (Lapham, Ibid.). At first injections are made daily, then every other day, then twice a week, then twice a month. The injection is made "over an area where the breath sounds and resonance are best" (Lapham, Ibid.). There is little danger in the method, but trouble may follow. There may be shock, dyspnea, or spasm of the glottis from pleural reflex. Other dangers are: gas embolism, convulsions, edema of the lung, empyema, pulmonary abscess (if the lung is stuck), cerebral embolism, and emphysema of the chest wall. A danger is an unfavorable influence on the other lung. (See Lapham, Ibid.; Mauclaire, "Abstract in Brit. Med. Jour.," from "Jour. des prat.," xxvi, 1911; Editorial in "N. Y. Med. Jour.," Oct. 26, 1912; Sorge, in "Wien. klin. Woch.," No. xxxiv, 1912.) (See page 907.)

Plastic Operations on the Chest Wall (Mobilization of the Thorax).—Freund and others asserted that a rigid thorax is a cause of phthisis. Allis[3] suggested that in extensive unilateral tuberculosis of the lung resection of a number of ribs will favor cure by permitting retraction of the chest wall. This operation is founded on the belief that the chief element in effecting a cure is the formation and contraction of fibrous tissue. Pulmonary collapse and abolition of movements favor the formation of fibrous tissue. In this

[1] "La Tribune médicale," Sept. 21, 1893.

[3] To State Med. Soc. of Penna., in 1891.

operation the pleura is not opened. Quincke, Landerer, and others remove portions of ribs with periosteum along the axillary line. Some surgeons remove portions of ribs and periosteum from directly over the lesion. In tuberculosis of the apex in a person with a narrow and rigid chest the followers of Freund remove the first rib. Freeman removes portions of ribs without periosteum and applies a truss to push in the chest wall ("Annals of Surgery," July, 1909). Friedrich, of Marburg, removes all the ribs from the second to the tenth inclusive and mobilizes the first rib (*thoracicoplastic pleuropneumolysis* with *subcostal apicolysis*). The pleura is not opened. He used to remove the periosteum, but does so no longer. He now leaves the periosteum so that after a time enough bone will re-form to prevent lung bulging on coughing. Sauerbruch, Wilms, and others have individual operations. The results of none of the above operations seem very encouraging (Mauclaire, "Abs. in Brit. Med. Jour.," from "Jour. des prat.," xxvi, 1911; Editorial in "N. Y. Med. Jour.," Oct. 26, 1912; Sorge, in "Wien. klin. Woch.," No. xxxiv, 1912).

Operations On Pleura and Lungs

Intrathoracic Operations Under Positive or Negative Air=pressure.—(This subject has been fully and judicially discussed by Jopson in "Annals of Surgery," May, 1911.) When under ordinary conditions the chest

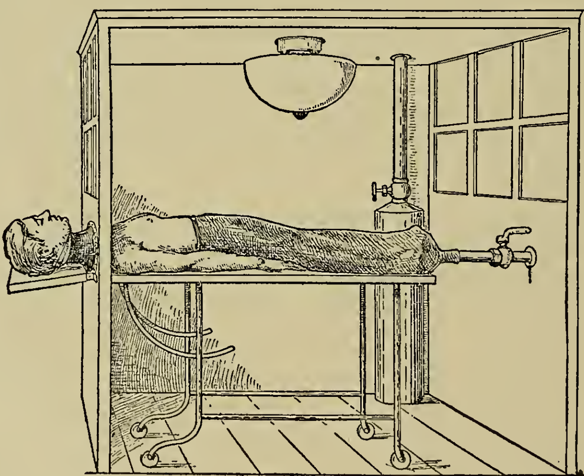

Fig. 568.—Sauerbruch's cabinet: Position of patient in chamber ready for operation under negative pressure.

wall is widely opened the lung often rapidly collapses and the patient is placed in deadly peril (see Acute Traumatic Pneumothorax on page 895). The reality of the danger has to a great extent retarded progress in the surgery of the heart, lungs, and lower portion of the esophagus. Of late, however, methods have been devised for maintaining normal respiratory movements and preventing pulmonary collapse during operations which open the pleura. There are two forms of pressure apparatus and each form finds warm advocates. Negative pressure is the form that is advocated by Sauerbruch. In Sauerbruch's negative pressure chamber the lung is kept from collapse by suction exerted upon its exposed surface. Positive pressure is advocated by Brauer. Positive pressure keeps the lung from collapsing by distending it from within. The two methods act similarly in many respects. Clinical observations and numer-

ous experiments seem to prove that "emphysema, persistent pneumothorax, difficulty of narcosis, and infection of the pleura are not dangers associated with the use of positive pressure as such" (Samuel Robinson and George Adams Leland, in "Surg., Gynecol., and Obstet.," March, 1909).

The Sauerbruch Chamber (Fig. 568).—This is an air-tight cabinet. The sides are of boards covered with tin, the corners being soldered. The roof is of glass. The sides contain air-tight windows. There is one air-tight door.

The room is lighted by electricity and contains a telephone. The larger chambers have a communicating room. Instruments which are wanted can be placed in this room so that the surgeon may reach them. The patient's head projects outside of the cabinet and a tightly fitting rubber collar is placed around the neck. The body and legs are surrounded by a canvas-covered rubber sac the interior of which is in communication with the external air.

The chamber is sufficiently large to hold the patient, the surgeon, and the assistant. By means of an electric suction air pump, the valve of which is in the wall, negative pressure is obtained and is continuously maintained in the cabinet. The patient's thorax is exposed to the suction of negative pressure, but the bronchioles are subjected to ordinary atmospheric pressure, hence, even when a wide opening is made in the chest wall, the lung does not collapse. The operator does not suffer from the negative pressure.

The Positive Pressure Apparatus.—Numerous apparatuses have been devised. Positive pressure used to be obtained by the Fell-O'Dwyer apparatus (see Fig. 567). The larynx was intubated and bellows were used. It can be obtained with this, but the apparatus is uncertain and difficult to use.

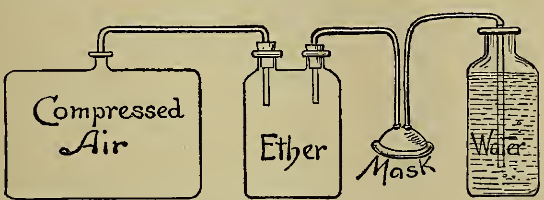

Fig. 569.—Scheme of apparatus for the maintenance of distention of the lung by positive pressure (Robinson and Leland).

Brauer advocated the following plan: When the patient has been anesthetized and the surgeon is ready to open the pleura, a glass case is placed over the patient's face and the air in the case is condensed by means of an apparatus.

Bauer subsequently modified the head chamber so that the hands and wrists of the anesthetist are admitted within it. Some surgeons have given compressed air by the nose, the mouth being sealed. Some give it by intubation from the mouth. The trouble with this method in man is that no completely satisfactory tube has yet been made. As a general thing the best way to give it is by a well-fitting face mask. A small motor runs a rotary air pump and thus we dispense with the trouble and uncertainty of clumsy reservoirs. Robinson and Leland (Ibid.) state that any positive pressure apparatus consists of four elements: (1) A supply of compressed air; (2) an anesthetizing segment; (3) a device for introducing air and ether into the respiratory tract; (4) a means of varying the resistance of exhaled air (Fig. 569).

Intratracheal Insufflation (Method of Meltzer and Auer).—This method is highly valuable. It can be used to maintain respiration and, at the same time, to give ether. The patient is first anesthetized by the ordinary method. A flexible and elastic tube is then carried through the larynx well into the trachea. In order to get it into the larynx use a tube director (Cotton and Boothby), or use Chevalier Jackson's direct laryngoscope, as do Elsberg and

Peck. The tube usually enters the right bronchus before it blocks. When it blocks it should be drawn back 5 or 6 cm. (Meltzer, in "Keen's Surgery," vol. vi). The tube is an English catheter or, as Elsberg prefers, a woven silk catheter. The eye should be at the end. It is always decidedly less in diameter than the trachea. Meltzer says the largest size used should not exceed 8 mm. in diameter. The tube is attached to the insufflation apparatus. This forces the air, the air and ether, or the oxygen and ether into the lungs, and the vapor returns between the tube and the tracheal wall.

Elsberg's apparatus is shown in Fig. 570. An electric current is turned on at the switch A. It is carried by wire to the motor C. This motor drives blower D. The air passes through a tube E, an oil filter F, and a tube G, into a bottle H, containing hot water. The air is then forced through the tube I to a rubber tube connected to the tracheal catheter. The tube I is also connected to the ether jar J. The tube P is joined to a foot bellows. This is a "safety device," for use if the motor or blower fails or if electricity is not available.

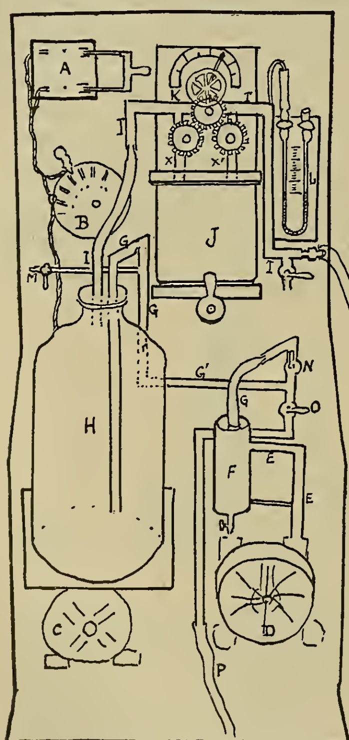

Fig. 570.—Diagram of Elsberg's apparatus showing essential parts.

Exploratory Puncture of the Pleural Sac.—Puncture often gives valuable information as to the existence of fluid in the pleural sac and as to the nature of the fluid. The operation must be performed with aseptic care, otherwise a serous effusion might be converted into a purulent effusion, and either a serous or a purulent effusion might be rendered putrid. A large hypodermatic syringe with a long and strong needle is used for exploratory puncture. A slender needle breaks easily and is unsafe. In order to prevent breaking the needle impress upon the patient the absolute necessity of keeping quiet and avoiding any violent respiratory or general movement during the operation. It is not desirable to stick the lung, although harm rarely results from such an accident. If no fluid is found in the pleura on one trial, several other punctures should be made. What is known as a dry tap may be due to the entire absence of fluid, to encapsulation of fluid in a region not invaded by the needle, to the lodgment of the point of the needle in thickened pleura or in an adhesion, or to blocking of the lumen of the needle with coagula. Fowler[1] points out that if a person has been recumbent for a long time the upper layer of fluid may be clear, while the lower layer is purulent. The fluid should be collected in a sterile glass tube and subjected to a careful bacteriological study.

Paracentesis Thoracis.—The operation of tapping with a trocar and allowing the fluid to flow out through the cannula is no longer practised except in an emergency, when an aspirator cannot be obtained, or in an early stage of non-traumatic pneumothorax. An aspirator is a much better instrument.

Aspiration consists in the introduction into the pleural sac of the tip of a hollow needle, the other end of which is attached by means of a rub-

[1] "Annals of Surgery," November, 1896.

ber tube to a bottle from which the air has been exhausted. The fluid does not run out, but is sucked out, air is excluded, and bacteria do not enter the pleural sac. Fig. 434 shows a pneumatic aspirator. No anesthetic is required. The patient's skin, the instruments, and the surgeon's hands must be thoroughly asepticized. The patient is given a little whisky, and, unless he is very weak, he assumes a semi-erect attitude, with the arm hanging by the side. The trocar is introduced in the fifth interspace, just in front of the angle of the scapula. The surgeon marks the upper border of the sixth rib with the index-finger, and plunges in the trocar just above the finger, thus avoiding the intercostal artery, which lies along the lower border of the rib above. He guards the needle with the index-finger to prevent its going in too far. The fluid is withdrawn rather slowly in order that the patient may escape syncope and violent cough. If the patient becomes very faint the operation should be abandoned. All the fluid present should not be removed at one sitting—complete removal of a large effusion is not safe. The operation can be repeated if necessary. After withdrawing the cannula place iodoform collodion over the opening in the chest. In an early stage of non-traumatic pneumothorax perform paracentesis without suction. In non-purulent pleuritic effusion, if the lungs will not expand after tappings, perform thoracotomy. In some cases aspiration is followed by pulmonary embolism or embolism at a distance. Syncope is a not unusual result. Convulsions occasionally occur. In rare cases the sudden withdrawal of a large effusion is followed by *albuminous expectoration,* as was pointed out by Pinault in 1853. It usually begins from a few minutes to half an hour after aspiration. When this complication arises the pulse is very weak, there are severe dyspnea, cyanosis, cough, and the expectoration of quantities of a yellow, frothy fluid. Riesman ("Amer. Jour. Med. Sciences," April, 1902) demonstrates that the condition is due to pulmonary edema and not to puncture of the lung. The sudden withdrawal of fluid by aspiration relieves the pressure which was compressing the lung, the lung becomes congested with blood (*congestion by recoil,* Riesman calls it), the blood distends weakened vessels, and profuse transudation takes place into the air-cells. Most cases recover in a few hours or a day or two. Severe cases die from asphyxia. Terrilon collected 23 cases, with 2 deaths. If albuminous expectoration arises, dry cup the chest and counterirritate with mustard plasters. Perform venesection. Give oxygen by inhalation. Administer atropin hypodermatically. Employ artificial respiration if necessary.

The Operation for Creating Artificial Pneumothorax.—Murphy's apparatus as modified by Brauer is shown in Fig. 571. The manometer is on the left-hand side of the figure. The jar for nitrogen (*A*) contains a solution of corrosive sublimate through which the gas flows. The water jar (*B*) is lowered and the nitrogen tube is opened, and as the stream of nitrogen passes along the glass tube it goes through a filter of sterile cotton. The tube from the jar of nitrogen joins a three-way stopcock (*C*). The nitrogen may be made to flow through the needle (*H*), or deliver the intrapleural pressure to a water manometer and a mercury manometer. After determining that the functional capacity of the other lung is sufficient to sustain the demands about to be put upon it, proceed with the operation. Follow Brauer's plan because it is the safest. Select a spot where the healthy sounds and resonance are best heard (Mary E. Lapham, "Amer. Jour. Med. Sciences," April, 1912). Expose the pleura by an incision. If adhesions are absent, puncture by a blunt instrument and explore by a catheter to be sure there is a pleural cavity. If a cavity exists attach the needle to the apparatus and inject the nitrogen. After injection suture the wound. Subsequent injections are made by the needle alone, no incision being required.

Thoracotomy is an incision into the cavity of the pleura. It may be merely an intercostal incision, or may be an opening into the chest after resecting a portion of a rib. Often in a child with empyema good drainage can be obtained by an intercostal incision, but in most children and in all adults a rib should be resected.

If there is very little dyspnea, ether may be given. If there is considerable dyspnea, chloroform should be given. If there is severe dyspnea, no general

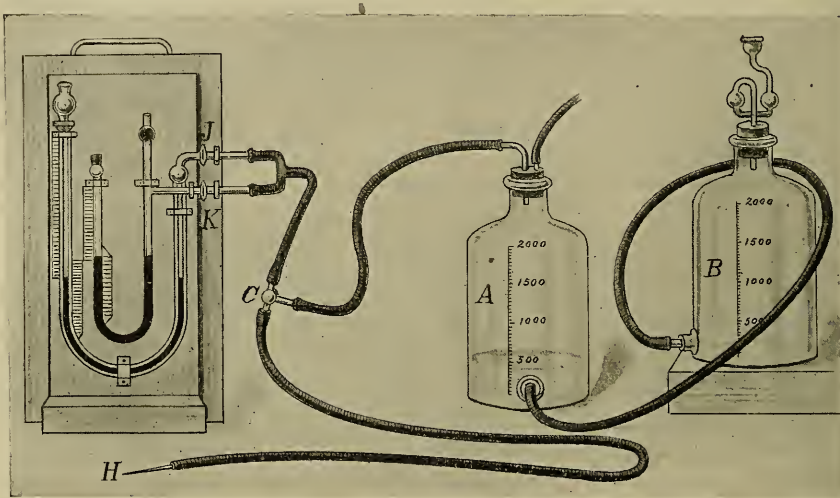

Fig. 571.—Brauer and Spengler's modification of Murphy's apparatus for nitrogen injections.

anesthetic is admissible. In severe dyspnea the patient is using certain voluntary muscles to aid him in obtaining air. A general anesthetic abolishes the activity of the voluntary muscles of respiration, and so might cause suffocation. In such cases the operation can be done with fair satisfaction after the injection of eucain or after infiltrating the superficial tissues of the chest wall with Schleich's fluid, or, what is better, preliminary aspiration can be performed. Aspiration will permit of the subsequent administration of a general anesthetic. The patient on whom thoracotomy is to be performed is placed supine, the diseased side being at or over the edge of the table. He must never be placed on the sound side, because he breathes only with that side, and pressure on it may be dangerous.

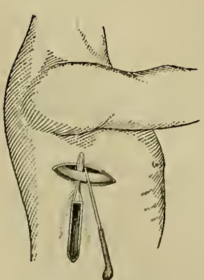

Fig. 572.—Resection of a rib (Esmarch and Kowalzig).

The arm of the diseased side should be elevated to a right angle with the body. If the surgeon desires to obtain only intercostal drainage, he should make a longitudinal incision about 3 inches in length at the upper border of the sixth or seventh rib, and the middle of this incision should correspond to the midaxillary line. This incision is carried, layer by layer, to the pleura. If, as will usually be the case, he wishes to remove a portion of a rib, he will make an incision about 3 inches in length directly upon the outer surface of the rib he wishes to remove, and the middle of this incision corresponds to the midaxillary line. Some surgeons resect a portion of the fifth rib, some remove a bit of the eighth rib, and Munro[1] shows that at the level of the eighth rib there is no danger of

[1] "Medical News," Sept. 2, 1899.

injuring the diaphragm. By many operators a portion of the seventh or eighth rib is removed in front of the line of the posterior axillary fold.

I agree with Hutton that a portion of the sixth rib in the midaxillary line should be removed.[1] The reasons given by Hutton for the selection of this rib are: (1) It is over the portion of the lung which expands last. An empyema is drained only partly by gravity, and most of the fluid is really forced out and the cavity is obliterated by lung expansion. If an incision is made anterior or posterior to this point the expanding lung will block the drainage opening, and a pus-cavity without drainage will remain in the midaxillary line. (2) Such an incision permits a patient to lie on his back without making pressure on the drainage-tube.

The periosteum of the outer surface of the rib must be divided in the same direction as the superficial incision. The exposed rib is stripped of periosteum front and back by means of a periosteal separator, and with the periosteum at the lower border of the rib the intercostal artery is lifted out of harm's way. The rib can be divided by means of cutting forceps or a Gigli saw. The usual method is to push a periosteal separator under the rib and saw the bone in two places by means of a metacarpal saw (Fig. 572). I prefer a costotome, as it accomplishes the section most rapidly. An inch or more of the rib should be removed. The intercostal artery is ligated at each end of the incision, the periosteum is removed, and the pleura is opened. The object of removing the periosteum is to prevent the rapid formation of bone which might narrow the opening and interfere with drainage. The actual opening of the pleura is carried out in the same way in intercostal incision and after rib resection. A grooved director is pushed into the pleural sac, and the opening is enlarged by means of the forceps and the finger.

The finger removes all masses of tuberculous material or aplastic lymph within reach. If the finger finds the lung firmly bound down by dense adhesions so that it cannot expand, simple rib-resection will not cure the patient. If the adhesions between the parietal and visceral pleura can be separated by the finger the lung may expand. In order to accomplish this separation a piece of more than one rib must be removed, because it is necessary to insert more than two fingers (Samuel Lloyd, quoted by Lund, in "Jour. Am. Med. Assoc.," August 26, 1911). If adhesions cannot be separated so that the lung can expand, Estlander's, Schede's, or Fowler's operation should be done. Some surgeons advocate immediate irrigation after opening an acute empyema, but this procedure is unsafe. It is true that in most cases irrigation does no harm, but in no case will it sterilize the cavity, and in some cases it is very dangerous. The pleura is very susceptible to the action of irritants. This is especially true of young children. It happens occasionally that the injection of the blandest fluid is followed by intense dyspnea, great shock, disturbances of respiration and circulation, convulsions, and even death (Quénu). The convulsions which occasionally follow pleural irrigation were called by de Cerenville *pleural epilepsy*. In putrid empyema it is proper to irrigate. Irrigation will remove part of the actively poisonous putrid matter, and the retention of putrid matter is a greater danger than irrigation. It was formerly a common custom to make a counteropening by cutting down upon the long probe pushed against the chest wall after being introduced through the incision, but a counteropening is of no particular use. A drainage-tube about 2 inches in length is introduced and stitched in place. The tube must not be long enough to touch the lung. A safety-pin is clamped upon the tube to keep it from slipping into the chest. A tape should be fastened to each side of the tube and tied about the chest to prevent it from slipping out. Arrest bleeding, suture the skin, dress with gauze and

[1] See W. Menzies Hutton on "Empyema," in "Brit. Med. Jour.," Oct, 29, 1898.

a binder, and have the dressings changed as soon as they become soaked at one point. Several times a day change the patient's position. At each change of dressings direct him to lie on the diseased side with the foot of the bed raised for half an hour. Healing takes place by ascent of the diaphragm, expansion of the lung, and retraction of the chest wall. Expansion of the lung is favored by expiratory acts; hence cause the patient several times a day to blow through a rubber tube into a 1-gallon Wolff bottle filled with water. The water is blown into another bottle attached to the first by a tube. Remove the drainage-tube when the discharge becomes thin and scanty (about the eighth or tenth day, as a rule). If an empyema ceases to improve and remains stationary for months after it has been drained, firm adhesions exist. If after one year has passed a cavity still exists and there is a flow of pus, the surgeon must perform the operation of Schede, Estlander, Fowler, or Ransohoff.

Thoracoplasty (Estlander's operation) was first proposed by Warren Stone, an American surgeon, but was set forth in detail by Estlander, of Helsingfors, in 1879. It is employed in old cases of empyema in which drainage has failed and in cases with retracted chest wall, collapsed lung, thickened pleura, and cavities whose rigid walls will not collapse. The procedure recognizes the fact that after pus is evacuated, if the lung is adherent, it cannot expand to fill the space once occupied by fluid, and that the rigid chest wall cannot fall in as a substitute for the lung. It seeks to destroy the rigidity of the chest wall and to permit it to collapse and thus obliterate the cavity of the empyema. In this operation a piece is removed from every rib which overlies the cavity. When the surgeon resects a rib and finds a cavity with uncollapsible walls, or a lung bound down with firm adhesions, he should perform thoracoplasty. This operation causes the obliteration of the cavity by collapsing that portion of the chest wall overlying it. The cavity is usually in the upper or central part of the pleural space. The instruments required are the same as those for resection of a rib. The position is the same as that for rib resection. The length of the incision depends on the size of the cavity. The surgeon usually removes portions of the second, third, fourth, fifth, sixth, and seventh ribs. Make a transverse incision along the center of an intercostal space, and through this incision remove the ribs above and below by the method set forth on page 908 (the removal of six ribs will require three incisions). Instead of this incision, we can make a vertical incision or a U-shaped flap. Always take away the periosteum in order to prevent reproduction of the ribs. In cavities which are surrounded by firm adhesions, and in old cases in which the pleura is greatly thickened, irrigation is safe. If the cavity is small, it should be packed with iodoform gauze and allowed to granulate; if large, it should be drained by a large tube, the skin being sutured by silkworm-gut.

Schede's Operation.—Schede, of Hamburg, showed that when the pleura is much thickened, even Estlander's operation will not permit the chest wall to collapse and fill the cavity once occupied by the fluid. The instruments used are the same as for Estlander's operation. A U-shaped flap is made from the level of the axilla in front to the level of the second rib and between the scapula and spine behind. The lowest level of this incision corresponds to the lowest limit of the pleura (Fig. 573). The flap is loosened and raised and the scapula is lifted with it. The ribs from the second rib down and from the costal cartilages to the tubercles are removed, along with the intercostal muscles and the pleura. This is accomplished by cutting with bone-shears and scissors. Hemorrhage is arrested. The pleura is curetted. A drainage-tube or a piece of iodoform gauze is introduced, and the raw flap is laid against the visceral layer of the pleura. The superficial incision is

sutured, except at the point where the tube or the gauze emerges. The average mortality from Schede's operation is from 15 to 20 per cent. The operation is far more often necessary in adults, but the results are much better in children.

Total Pleurectomy or Pulmonary Decortication (Fowler's Operation).—In the spring of 1893 de Lorme, of the Val de Grace, performed some experiments on dogs looking to the development of the operation. In October, 1893, the late George Ryerson Fowler, of Brooklyn, having no knowledge of de Lorme's investigation, operated on a man and cured a chronic empyema. The French surgeon's first operation was months later. De Lorme sought to do without the great mutilation of the Schede operation. His idea was to make an opening in the chest wall large enough to work through (but not nearly so large as that caused by Schede's operation), incise the dense fibrous membrane which binds down the lung, and allow the lung to expand and fill the cavity. De Lorme makes a trap-door incision. Fowler resected ribs extensively to obtain room. The thickened fibrous membrane is removed from the chest wall, lung, pericardium, and diaphragm, any sinus is extirpated, and all granulation tissue is taken away. The shrunken lung expands to fill the cavity.

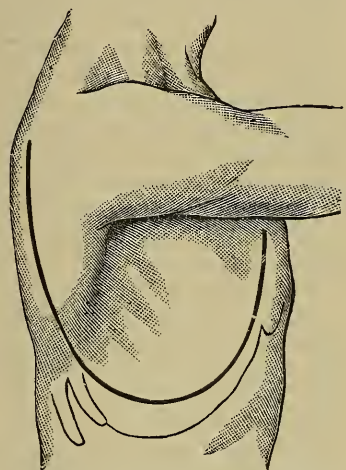

Fig. 573.—Incision for Schede's operation of thoracoplasty (Esmarch and Kowalzig).

Lund describes the operation as follows ("Jour. Am. Med. Assoc.," August 26, 1911): "In regard to the technic of the operation, the method of the resection of $1\frac{1}{2}$ inches of five or six ribs, through an incision running upward and forward from the anterior end of the old drainage incision, has proved, to my mind, very satisfactory. In slitting up the thickened pleura beneath the ribs I have had, in one or two cases, to grab the intercostal artery, but have been very much surprised to find how little trouble there has been from bleeding. The visceral pleura, which is about $\frac{1}{4}$ inch thick and which is more like the sole of an old rubber shoe than anything else, is carefully incised with a knife over the lower part of the lung. The finger is inserted through the incision and, as soon as the soft surface of the lung is felt, is swept to an fro with the pulp of the finger toward the pleura and pressing outward so as to cause the least possible damage to the lung. Then a pair of blunt-pointed scissors is inserted and the membrane slit clear up to the top of the chest, and cleared off from the lung with the finger. A wound of one or two of the air-cells resulted in 2 or 3 of my cases, allowing the escape of bubbles of air on exploration, but so small an area of the lung was affected that, apparently, no harm resulted. In regard to the after-treatment, it is probable that after the patient is put to bed the lung does retract to a certain extent, but the occasional coughing keeps up the expansion. The thick, pus-soaked dressing, if tightly applied, to my mind, acts as a more efficient valve than any mechanical valve which one could employ."

Fowler made a report of 30 cases. Eleven cases were completely cured. In 17 cases the empyema was cured, but 6 of them had tuberculosis. There were 3 deaths. The combined statistics of Fowler, de Lorme, and Cestan show 35.7 per cent. cured, 19.7 per cent. improved, 33.9 per cent. not cured, and 10 per cent. died (Kurpjweit, in "Beiträge für klinischen Chirurgie," Bd. xxxiii, H. 3).

Discission of the Pulmonary Pleura (Ransohoff's Operation).—This operation was devised by Ransohoff, of Cincinnati. It can be employed when decortication is impossible, and it may be used as a substitute for decortication in certain cases. It permits the shrunken lung to expand. It is founded on the observation that if the thickened pleura over a shrunken lung is incised the cut widens with each respiration and quickly becomes a groove (Ransohoff, in "Annals of Surgery," April, 1906). The pulmonary pleura is divided by numerous parallel incisions $\frac{1}{4}$ inch apart, and then similar incisions are made to cross these. An incision is also carried through the costal side of the angle of reflection of the pulmonary and costal pleura.

Pneumotomy for Abscess and Gangrene of the Lung.—Pneumotomy is employed for abscess, gangrene, and bronchiectasis. Give chloroform or use a local anesthetic. Place the patient recumbent with the shoulders a little raised. Make a U-shaped flap over the seat of disease. Resect a portion of a rib. If it is found that adhesions do not exist between the pulmonary and costal layers of the pleura, stitch these layers together with catgut, and either postpone further operation for forty-eight hours or surround the area by gauze and operate at once. If adhesions exist, proceed at once. Chloroform can be put aside when the pleura is exposed. Fowler called attention to the fact that lung tissue is so insensitive that the administration of an anesthetic can be suspended as soon as the pleura has been opened. Incise the agglutinated layers of the pleura, and pass an aspirating needle into the lung in various directions. When the abscess is located, open it by the cautery. Carry the Paquelin cautery slowly into the lung in the direction of the abscess-cavity. The cautery knife should be at a dull-red heat.

When the cautery opens the cavity of the abscess, withdraw the instrument and insert a drainage-tube, and suture the flap of superficial tissue. If the abscess is not found after one or two punctures by the aspirating needle, abandon the attempt.

Tuffier explores for an abscess by what he calls *décollement of the parietal pleura*. He exposes the parietal layer of the pleura, passes his hand between this layer and the chest wall, strips the pleura off over a considerable area, and is able to feel the lung beneath and thus determine its condition.

Hartmann ("Presse Médicale," April 27, 1912) states that Garré collected 96 cases of abscess, with 19 deaths, and 122 cases of gangrene, with 42 deaths. In bronchiectasis pneumotomy may be employed. Hartmann (Ibid.) combines the cases of Körte and Sauerbruch, and states that in 149 cases there were 46 cures. In Sauerbruch's 133 cases there were 40 cures, 43 deaths, and 7 were improved.

XXVII. DISEASES AND INJURIES OF THE UPPER DIGESTIVE TRACT

Injuries and Diseases of the Face, Nose, Mouth, Salivary Glands, Tongue, Jaws, and Esophagus.—**Closure of the Jaws.**—This condition may be caused by tetanus, by the irritation of a non-erupted wisdom tooth, carious teeth, by cancer of the mouth, sarcoma of the jaws, alveolar abscess, cicatricial contractions due to burns or noma, and temporomaxillary ankylosis.

Temporomaxillary Ankylosis.—Ankylosis of the temporomaxillary joint may result from gonorrheal arthritis, rheumatoid arthritis, or fracture of the condyle. Even when one joint is completely ankylosed, the jaws upon the sound side can be somewhat separated because of the elasticity of the mandible.

Treatment.—Gradual dilatation by means of box-wood screws is useless. Violent separation is without value. After either method the condition always

recurs rapidly. Esmarch removed a wedge-shaped piece of bone from the angle of the jaw in order to form a false joint. Other operators do a like operation on the ramus. A simple osteotomy is certain to fail because bony union will occur. That is the trouble with Swain's operation (sawing the body at the angle). Bony union may be prevented by resecting the zygoma and putting a flap of temporal muscle between the fragments (Helferich). Removal of the condyle and a portion of the neck is usually efficient. In double ankylosis both condyles should be resected. Verneuil, in 1860, suggested mobilizing the joint and interposing an attached flap of temporal muscle between the condyle and the socket. Such an operation may give a gratifying result.

Alveolar Abscess.—This condition is caused by a decayed tooth. A superficial abscess is known as a *gum-boil.* The process may spread to the jawbone, causing necrosis. From the maxilla the suppuration may enter the antrum. From the lower jaw pus may track into the neck.

Treatment.—Early and free incision, usually, but not always, the extraction of the offending tooth, and drainage.

Necrosis of the Jaw.—Extensive necrosis is much more common in the lower than in the upper jaw. Necrosis of the alveolar process of either jaw may be due to suppurative periostitis, the result of carious teeth. In suppurative periostitis of this form an alveolar abscess arises which is followed perhaps by circumscribed necrosis. In rare cases widespread suppurative periostitis occurs which may result in extensive necrosis.

Syphilis produces periostitis and osteomyelitis, but more commonly causes caries than necrosis. Tuberculous periostitis may result in limited necrosis. Its most common site is the orbital margin of the maxilla.

Actinomycosis is a rare cause of necrosis. In mercurial salivation extensive necrosis is prone to occur. A child suffering during dentition from an exanthematous fever or other virulent infection is liable to a violently acute suppurative periostitis and osteomyelitis with evidence of severe general infection. In the lower jaw particularly extensive and usually symmetrical necrosis follows.

Treatment.—In an acute suppurative periostitis remove a carious tooth (if one exists), incise the gum to the bone; if osteomyelitis exists open the outer plate of the bone, order frequent cleansing of the mouth by antiseptic washes. In syphilitic caries place the patient on antisyphilitic treatment and use a curet to remove carious bone. In tuberculous caries use a curet and employ antituberculous treatment.

When necrosis occurs it is usual to wait until the sequestrum loosens and to then remove it through the mouth or nose. Early sequestrectomy is a better plan. If there is profuse suppuration, remove the dead bone by subperiosteal resection (Tillmanns's "Text-Book of Surgery").

Phosphorus Necrosis.—This condition was first described in 1845 by Lorinser. It is seen among those who make matches from yellow phosphorus. Recent legislation against yellow phosphorus is wiping out the disease. It is most common in the lower jaw. The fumes enter carious teeth. About such teeth ossifying periostitis or suppurative periostitis and osteomyelitis occur. Even when the process begins as ossifying periostitis suppuration occurs, either between the periosteum and the new bone or between the new bone and the older bone. The bone enlarges enormously and very extensive necrosis takes place. The entire lower jaw may be lost. Bones of the base of the skull may be destroyed. Tillmanns (quoting Maas, Binz, and others) says that arsenic and pyrogallic acid tend, like phosphorus, to produce ossifying periostitis.

Treatment.—Entire removal of the victim from the fumes, living in the open air, the frequent use of antiseptic mouth-washes, incisions if pus forms, early subperiosteal sequestrectomy by means of a chisel and mallet.

Wounds of the Salivary Glands.—An aseptic wound usually heals and rarely results in a salivary fistula, although after healing it is not unusual for an encysted collection of saliva to gather under the skin. Such a collection of saliva, if it does not disappear spontaneously, can usually be gotten rid of by continued pressure. When a wound of a salivary gland is infected a single fistula or multiple fistulæ may be left as a legacy. A salivary fistula is very annoying, because the saliva flows constantly. A fistula of a gland usually heals spontaneously after a long time, but healing may be quickly brought about by touching the orifice with the Paquelin cautery.

Wound of Steno's duct is apt to cause a fistula, and the condition is often difficult to cure. In this condition, when the duct was cut across, the central end grows fast to the cutaneous surface. Fistula of Steno's duct may also be caused by obstruction and rupture of the duct and by suppurative or gangrenous processes.

In wounds of the duct the ends should be brought as near together as possible by catgut sutures which do not enter the lumen of the duct; if the mucous membrane is not already opened an incision should be made through it to permit drainage of saliva into the mouth, and the skin should be sutured. In some cases the central end of the duct may be carried into the mouth and sutured to the mucous membrane. If, after an injury of Steno's duct, saliva gathers under the skin, make an incision through the mucous membrane to give a route for the saliva to enter the mouth, and apply pressure externally. When an external fistula forms, it may perhaps be cured by the cautery and pressure, but, if the peripheral portion of the duct is obliterated (which can be determined by a sound) a cutting operation must be performed. Tillmanns advocates cutting out the external portion of the fistula by two elliptical incisions. A trocar is passed through the bottom of the wound in two places, about $\frac{1}{2}$ cm. apart; a piece of stout silk is drawn through the holes and tied tightly and the superficial incision is closed. The silk cuts through and makes an internal fistula. Another method is to make an incision, find and isolate the central end of the duct, open the mucous membrane, suture the duct to it, and close the superficial wound.

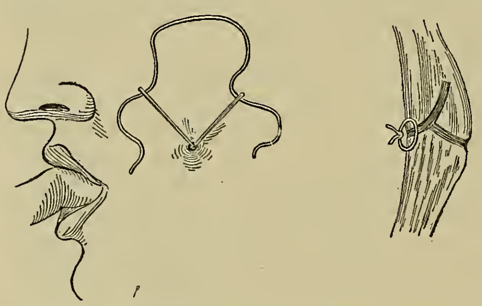

Fig. 574.—De Guise's operation for salivary fistula (Esmarch and Kowalzig).

De Guise's operation is shown in Fig. 574. He threads a piece of silk through two needles and carries the needles into the mouth so that the silk will embrace a bit of tissue $\frac{1}{2}$ cm. in length. The silk is tied tightly within the mouth, the ends are cut off, and the margins of the fistula at the surface are freshened and sutured. I prefer silver wire to silk.

Parotitis.—Mumps, or epidemic parotitis, is treated by the physician. In this condition the submaxillary and sublingual glands are usually involved as well as the parotid. In pyemia, metastatic abscesses may form in the parotid gland. Great swelling arises, respiration is often embarrassed, and early incision is necessary. Parotid inflammation other than mumps is usually due to the passage of bacteria up Steno's duct, the source of the microbes being a foul condition of the mouth, particularly noma or stomatitis. Hence such inflammation is most common during the existence of acute infectious diseases and sepsis. Suppuration or even gangrene may occur. As a rule, only one

gland is attacked, but both may be. It is a well-known fact that occasionally, though very rarely, after an abdominal operation inflammation of the parotid gland occurs. The condition is more common in adults than in children. This form of parotitis may, of course, be due to septic metastatis and may be produced by trauma, but I am satisfied that most cases result from foul mouths, the infection ascending from the mouth along the duct. Oral cleanliness tends strongly to prevent the so-called *sympathetic parotitis*. In about one-third of the cases the condition is not to be distinguished from mumps and is recovered from in seven to eight days. Mild cases seldom suppurate, and if they do, the pus may flow down the duct into the mouth. In nearly one-half of the cases, according to Marchetti ("Epitome of Surgery," in "Brit. Med. Jour.," March 6, 1909), there is phlegmonous inflammation with necrosis and suppuration of the tissues and formation of a salivary fistula. In non-suppurative parotitis there are pain, tenderness, obvious swelling, and hyperemia of the skin, and it is difficult to open the mouth or swallow. When suppuration occurs, all of the above symptoms are intensified, the discoloration becomes dusky, the skin becomes shiny and edematous, the constitutional symptoms of pus formation exist, and there is usually delirium.

Treatment.—In the non-suppurative form apply heat. Wash the mouth out frequently with an antiseptic wash and apply ichthyol and lanolin to the swollen region. In the suppurative form make several openings by Hilton's method, seeking for points of softening; apply hot antiseptic fomentations, wash the mouth frequently with an antiseptic fluid, and combat sepsis by appropriate constitutional treatment.

Salivary Concretions.—The saliva contains in solution certain salts which may be deposited. Deposited on the teeth they constitute tartar. Deposited in a salivary duct or the acini of a gland they constitute a calculus. The salts deposited are carbonate and phosphate of lime. A calculus may consist purely of these two salts or there may be a foreign-body nucleus. A calculus is a possible result of an inflammation which blocks, constricts, or roughens a duct or acinus and decomposes saliva. Small concretions are often passed. Concretions the size of a bean are retained. A concretion may attain the size of an English walnut. A concretion does not block a duct continuously, but does so now and then, causing swelling and tenderness of the gland. A retained calculus can be palpated by a finger in the mouth and a finger externally.

Treatment.—A calculus in a duct is extracted by making an incision through the mucous membrane. If a very large calculus forms in the submaxillary gland, the gland should be removed through an external incision.

Lymphomata of the Salivary and Lachrymal Glands (Mikulicz's Disease).—Mikulicz, of Breslau, described this condition in 1888. It is a chronic, brawny, and non-inflammatory swelling, painless though sometimes tender, and unconnected with any known systemic condition. In Mikulicz's early cases the lachrymal, parotid, and submaxillary salivary glands of both sides were enlarged, hence he regarded it as symmetrical. We now know that non-symmetrical cases occur, in fact, only one gland may be enlarged, although, of course, such cases may eventually develop growths on the other side. In some cases the sublinguals have been involved, in some the accessory lachrymals, in some the glands of Nuhn and Blandin. In a case of Osler's there was enlargement of the spleen, tonsils, and cervical lymph-glands. In a typical case the cheeks are much broader than natural, and the eyelids droop on the temporal side like "those of a bloodhound" (Ziegler, in "New York Med. Jour.," Dec. 11, 1909). The mouth is very dry because of deficiency of salivary secretion. The conjunctiva is dry for want of enough tears. Chronic inflammation in the nasopharynx is not unusual.

The condition may occur at practically any age after three or four. A case four years of age has been reported. The glands may undergo regression during pneumonia, appendicitis, or some other infection. The cause is doubtful. Some think it is due to bacteria, but the tissue is not inflammatory, being merely hyperplastic lymph tissue. Others regard it as due to a toxic material in the blood. Ziegler believes that the causal toxic material comes from the nasal sinuses.

Treatment.—Arsenic internally will perhaps produce cure. The iodids are used by some and pilocarpin has been recommended. The *x*-rays should be applied. Operative removal has not been successful. All diseased conditions of the nasopharynx should be corrected, if possible. (See Ziegler's thorough study, in "New York Med. Jour.," Dec. 11, 1909.)

Harelip and Cleft-palate.—*Harelip* is a congenital cleft in the upper lip due to defective development. *Cleft-palate* is a congenital fissure in the soft palate or in both the hard and soft palates. In harelip the cleft is usually complete, through the entire lip into the nostril, but in rare cases it may show only as a furrow in the mucous edge or as a split from the nostril partly into the lip. It is most common on the left side. In double harelip the central portion of the lip is often adherent to the tip of the nose. Double harelip may be free from complication, but is often associated with a malformation of the alveolus and palate. The term "harelip" is a poor one, as the cleft in a hare's lip is the shape of the letter Y, the stem of the Y being median and an arm entering each nostril. Median harelip is exceedingly rare. Dupuytren said it never occurred, but at least 9 cases have been reported (Ransohoff, in "Lancet Clinic," Nov. 2, 1912). Ordinary or lateral harelip is due to failure of fusion of the lateral maxillary and frontal processes. Median harelip is due to "failure of union between the lateral tubercles of the frontonasal process which is placed on each side of the middle line" (Ransohoff, Ibid.). We recall His's teaching, that the central portion of the upper lip is formed from the lower portion of the frontonasal process by the fusion of its two buds (Ransohoff, Ibid.). In cleft-palate the septum of the nose is usually adherent to the palatine process opposite the side upon which the fissure exists. In those rare cases of cleft-palate double in front, the nasal septum is attached only to the premaxillary bone, and the premaxillary bone is not attached at all to the superior maxillary bone. In harelip there is frequently a cleft in the alveolus, and almost always flattening of the corresponding side of the nose. Harelip is often associated with cleft-palate, talipes, and other deformities. It is a great deformity, and interferes with sucking, swallowing, and articulation.

Operation for harelip uncomplicated by cleft-palate should be performed between the third and sixth months of life in a child in good health, free from stomach trouble, cough, or coryza, but operation is not advisable in the early weeks of life. Always, if possible, operate before dentition begins (seventh month). If the child is in poor health, postpone the operation until restoration has so far advanced as to render operation safe. While waiting for operation be sure the child is getting enough food. If it cannot suck, feed it with a spoon. If a cleft exists in the palate, we sometimes operate first upon the lip, because the pressure of the parts after the edges of the gap are approximated aids in the closure of the bony cleft. In other cases we operate first on the palate. Cleft-palate interferes with sucking, deglutition, mastication, and articulation. In severe cases the food passes into the nose and excites inflammation. Loss of control of the palate muscles always exists, and liquids and solids are liable to pass into the wind-pipe. Clefts in the hard palate should not be operated on until the second year, but should be operated upon then, otherwise speech will be permanently affected. Some surgeons refuse to operare until the tenth or twelfth year, but operation done this late will not correct

speech defect. The patient at the period of operation should be well and free from cough. In many cases the passage of food and drink into the nose can largely be prevented by the use of a diaphragm.

Operation for Harelip.—Wrap the child in a sheet; place it in the Trendelenburg position, and rest the head upon a sand-pillow. The surgeon stands to the right side of the patient. Ether or chloroform is given. For *single harelip*, separate with the scissors the upper lip from the bone on each side of the cleft until approximation of the edges can be effected without tension. If the premaxillary bone of one side projects more than its fellow, grasp it with sequestrum forceps and bend it back (Jacobson and Treves). Clamp the upper lip at each angle of the mouth to prevent hemorrhage. If the edges are of equal or nearly equal length, and if the gap is not very wide, perform Malgaigne's operation. This is performed as follows: A flap is detached on each side, the detachment beginning at the upper angle of the gap; each flap is detached above, but remains attached below. The flaps are separated from the bone, and are drawn downward so as to form a prominence at the vermilion border (Fig. 575). If the edges are pared so that in closure the vermilion border is even, when the parts are healed a gutter will be visible at the line of union. The edges are approximated by an assistant, and silkworm-gut sutures or silver wires are passed by means of a straight needle. Each suture goes down to the mucous membrane. The first suture is passed through the middle of the lip, $\frac{1}{8}$ inch from the cleft. Three or four

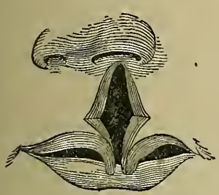

Fig. 575.—Malgaigne's operation for harelip.

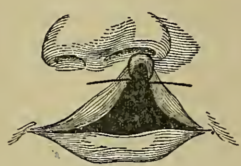

Fig. 576.—Mirault's operation for single harelip (Esmarch).

Fig. 577.—Incisions for double harelip (Esmarch and Kowalzig).

main sutures are passed through the thickness of the lip, and are tied and cut off. Two or three fine silk or catgut sutures are passed by a curved needle through the vermilion border of the lip and the mucous membrane of the mouth, and are tied and cut off. A small piece of gauze is placed over the lip and is held in place by straps of rubber plaster. After operation prevent the child crying by feeding it often and giving it small doses of laudanum. Heath orders 2 drops of laudanum in 1 oz. of distilled water, a teaspoonful to be given every two or three hours. About the sixth day one-half the sutures are taken out, and on the eighth or ninth day the remaining ones are removed. In many cases no further procedure is necessary, but if after some weeks the prominence at the lip border does not shrink, it can be readily clipped away. Harelip-pins are not used at the present time, and are not needed if the lip is well separated from the bone. If the edges of the cleft are of unequal length, Edmund Owen's operation can be performed (see below, under Double Harelip), or we can perform Mirault's operation, as shown in Fig. 576.

In *double harelip* the operation is similar to that for single harelip. If the intervening piece is vertical and is covered with healthy skin, complete each operation as for single harelip, closing both fissures at once with silver wire in a strong, healthy child, closing them at intervals of three weeks in one not so lusty (Fig. 577). Excise the septum if it is deformed. The premaxillary bone should in most instances be removed, the skin over it being preserved. Sir William Fergusson was accustomed to incise the mucous membrane and shell out

this bone. The premaxillary bone can be forced back into line, being held, if necessary, by catgut suture of the periosteum; but if saved, it is liable to necrose and its teeth soon decay. Heath removes this bone two weeks before operating on the lip. If there is much hemorrhage after removal of the bone, arrest it with a hot wire or with Horsley's wax. Figure 577 shows incisions for double harelip. Edmund Owen's operation is very useful (Figs. 578, 579). In this operation very thick flaps are cut. The prolabium and incisive bone are removed. The flaps are cut as shown in Fig. 578, on one side by a line *a–b*, and on the other side the piece *c–d–e* is removed; *a* is brought to *e*, *b* is brought to *d*, *f* is brought to *c*, and sutures are applied (Fig. 579).

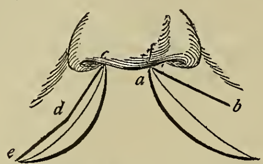

Fig. 578.—Double harelip, the prolabium and incisive bone having been removed (Owen).

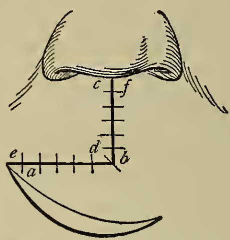

Fig. 579.—The two sides of the lip drawn together and secured by sutures (Owen).

Operation for Cleft-palate.—It is true that during the early years of its growth a cleft diminishes in size, and particularly if a harelip is closed, but to wait too long before we operate means permanent speech impairment. Bony clefts should be operated upon early in the second year. Clefts of the soft palate only may be operated upon during the first six months of life. If both the hard and soft palates are cleft, close both at one operation. In an ill-nourished child in which the covering of the bone is obviously thin it is best to postpone any operation upon a bony cleft until the end of the third year. I agree with Berry that operation is justifiable up to the age of twenty, but early operation is highly desirable. Edmund Owen put forth a convincing plea for early operation.[1] He says he is operating earlier and earlier, and quotes Chilton as the gentleman who led him to do so. Owen maintains that if speech is to be improved, operation must be done early, and he formulates some very valuable rules for preparation and care. I have never been convinced that operation in early infancy is sufficiently safe or has any notable advantages. When one comes to treat congenital clefts of the lip, the alveolar process, and the hard and soft palate, the necessities one should seek to obtain are the surgical closure of the clefts, the establishment of the function of the involved tissues, the correction of the congenital deformity, and the prevention of postoperative or acquired deformity. There are few if any cases of cleft-palate that cannot be successfully treated by surgical means; and it is a very unusual thing for a case really to need any mechanical appliance, such as the obturator and velum.

In deciding upon the time for operating and the nature of the operation, the safety of the patient should be the first consideration. One must carefully consider the physical condition, especially in respect to nutrition. An operative method that has a greater mortality than is incident to minor surgery ought not to be selected, and no operation should be performed until the condition of the patient justifies it. Having considered the physical condition of the patient and the relative safety of different operative plans, a careful study of the individual case should be made, and in this study each of the four requirements above set forth must be attentively regarded. If we succeed in closing the cleft without establishing the function of the tissues, without correcting congenital deformity and without preventing postoperative

[1] "Lancet," Jan. 4, 1896.

or acquired deformity, we leave the patient worse off than he was before, and perhaps render subsequent satisfactory treatment impossible.

We should attempt to secure closure of the cleft with the least possible formation of cicatricial tissue. The simplest technic is the best, and we should endeavor to avoid all unnecessary additional traumatism. One should refrain from passing additional approximation sutures, from bruising the tissues by overtension or by traction-forceps, and from using large needles and coarse suture materials, which make large suture-cicatrices. The amount of scar tissue bears directly upon the functional result. In addition, when dealing with the lip, and especially with the soft palate, one must seek to avoid incisions that involve muscles, and particularly the nerve-supply of muscles.

The periosteal-flap operation separates portions of the soft palate from the palatine bones. A large amount of cicatricial tissue is necessary to effect repair, and this mass of new tissue lessens the good functional results. In the periosteal-flap operation the repaired soft palate is anterior and inferior to the position secured by the osteoplastic method and, to that extent, interferes with the closure of the nasopharynx. Nevertheless, in my opinion, the operation which uses the soft tissues only is by far the safest and is the one I usually employ. In cases of complete cleft associated congenital deformities are especially manifest in the nose, lips, premaxilla, and maxillæ.

To correct congenital deformities and to prevent postoperative or acquired deformities is the most neglected and the least understood phase of the subject, and it is a very complicated question to hope to make clear in a brief statement. The key to the difficulty is the normal contour of the face as established by the proper occlusion of the permanent teeth. In finding this out there is no better guide than the rules laid down by Dr. Angle in the latest edition of his "Orthodontia." He maintains that every tooth must be held in its proper relation and occlusion; and that if any teeth are lost they must be replaced in order to establish or restore the proper expression and contour of the face. To comply with the foregoing requirements one should avoid any operation that would not maintain or would fail to replace the normal position of the premaxilla and the maxillæ and their future complement of teeth. If the premaxilla is only slightly in advance of its normal position, the early closure of the cleft of the lip will help to replace it. If, however, the premaxilla is far in advance of its normal position, it is hopeless to expect the pressure of a reunited lip to restore it to position. In such a case sufficient of the nasal septum posterior to the premaxilla must be resected, and the premaxilla must be carried back and sutured in position; but this operation should be done after the closure of the cleft soft and hard palates, and seldom at the same operation. If the cleft is unilateral in relation to the premaxilla and that bone is swung to the opposite side, and anterior to its normal position, the pressure exerted by an early repaired lip will often correct the condition. Until the deciduous incisors have erupted it is difficult to determine how far the intermaxillary bone really protrudes; and it is often surprising to observe how little correction is needed in what had appeared to be marked protrusion of the premaxilla in a unilateral or bilateral cleft. If in doubt about this point it is better to wait until the eruption of the deciduous incisors, when one may decide with certainty whether there is enough anterior protrusion to warrant the closure of the lip before operation on the palate. Early closure of the cleft of the lip brings very considerable pressure to bear, especially in double cleft or the typical harelip, as the lateral portions are comparatively short and the lip is usually quite tense. Sometimes this pressure is quite efficient, when exerted upon these cases of protrusion of the premaxilla, which are frequent, and of lateral separation of the maxillæ, which are infrequent; but when such pressure is exerted upon cases without protru-

sion or separation, it produces an unfortunate postoperative deformity, and one that is too frequently encountered. It causes the alveolar arch to lose its parabolic curve, and what should be an arch is frequently V shaped or triangular, and not infrequently the cuspid teeth are closely approximated. One thus gets marked flattening of the anterior lateral region of the face or cheek, with loss of contour and position of the upper lip and apparent protrusion of the lower lip and chin. It is true that such a postoperative deformity can be corrected by modern orthodontic methods, but it is better to prevent it than to be obliged subsequently to correct it.

From the preceding remarks it is evident that it is to be regarded as advisable in many cases to close the cleft in the soft and hard palates before operating upon the lip. The best time for operating is just before the patient begins to employ articulate speech. In most cases the cleft in the alveolar process, including the floor of one or both nares, should be repaired separately, and subsequently to the repair of the hard and soft palates. A comparatively short time after operating upon the palate the lip may be repaired, and the lip also should be repaired before the establishment of articulate speech. An advantage in operating with the harelip still unclosed is that one can see better and work better during the operation on the palate, and can give the palate better local care after the operation. Unfortunately, however, many children with cleft palates are never brought for advice until they have cultivated articulate speech. It is always very difficult and often impossible to correct the manner of speaking that they have taught themselves. Only long training and much perseverance is of any avail. The earlier the operation is performed, the better will be the result—not only from the functional standpoint, but also as regards the correction of existing deformity and the prevention of future deformity. So far as obtaining good surgical results go there is practically no set age limit.

If operation is refused for cleft of the hard palate, if it offers no real hope, or if it is very dangerous, an obturator must be worn. An obturator is made by a dentist. In preparing a child for operation I follow Edmund Owen's rules, viz.: Have the child in the best condition, free from cough and stomach disorder. Operate in summer. Place the child under the charge of a nurse several days before the operation.

Operation for Suture of the Soft Palate (*Staphylorrhaphy*).—The operation of staphylorrhaphy, which is applied to clefts of the soft palate alone, is a comparatively easy procedure. In performing this operation the patient should be anesthetized and be placed in the Trendelenburg position, or else with the head hanging over the end of the operating table. The mouth is held open by Whitehead's gag, and an assistant holds an electric light and a reflector to illuminate the oral cavity. If the patient is not a young child, the operation may be done under cocain, with the subject sitting erect in a chair and the surgeon sitting directly in front of him.

The surgeon should have at hand several knives of different shapes. The double-edged, pointed knife is an excellent one for freshening the margins of the palate. Special forms of needle-holders have been devised for the purpose of carrying the needle. The heavy, curved, sharp-pointed bistoury is the best instrument for dividing the muscles of the palate; and a sharp hook should be at hand, in order to catch the edge of the cleft, if necessary.

The surgeon first of all separates the soft palate from the posterior edge of the palate bones and from the nasal mucous membrane. This step is necessary in order that the edges may meet in the middle line (Berry). One edge of the cleft uvula is now grasped with a pair of forceps or a sharp hook, and is pulled upon to make it tense. This edge is then pared from below

upward, the piece being continuous from the base to the apex of the cleft. This piece is severed, and then the other margin of the cleft is pared in the same way. It is now advisable to free the margins of the wound from tension. These lateral incisions not only relieve tension, but temporarily paralyze the soft palate. Figures 580 and 581 show the incisions as recommended by Berry. These incisions divide the tendons of the levator palati and the palatopharyngeus muscles and temporarily paralyze the palate. The impairment of palate function is not permanent, as the nerves to the muscles are not cut.

The sutures are inserted by means of a special needle-holder, so arranged that the needle may be directed in many different positions when grasped. The sutures are introduced from below upward, silkworm-gut being used for the uvula and the lower part of the velum, and silver wire for the balance of the cleft. Each suture, as it is passed, is tied or twisted, and it is not cut off until the next suture is inserted, and thus serves as a handle. If there is too much tension to allow of the sutures being tied as they are inserted, all the sutures are passed and lightly twisted before one is tied.

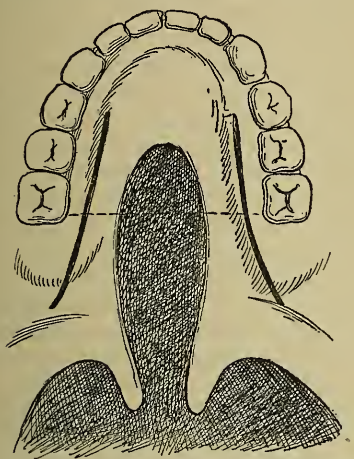

Fig. 580.—Cleft of soft and part of hard palate. Shows exact situation in which the lateral incisions should be made (Berry).

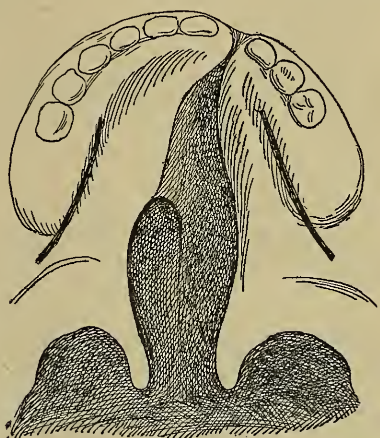

Fig. 581.—Semidiagrammatic view of complete left cleft palate. The septum nasi is attached to the palate on the (patient's) right side. The mucous membrane on the left side of the septum may be detached and brought down if necessary to help in the closure of the anterior half of the cleft. Shows exact situation in which the lateral incisions should be made (Berry).

Closure of Clefts in the Hard Palate (*Uranoplasty*).—As previously stated, the best time to perform these operations is during the second year of life. In some few cases we postpone the operation until the end of the third year. If the child learns to talk with the palate cleft, articulation will never be very greatly improved, even by operation. One should, therefore, try to operate before the child learns to talk. Even after the closure of the cleft the speech does not become entirely normal; in fact, as Berry says, it never becomes even very good. One should exercise the greatest care in forming the soft palate, because good articulation is largely dependent upon a well-formed soft palate (Berry, in "Brit. Med. Jour.," Oct. 7, 1905). The surgeon may be able to close the entire gap at one operation; or, owing to undue tension, he may be forced to close it but partly, completing the closure at some subsequent period.

The operation that to my mind is the best is one that uses the soft tissues alone—such a one as is advised by Berry. I have entirely abandoned the operation of wedging the bone over with a chisel. I am satisfied that it

is far more dangerous than is the other method; it is more liable to fail; and, if it fails because of necrosis, it is difficult or impossible to cure the defect by a second operation. The essence of a successful operation, using the soft tissues alone, is, as Berry insists, the complete detachment of the soft palate from the posterior edge of the palate-bone (Fig. 582), because, if one fails to secure this, the edges of the gap will not approximate in the median line. One should also separate the soft palate from the mucous membrane of the nose (Fig. 582).

A second very important point is the imperative necessity of making incisions to the sides to relieve tension and to paralyze for a time the soft palate. The incisions, as recommended by Berry, are shown in Figs. 580, 581. The cut is close to the teeth, and is taken as far posterior as the middle of the soft palate, at the junction of that structure with the lateral pharyngeal wall. In this cut there is some risk of dividing the anterior palatine artery, but hemorrhage from this vessel can be arrested by pressure. Berry insists that the incision need not go forward more than the level of one or two premolar teeth; or, in older children, to the first or second molars. The edges of the fissure are pared on each side, from the tip of the uvula to the top of the gap. Strips of the mucoperiosteum are lifted up on each side of the gap and shifted toward the cleft, and at this stage the posterior border of the soft palate is separated from the posterior border of the hard palate (Fig. 582).

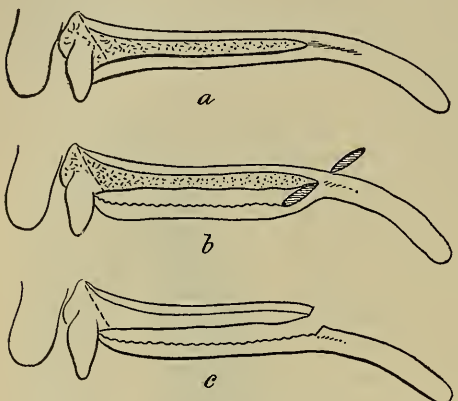

Fig. 582.—Longitudinal vertical section through the hard and soft palates: *a*, Before operation; *b*, palatine mucoperiosteum detached and brought down, blades of scissors introduced to cut attachment of soft palate to the bony palate and to the nasal mucous membrane; *c*, the same after the cut has been made and the soft palate thus brought down (Berry).

The parts are sutured with silver wire, following the advice of Edmund Owen to twist and cut each wire, leaving an end $\frac{1}{8}$ inch in length. This procedure causes the child to keep his tongue from the suture line.

For the first twenty-four hours only water is given. After this period the patient is fed with jelly and liquids. Only fluid or soft food is used for two or three weeks. Talking is forbidden. A day or two after the operation the child should be taken into the open air and kept in it all day. As Owen shows, this greatly stimulates vital resistance and lessens, to a considerable extent, the danger of sloughing of the suture line. The mouth is washed frequently, and always after taking food, with Condy's fluid. The sutures are allowed to remain between two and three weeks.

Sir William Fergusson's Operation.—In this operation the mucous edges are pared, the bones are drilled for wires, and the sutures are inserted, but not tied. An incision is made on each side of the cleft down to the bone, each incision being midway between the cleft and the corresponding alveolus. The bone is divided on each side, by means of a chisel, to the full length of the incision; and the chisel is used as a lever to force each half of the bone toward the gap. The sutures are tied, and each lateral incision is plugged with iodoform gauze.

Brophy's Operation.—This operation is employed particularly for children under three months of age, and cannot be used when the child is over six months. In this operation the palate is closed before the harelip is touched. Operating at this time the bones are soft, and by leaving the harelip untouched

the surgeon has more room to work. The author of the operation believes that when it is performed at this early age the palate muscles do not atrophy, but develop, and that the patient does not form the evil habit of talking through the nose.

In performing this operation the very strong-handled needles of Brophy are necessary. The patient is anesthetized and put into the Trendelenburg position and a strong piece of silk is put through the tip of the tongue as a traction-suture. The edges of the cleft in the hard palate are pared, a little of the bone being taken away with the paring. Then the edges of the cleft in the soft palate are pared. The needle is threaded with strong silk; the cheek is lifted, and the threaded needle is forced through the superior maxillary bone from without inward, starting just back of the malar process and just above the palate. As the needle shows in the cleft the thread is picked up with a pair of forceps, and the needle is pulled out, the loop of thread remaining in the cleft. Through a part of the opposite superior maxillary corresponding with this first point of entrance the needle is entered again and another loop is got into the cleft. The second loop is caught into the first loop, and when the former is pulled out it carries the latter with it. This thread now passes through both the superior maxillary bones and usually through the nasal septum as well. This thread is used to pull a piece of strong silver wire through. One other silver wire is introduced in the same manner more to the front. The silver wire ends are threaded through perforated lead plates, which fit the external outline of the bones on each side. The wires are tightened and twisted. For instance, on one side the end of the anterior wire is twisted to the end of the posterior wire, and so on. The thumbs are used to jam the two ends of the maxillary bones forcibly together, thus closing the cleft, and then the wires are twisted more firmly to hold the edges in contact. The cleft in the soft palate is then sutured, although the surgeon may deem it advisable to wait one day before doing so. After the palate heals the harelip is closed.

Carcinoma of the Lower Lip.—Cancer frequently arises in the lower lip, very rarely in the upper lip. Males suffer frequently, but females are not very often attacked. In some cases it seems to arise in smokers at the point on the lip where the pipe habitually rests. A short-stemmed clay pipe, which grows hot when it is smoked, is particularly apt to lead to the causal irritation. The region of the lip which is most liable to cancer is the junction of the skin and mucous membrane. The growth may begin in a fissure or abrasion, may start in an eczematous area, but most frequently arises as an indurated area which quickly ulcerates. After a cancer has existed for a variable time the submental, submaxillary, and cervical lymphatic glands become diseased. These glands are usually involved within three months of the beginning of the cancer. In a case of my own they were found to contain carcinoma cells in less than three months after the origin of the carcinoma of the lip. This involvement cannot be detected by external manipulation in the earliest stages, hence it is not proper to conclude that the glandular involvement is absent simply because it cannot be palpated. It occasionally happens that glands enlarge because of septic absorption, and this enlargement may even precede carcinomatous involvement. From an operative point of view the glands should always be regarded as carcinomatous. If cancer is not operated upon it destroys the lip, extensively involves the glands of the neck, the floor of the mouth, the periosteum and the lower jaw, and produces death in from three to five years. If the jaw is involved the prognosis is bad, and it is almost hopeless if the floor of the mouth is involved.

The *treatment* consists in the early and thorough removal of the growth by the knife, and also in the removal of the fatty tissue and glands from the

submaxillary triangles, from the submental region, and down to the carotid bifurcation. The growth must be thoroughly removed, that is, the incision must be at least ½ inch wide of the disease. For many years a favorite operation was the V-shaped incision, the skin edges being sutured by silkworm-gut, the sutures being passed almost to the mucous membrane and being inserted so as to compress the vessels when tied, and the mucous membrane being sutured with fine silk or catgut. The V-shaped incision should be used only for a very small and very recent growth. After the removal of the growth from the lip a vertical incision is made from the point of the V over the cricoid cartilage, and from the origin of this incision incisions are made in each direction along the under surface of the body of the jaw. The glandular area is thus exposed, and after the removal of the fat and glands the wound is sutured with silkworm-gut. Far better than the V-shaped incision is the operation devised by W. W. Grant, of Denver.[1] In this operation the growth is removed and cheiloplasty is performed.

Grant's Operation for Cancer of the Lip.—This operation gives a useful mouth and a more natural-looking lip than does the ordinary operation, and there is decidedly less tension on the suture line. Furthermore, the suture line in a man is apt to be soon covered with a beard. The procedure has

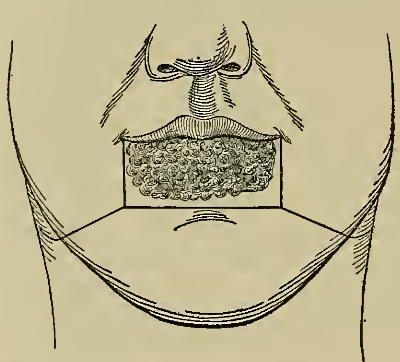

Fig. 583.—Grant's method for removal of carcinoma of the lower lip. The incision.

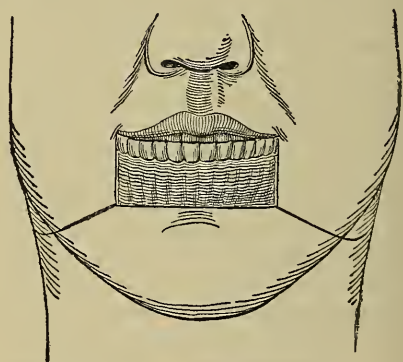

Fig. 584.—Grant's method for removal of carcinoma of the lower lip. Second step. The mass removed.

great advantages over the ordinary V-shaped operation, which greatly lessens the size of the mouth, making it what is known as a sucker-mouth, and the new lip is rigid and ugly.

In Grant's operation two vertical incisions are made, one on each side of the growth, and these are connected by a horizontal incision at the base (Figs. 583, 584). Thus, a quadrangular gap is formed, which must be filled by flaps. An incision is made on each side from each inferior angle of the wound, obliquely downward and backward beneath the maxilla, on a line about midway between the angle of that bone and the apex of the chin (Fig. 583). Its further extension is determined by the amount of lip removed and by the degree of glandular involvement.

The submaxillary lymph-glands are removed through these incisions. The glands in the midline, however, beneath the chin may require a separate incision. If the lip is extensively involved, the cheek ought to be completely separated from the inferior maxillary bone to the middle of the masseter muscle (Fig. 585). When the glands have been removed, the triangular flaps are brought together and united, first of all, in the middle line (Fig. 586). If the tension is marked, owing to the amount of tissue excised, it is wise to insert

[1] "Medical Record," May 27, 1899.

a traction suture, $\frac{3}{4}$ inch from the center line, and tie it over pads of gauze covered with muslin. One thus prevents undue tension upon the sutures in the center of the flap. The stitches that unite the cheek posteriorly are inserted and tied, and the entire thickness of the cheek must be included. Silkworm-gut sutures are used. A drainage-tube is inserted in the posterior angle of the wound on each side. It is very useful to use also a T-drainage-tube as advised by Grant. This tube is about the diameter of a lead pencil and the cross-piece rests behind the incisor teeth or symphysis and beneath the tip of the tongue. It drains away all of the mouth secretions, saves the lines of incision from being constantly bathed in them, and renders very frequent changes of dressing unnecessary.

I have employed this operation repeatedly, and regard it as the most useful method we have for the purpose. Thorough removal of the carcinoma of the lip and of the related glands will cure from 60 to 70 per cent. of cases.

Carbuncle of the Upper Lip.—In contrast to carbuncle in other regions of the body, facial and labial carbuncles are most common in young persons. Carbuncle of the lip is due to staphylococcus infection and begins as a papule. Numerous pustules appear, and sloughing usually takes place. There may or may not be serious constitutional involvement. The condition is very dangerous, as thrombophlebitis may arise and track up into the cranium by way of the ophthalmic vein and cavernous sinus. I have known two persons to die from carbuncle of the lip.

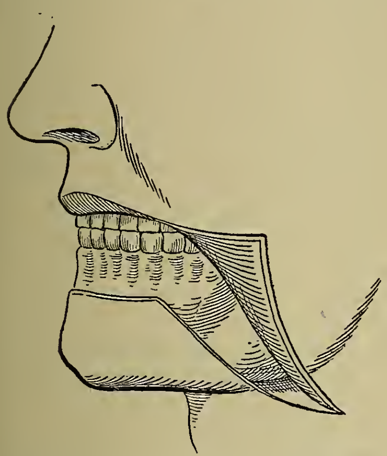

Fig. 585.—Grant's method for removal of carcinoma of the lower lip. Dissection preliminary to suturing.

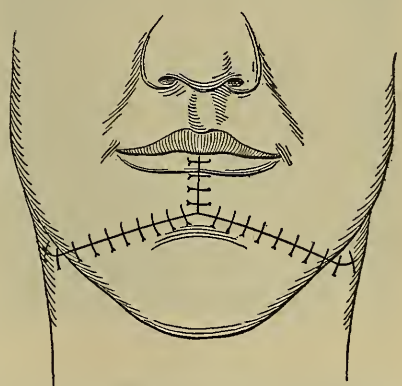

Fig. 586.—Grant's method for removal of carcinoma of the lower lip. The wound sutured.

Treatment.—Excise if possible. If excision is impossible, make a crucial incision, cutting away the corners and edges with scissors. Scrape out the carbuncle with a sharp and strong curet, swab with pure carbolic acid, pack with iodoform gauze, and dress with antiseptic poultices.

Tongue-tie (*congenital ankyloglossia* or *adherent tongue*) is congenital shortness of the frenum, the tip of the tongue adhering to the floor of the mouth. It is due to the projecting portion of the tongue being incompletely developed from the tuberculum impar. "In many of the slighter cases the development has merely lagged behind, and will be completed as the child grows after birth" ("Diseases of the Tongue," by Henry T. Butlin, Second Edition). The tongue cannot be protruded beyond the incisor teeth. Swallowing is interfered with, and later in life articulation is impeded. It is not very unusual in infants, but in the great majority of cases disappears as the

child grows older. Persisting tongue-tie, Butlin says, is one of the rarest of conditions, and my experience is in absolute accord with his—in fact, I have never seen a single case. Many unnecessary or even harmful operations are done for a condition which, if let alone, will usually correct itself. Improper operation may result in fatal hemorrhage or in "swallowing of the tongue." The operation usually done is to tear up the frenum with a thumbnail. This is unsurgical and makes a lacerated wound. A better way is to raise the tip of the tongue to make the bands tense, and then snip with the scissors close to the mucous membrane of the lower jaw. The slit in the handle of the grooved director was placed there to catch the frenum in, but a short frenum will not enter it (Butlin).

Ranula is a retention-cyst of the duct of the submaxillary or the duct of the sublingual gland. A ranula when first formed contains saliva, but after a time the saliva undergoes a change, and in appearance comes to resemble mucus. *Mucous cysts* occur in the floor of the mouth, resulting from obstruction of the ducts of the *mucous glands of Nuhn and Blandin.* These glands lie on each side of the frenum of the tongue. Such a cyst is often spoken of as a ranula. A *cyst of the incisive gland* forms just back of the lower jaw and lifts up the frenum. A true ranula appears upon the floor of the mouth on one side and pushes the tongue toward the opposite side (Fig. 587). The *treatment* of a mucous cyst is by excision of a portion of the cyst wall and cauterization of the interior with pure carbolic acid; or by cutting a flap from the cyst wall and stitching it aside so as to keep a permanent opening. Such an operation may cure a genuine ranula, but will often fail. In true ranula an external incision should be made, and through this both the cyst and the gland should be removed. This plan is recommended by Mintz.[1]

Fig. 587.—Ranula.

Thyrolingual or Thyroglossal Cysts and Sinuses.—In early embryonal life the thyroid gland has a duct which passes from the thyroid isthmus to the foramen cæcum of the dorsum of the tongue. The duct may be lined with one layer, two layers, or several layers of epithelium, and there are mucous glands and lymph-follicles in its walls, these structures being derived from the mucous membrane of the tongue. The wall of the duct presents numerous irregularly placed and irregularly shaped diverticula. It is known as the thyroglossal or thyrolingual duct. The duct runs from the base of the tongue down the midline of the neck. It is connected with the body of the hyoid bone, with the periosteum in front of the bone, and with the thyrohyoid bursa behind the bone. It passes to the upper portion of the front surface of the trachea, where it bifurcates, each branch passing to a lateral lobe of the thyroid gland. This fetal structure under normal conditions begins to atrophy in the fifth week and closes by the eighth week, the foramen cæcum marking its old orifice on the dorsum of the tongue. When the duct is obliterated, it becomes a cord of epithelium. In more than 30 per cent. of bodies the remains of this primitive passage can be found (Weglowski, in "Zentralb. f. Chir.," 1908, xxxv, 289). The duct may persist between the foramen cæcum and the hyoid bone, developing, it may be, into a *sublingual dermoid.* The portion behind and below the

[1] "Zeitschrift für Chirurgie," March, 1899.

hyoid may remain and develop into a *subhyoid cyst.* The part inferior to the hyoid may persist, give origin to a cyst which ruptures, and constitute an *incomplete median cervical fistula.* The duct may remain open from the mouth and make, by bursting an opening in the neck, a *complete median cervical fistula.* A patent duct may exist for years and announce its existence by some acute inflammatory process. The small diameter of a cervical fistula renders probing to any depth impossible. Some have told us to determine if a fistula is complete by injecting quassia solution into the lower end. The patient will perhaps experience a bitter taste. If we inject a colored fluid we may see it if it runs from the mouth. I have never succeeded in doing either. Tumors may spring from the duct.

Treatment.—If a thyroglossal cyst or tumor arises on the dorsum of the tongue, and if it is increasing in size and interferes with swallowing and speech, it must be removed through the mouth. A general anesthetic should be given. In some cases preliminary tracheotomy is necessary.

A cyst, tumor, or fistula about the hyoid bone requires excision, the patient being under the influence of a general anesthetic. A portion of the cyst wall adheres strongly to the posterior surface of the hyoid bone and must be carefully removed even if it is necessary to split the bone to accomplish it. In treating fistula the surgeon makes an elliptical incision of the skin about its orifice so as to free the fistula from the subcutaneous tissue. When traction is made upon the cutaneous end of the duct it will stand out clearly and can be dissected out (M. S. Seelig, in "Surg., Gynecol., and Obstet.," May, 1907). It is useless to try to cure a fistula by cauterization. A fistula requires the complete removal of its epithelial-lined walls. No lesser operation will cure. In 1 case I operated four times before securing success. In another case I divided the hyoid bone, removed the fistula, sutured the bone by chromic gut, and obtained a cure.

Carcinoma of the Tongue.—This is one of the most dreadful forms of cancer. It is a quite common disease. In most of the cases I see it is far advanced when first brought to the hospital. The only form of cancer which attacks the tongue is epithelioma. It is much more common in men than in women. It is a disease of adult life and is very rare before the age of thirty-five. It begins, as a rule, near the tip, on the side or at the base of the anterior two-thirds of the tongue, as a warty growth, as an ulcer having at first a papillary structure, as a fissure which indurates, or as an indurated area which ulcerates. The cause of the growth may sometimes be traced to the irritation of a jagged tooth or an ill-fitting plate, or to the smoking of a pipe, or to holding nails in the mouth, as is done by those who nail laths. Cancer may follow a chronic inflammation—leukoplakia, for instance. Chronic ulcers are liable to become cancerous and any indurated ulcer has potentialities of deadly peril and should be promptly removed. Fournier regards syphilis as an influential cause, and states that in 184 cases of cancer of the mouth or tongue 155 had had syphilis. There has been no such proportion of syphilitics in my personal cases. In Whitehead's 104 cases only 7 had had syphilis. As in cancer of the lip, men are much more frequently affected than women. In most cases the disease spreads rapidly; produces early and extensive glandular involvement; disease of the floor of the mouth; dribbling of saliva; difficulty in masticating, swallowing, and talking; foulness of the breath; severe pain which usually radiates toward the ear, and often a fatal septic trouble. Cases not operated upon usually die decidedly within two years. There is a very rare form of carcinoma described by Wölfler, which grows very slowly or even remains latent for years.

One reason why cancer of the tongue grows so rapidly has been pointed out by Heidenhain, of Greifswald. The lingual muscles are contracting almost

constantly, and as a result cancer-cells are forced along the lymph-spaces to healthy areas.

Treatment.—A cancer of the tongue should be removed radically at the earliest possible moment. Specific treatment for diagnostic purposes should not be continued beyond a very few weeks. In doubtful cases a Wassermann test is made, and if it is positive, salvarsan is given intravenously. If still in doubt as to the nature of the growth, remove it and have a pathologist at hand to immediately study it by frozen sections (Warren, in "Annals of Surgery," Oct., 1908). Have permission beforehand to proceed at once to radical operation if conditions demand it. The study of a small piece is always of uncertain value, hence, take out the growth. Whatever it is, it should be removed. Before any operation is undertaken all stumps of teeth should be extracted and a dentist should clean tartar from the teeth. During several days preceding an operation the teeth should be scrubbed twice a day with a brush and soap and the mouth rinsed with hydrogen peroxid. The nares and nasopharynx should be sprayed with peroxid of hydrogen and then with boric acid solution every second or third hour when the patient is awake.

In some cases the entire tongue is removed; in some, half of it; in some, only a piece of it. Not only the diseased tongue, but also the adjacent lymphatic glands must be removed. Cancer of the tip of the tongue, as a rule, involves the submental and sublingual group of glands early. Cancer of the anterior two-thirds of the dorsum of the tongue first involves the lingual and submaxillary lymph-nodes. Cancer of the under surface of the tip of the tongue first involves the submaxillary glands. Sooner or later the superior deep cervical glands about the carotid bifurcation become involved as a result of cancer of the tip or edges of the anterior portion of the tongue. In cancer of the dorsum the deep cervical glands become involved as well as the superficial nodes. The lymphatic system of the base of the tongue is distinct from that of the balance of the organ. It drains into the deep cervical groups.

It was formerly my belief that in a very recent and limited case only the glands on the diseased side require removal, but that in an advanced case the glands must be removed from *both sides* of the neck. Experience has convinced me that in any case the glands on both sides should be removed. Kuttner, of Tübingen, has demonstrated that lymph from one side of the tongue may flow to glands on the same side of the neck, but some also may flow to the opposite side of the tongue. Remove the obviously involved glands by the *block dissection* of Crile. In a bad case everything is removed but the carotid arteries. The sternocleidomastoid muscle, the omohyoid, the jugular vein, even the pneumogastric and phrenic nerves of one side may be taken away. After a week or two the other side of the neck should be operated upon. It seldom requires a wide removal of structures. If the pneumogastric or phrenic were cut on one side it must be preserved on the other. The jugular vein can be removed after a collateral circulation has been established subsequent to removing the jugular of one side. Two operations are to be considered: partial removal and complete removal.

Partial Removal of the Tongue.—This operation is restricted to recent cases in which one side only of the anterior portion of the tongue is involved. The operation does not offer as good a chance of cure as complete excision, because lymph containing cancer-cells may have reached the opposite side of the tongue. Even in partial removal the glands should be removed from both sides. Intratracheal anesthesia is employed.

In performing the operation of partial excision introduce a mouth-gag, pass a silk ligature through each half of the tip of the tongue, and draw the organ out of the mouth. Place the patient recumbent with the head a little raised. Split the tongue back in the middle line by the scissors, and loosen

the cancerous side from the floor and side of the mouth. Pass a stout silk ligature through the base of the tongue posterior to the cancer. Draw the organ out and cut off the diseased side in front of the ligature, but well back of the disease. Tie the vessels, remove the traction threads, and treat subsequently as in cases of complete removal.

Complete Removal of the Tongue (*Kocher's Method*).—Kocher recommends a preliminary tracheotomy in tongue excision, but the Trendelenburg position renders this procedure unnecessary so far as fear of the passage of blood into the larynx and trachea is concerned. I operated many times with the patient in that position. At present I operate with the head a little raised and the patient taking ether by intratracheal insufflation. Because of the insufflation there is no respiratory difficulty and the stream of escaping air and ether keeps blood out of the bronchial tubes. The method is most satisfactory. The surgeon stands to the side. Ether is given by intratracheal insufflation (see page 1199). Ligate the lingual artery on the side opposite to the one where the main incision is to be made. Remove the glands on that side and suture the wound. An incision is then made on the side opposite to that on which the artery was ligated. This incision passes from behind the lobe of the ear, along the anterior edge of the sternocleidomastoid to about the middle of the margin of this muscle. From this point the incision is carried to the level of the hyoid bone and then to the symphysis menti, along the anterior belly of the digastric muscle (Fig. 588). The flap is dissected and turned up; the facial and lingual arteries are ligated; "the submaxillary fossa is evacuated" (Treves); the sublingual and submaxillary glands are removed; the mylohyoid muscle is divided; the mucous membrane is incised close to the jaw, and the tongue, caught by tenaculum forceps, is drawn through the opening. The tongue is split in the middle by scissors, and the near half is removed, bleeding is arrested, the remaining half of the tongue is cut through, and the vessels are tied. Stitch the mucous membrane of the stump to the mucous membrane of the floor of the mouth with catgut sutures. Kocher does not suture the skin wound. I prefer to suture it and employ drainage-tubes. I follow the suggestions of Treves as to after-treatment. Some hours after the operation, when oozing has ceased, dust the mouth wound with iodoform. The patient, as soon as possible, is propped up in bed, and he must not swallow the discharges if it can be avoided. The mouth, every half-hour, is sprayed with peroxid of hydrogen and washed with a carbolic solution (1 : 60). Every three hours, after washing the floor of the mouth and the stump, the parts should be dried with absorbent cotton and dusted with iodoform. For twenty-four hours after the operation nothing is given by the mouth except a little cracked ice, the patient being fed by rectum. At the end of twenty-four or forty-eight hours some liquid food is given from a feeding-cup. The patient will soon learn to swallow; but if he cannot swallow easily, he is fed by a tube. Treves, in his clear and positive directions for after-treatment, states that nutrient enemata are to be continued until sufficient nourishment is taken by the mouth; that the mouth should be flushed by irrigation, and must be washed immediately after taking food; that morphin is to be avoided, and that the patient can usually leave the hospital in from seven to ten days.

Fig. 588.—Kocher's excision of tongue (Esmarch and Kowalzig).

Whitehead's Operation.—Whitehead removes one-half of or the entire tongue from within the mouth by the use of scissors. He passes a ligature through the tip, cuts the frenum, draws the tongue strongly forward, and separates by a series of clips with the scissors. The lingual arteries are tied as cut. "The stump should be kept under control, as regards hemorrhage, by a stout silk ligature passed through the remains of the glosso-epiglottidean fold and retained for twenty-four hours."[1]

Heath has shown that if the forefinger be passed to the epiglottis and used to "hook forward" the hyoid bone, the lingual arteries are stretched and portions of the tongue can be removed almost without bleeding. It is rarely desirable in Whitehead's operation to remove the glands and the tongue at one séance. To do so increases shock and the danger of death. The rule of procedure set forth by W. Watson Cheyne[2] is eminently wise. This rule is as follows: If glandular involvement is trivial or not detectable, it is perfectly proper to remove the tongue first, and after a week or so remove the glands. If the glandular involvement is marked, growth in the glands will be much more rapid than growth in the tongue. In such a case the glands should be removed before the tongue, because, if the tongue is removed before the triangles are cleared, in the week or two of waiting the case may become inoperable. In the majority of cases clear out the triangle before removing the tongue, doing the other operation in one or two weeks when the wound in the neck is healed. If the disease in the mouth is far advanced, do both operations at one séance.

Examination of the Esophagus.—The *x*-rays are of great value not only in detecting foreign bodies, but in finding carcinoma, pouches, and constrictions. As Waggett ("Brit. Med. Jour.," Oct. 19, 1912) says, by means of the *x*-rays we may learn that there is a stricture (or are strictures), where it is (or they are), how narrow it is (or they are), and whether or not there is extrinsic pressure. In this examination the patient first swallows material through which the rays pass with difficulty. A salt of bismuth is generally used. The carbonate of bismuth is a safe and satisfactory salt. It is given in glutoid capsules (Kohler, Ibid.).

Esophageal Sounds and Bougies.—These instruments were long our only mechanical means of diagnosis. They are used far less than formerly. They possess certain dangers. For instance, if an aneurysm exists and we are misled in believing that the condition is stricture, the rigid sound and even the flexible bougie may penetrate the sac of the aneurysm and cause death. I have personal knowledge of such a case. If a person has ever brought up blood, neither a sound nor bougie should be used. Again, neither the bougie nor sound can prove the existence of a slight stricture. They give no information at all as to the nature of a stricture. I find their greatest diagnostic use is to locate the situation of a constriction before passing the esophagoscope. In view of the fact that such an examination may cause bleeding, and that blood interferes with an examination by the esophagoscope, the bougie or sound, if used at all, should be employed the day before the introduction of the esophagoscope.

The olive tip bougie is flexible, and is made from elastic web. It is a safer instrument than the bulbous sound (see Fig. 597, E). The latter has a series of removable ivory or metal tips which vary in size. Used diagnostically, the olive tip bougie is to impart information as it enters; the bulbous sound, as it enters and as it is within. On withdrawing the bulbous sound it may catch upon the lower border of a constriction which it passed on entering.

Before being passed the bougie or sound should be warmed and greased with glycerin. The patient sits in a chair and throws the head well back against the breast of an assistant. The mouth is opened widely and is held open by a

[1] "American Text-Book of Surgery."
[2] "The Practitioner," April, 1899.

large cork or by a gag. The patient is directed to breathe deeply and regularly while the instrument is being passed. Depress the tongue with the finger and carry the instrument beyond the glottis. As it reaches the back of the pharynx the patient will gag and choke. Tell him to swallow and breathe regularly. The fact that he can breathe regularly shows that the instrument is not within the larynx. It may then be gently urged along the gullet. All maneuvers are to be conducted with the utmost gentleness. Force means danger.

Remember that in an adult the esophageal orifice is 5 or 6 inches from the incisor teeth, that the esophagus has a length of from 9 to 10 inches, hence, that the cardiac orifice of the stomach is from 14 to 16 inches from the incisor teeth (Maylard's "Surgery of the Alimentary Canal"). It is further important to remember that the normal esophagus is of smaller caliber in some regions than

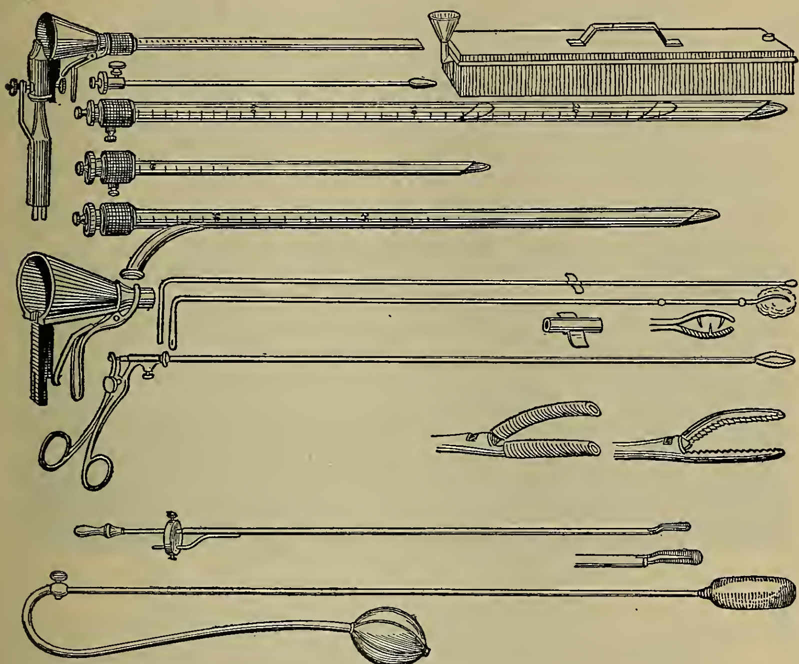

Fig. 589.—Von Mikulicz's set of instruments for esophagoscopy.

in others. There are four points of physiological narrowing, viz.: On a level with the cricoid cartilage, where it is crossed by the aorta, where it is crossed by the left bronchus, and where the tube passes through the diaphragm.

Auscultation may enable the surgeon to hear the food bolus rub against a stenosis and to note delay in the passage of liquid. Fluid normally passes in four seconds.

The Esophagoscope.—This instrument is of the highest value, a value just beginning to be properly appreciated. It is not altogether free from danger. Deaths have occurred from it. The mandrel does the harm, and should not be used at all or should be withdrawn as soon as the tube has passed the cricoid constriction. The rest of the way the instrument is carried along while the surgeon is looking through it and seeing what is ahead. It is not carried into a constriction; it is not carried by an ulcer or a pulsating lump. It enables us to make diagnoses otherwise impossible, to diagnosticate cancer in an early stage, to treat local conditions, and to remove a fragment of tissue for examination.

I prefer to pass the instrument without general anesthesia except in children, highly nervous people, or cases of very severe spasm. Apply cocain to the back of the tongue, pillars of the fauces, epiglottis, and pharynx. Place the patient on the right side with the head thrown back. This is known as *Starck's position*, and, as Gottstein shows, it relaxes the diaphragmatic crura. An assistant supports the head and follows every movement of the surgeon. The patient is cautioned to breathe tranquilly, and is told if the pain or annoyance becomes intolerable to raise his left arm, when the surgeon will cease for a time. The surgeon must, of course, keep his word on this point. Artificial teeth are removed. The instrument is kept in the midline and is inserted as is a sound or bougie. As soon as it passes the cricoid narrowing the mandrel is withdrawn, and the instrument is passed slowly and gently along while the surgeon is looking through and ahead of it. For Chevalier Jackson's method of esophagoscopy see page 888.

Fig. 590.—Position of patient during esophagoscopy (after von Mikulicz).

The cervical esophagus is closed and seems to unroll before the instrument. The thoracic esophagus is open, and while the esophagoscope enters into the upper part of this region, if the gullet is normal, the surgeon can see all the way down to the diaphragm. At the diaphragm the esophagus bends forward and to the left and this point must not be mistaken for the cardia (Kohler, in "Brit. Med. Jour.," Oct. 19, 1912).

The cardia may be found closed or may be seen to open and close with respiration. This instrument is of great value in the extraction of foreign bodies, in the diagnosis and treatment of many esophageal diseases, and in the diagnosis of certain peri-esophageal conditions. Every surgeon should be able to use the esophagoscope. (See Gottstein, in "Keen's Surgery," vols. iii and vi; Waggett, in "Brit. Med. Jour.," Oct. 19, 1912; Kohler, in "Brit. Med. Jour.," Oct. 19, 1912; "Reports of Eightieth Meeting of the British Medical Assoc.," July, 1912; Lewisohn, in "Annals of Surgery," Jan., 1913.) For Chevalier Jackson's directions as to the use of the esophagoscope see page 888.

Stricture of the Esophagus.—*Fibrous* or *cicatricial* stricture or scar of the esophagus is due to the healing of an ulcer, and results from traumatism, chronic inflammation, scarlet fever, syphilis, tuberculosis, chronic ulcer, prolonged vomiting, variola, gout, or to swallowing a corrosive substance or a boiling

liquid. In about 15 per cent. of cases of scarlet fever there is inflammation of the esophagus and larynx and stricture may result. Fibrous stricture is commonest in the young, and is apt to be situated opposite the cricoid cartilage, at the tracheal bifurcation or near the cardiac end. Cicatricial strictures, except when due to boiling or corrosive liquid, are usually single, but may be multiple. A cicatrix may be of irregular shape, may be cylindrical, may be annular, may be narrow, or may be broad. Stricture following impaction of a foreign body is located at the seat of impaction unless the tube has been injured by efforts at extraction, in which case multiple strictures may exist (Maylard). Strictures which result from swallowing boiling fluid or corrosive liquid are usually very extensive, may be multiple, and give early symptoms. In

Fig. 591.—Cicatricial stricture of esophagus.

some cases they are slight and may not give symptoms for years after the injury. Syphilitic stenosis is due to the healing of a gummatous ulceration, but there is nothing characteristic in this kind of stenosis. Tuberculous stenosis is extremely rare. The esophagus above an extensive scar is usually dilated.

Symptoms of Cicatricial Stenosis.—The condition is most common in youth, but may begin at any age. The chief symptom is difficulty in swallowing, at first slight, but becoming more and more pronounced until swallowing is almost or quite impossible. The dysphagia is first manifested to dry solids, then to all solids, and finally to liquids. In some cases vomiting occurs after swallowing. If the stricture is high up, the vomiting is almost immediate; if it is low down, the vomiting is delayed, especially if the canal is dilated above the stricture. From time to time the patient vomits independently of taking food, the ejected matter containing no gastric juice, only saliva and mucus which gathered in the dilated gullet about the scar. The vomited matter is not bloody. The

patient feels weak, hungry, and thirsty, becomes exhausted and emaciated, and suffers from flatulence, gastralgia, and constipation.

There is occasionally slight uneasiness or even pain in the region of the stricture, possibly "about the epigastrium or between the shoulder-blades" ("The Surgery of the Alimentary Canal," by Maylard). If there is certainly no aneurysm and if blood has never been brought up, the flexible bougie may be used first and then the solid tipped sound, in order to find a stricture. The stricture may be located by auscultation over the spine on a line with the supposed obstruction. While a patient is swallowing water, the arrest of the fluid at the seat of stricture may be audible. Even if the fluid passes, it will be delayed for a time and the duration of deglutition is thus prolonged. In order to determine the time of deglutition put the ear just below the angle of the left scapula, or else between the left sternocostal margin and the xiphoid cartilage, place a finger on the patient's Adam's apple, and hold a watch in the other hand. Have the patient take a drink of water. Count the time from the moment the Adam's apple begins to rise until the fluid is heard to gurgle into the stomach (Ogston's method). It ordinarily requires four seconds for fluid to pass from the mouth into the stomach (Maylard, Ibid.). The x-rays are used to diagnosticate stricture and to locate it. They are valuable in diagnosis. An emulsion of bismuth is swallowed and a skiagraph is taken. The bismuth is seen on the plate as a black mass extending above the seat of constriction (Fig. 591). A bougie can be passed until it reaches the block and a skiagraph may be taken with the bougie in position.

In a case reported by Seelig ("Surgery, Gynecology, and Obstetrics," Sept., 1908) the patient was directed to swallow a fine gold chain as thick as ordinary wrapping twine. The chain was about 2 feet long. If a diverticulum exists the chain will fill the sac and a skiagraph will show the position of the diverticulum. If no diverticulum exists the plate will show the chain nearly in the middle line of the body. The esophagoscope should be used (see page 931).

The history of the case is of much importance in diagnosis. The surgeon must inquire about impaction of a foreign body, or swallowing of acids, alkalis, or boiling fluids; and must examine for evidence of syphilis. If there is no history of injury, syphilis, tuberculosis, scarlatina, variola, or prolonged vomiting, and the patient is over forty years of age, the indications point to cancer rather than cicatricial stenosis. The easy passage of a bougie when the patient is anesthetized shows that spasm is the cause, and not organic disease. Narrowing due to external pressure (*compression stenosis*) is marked by positive symptoms of the causative disease.[1] Compression stenosis may arise in goiter, vertebral growths, enlargement of the heart, glandular enlargement, peri-esophageal abscess, aneurysm, lordosis, and mediastinal tumor (Kohler, in "Brit. Med. Jour.," Oct. 19, 1912).

Treatment.—Thiosinamin is given by some physicians, but I have never seen it accomplish the slightest good. Telleky[2] recommends it in old scars without inflammation. He makes a 15 per cent. alcoholic solution and injects from $\frac{1}{2}$ to 1 syringeful at a dose, throwing the fluid beneath the skin between the scapulæ. He uses twenty doses in the course of two weeks. *Gradual dilatation* through the mouth is a method employed for at least a time in almost every case. It is the method of choice when it can be carried out, and usually it can be carried out. Begin with the largest flexible bougie which will easily pass. Warm the bougie, oil it, pass it gently, and hold it in position for several minutes, prolonging the time of retention of the bougie as treatment progresses. Pass an instrument every second or third day, gradually increasing the size. Plummer ("Northwestern Lancet," Jan. 15, 1912) dwells on

[1] See the valuable article in Maylard's "Surgery of the Alimentary Canal."
[2] "Wien. klin. Woch.," Feb. 20, 1902.

the danger of using bougies, especially in cancerous constriction, and advocates the use of the string guide of Mixter in tight or tortuous stenoses. Mixter's plan is to have a patient put a piece of silk on the back of the tongue and swallow it while drinking water. The string may thus be floated through. Plummer proceeds as follows: He takes a spool of buttonhole twist and inserts a safety-pin so as to make a reel. He unwinds the thread, marks it with black ink at intervals of 1 yard, rewinds it, takes a few inches of the free end of the thread, moistens it, places it on the back of the patient's tongue, and gives the patient a swallow of water. The patient is directed to swallow 2 or 3 yards before bedtime, "and an equal amount at the rate of a foot an hour the following forenoon." The first portion, in a state of snarl, enters the intestine during the night. By afternoon the thread may be rendered taut by pulling upon it, yet it will not be pulled out. The thread may remain in place for some time, dilating the stricture. It may be used as a guide to direct a bougie through a tight or tortuous constriction, the eyed bougie being threaded upon the strand (Plummer, in "Collected Papers of the Mayo Staff in Rochester," 1911). If the stenosis involves a considerable portion of the esophagus, gradual dilatation will almost certainly fail to cure.

Symonds advocates the insertion of a tube through the stricture and leaving it in place until there is decided dilatation, and then replacing the tube with a larger instrument. The patient is fed through the tube (Fig. 592). In some cases in which it is impossible to pass a bougie through the stricture

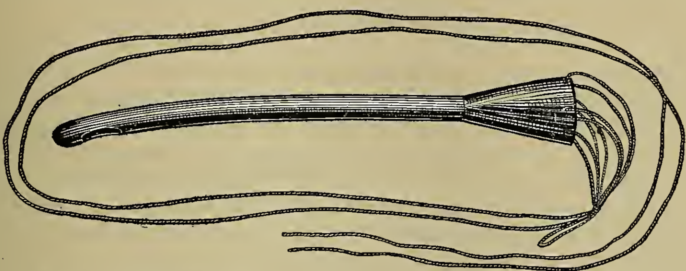

Fig. 592.—Symonds's short tube for intubation of the esophagus (Morrow).

by the ordinary plan it is possible to pass one when viewing the opening through the stricture by means of the esophagoscope. Whalebone or olive-tipped instruments may be passed in increasing sizes. Strands of silkworm-gut may be gotten through. If they are, they can be left in place a few hours, when a larger bundle of gut or perhaps an instrument can be passed. Surgeons have divulsed strictures and performed internal esophagostomy through an esophagoscope. Either of these plans is preferable to forcible dilatation or internal esophagostomy by a special instrument, but without the esophagoscope.

Electrolysis has been advocated by Fort and others. Gradual dilatation from below has been practised in cases in which a bougie could not be passed from the mouth. A gastrostomy is performed, and after the fistula has become sound the patient is made to swallow "a shot to which is attached a silk thread" (Maylard). The silk thread is brought out through the fistulous orifice and is attached to a bougie, and the dilating instrument is pulled up through the esophagus. *Forcible dilatation* can be employed through a gastrotomy opening, by means of bougies, tents, or divulsing instruments. A fibrous stenosis in the region of the cricoid cartilage which is not cured by gradual dilatation should be treated by the operation of *external esophagotomy.* In this operation the stricture is divided by a longitudinal incision; "funnel-shaped retraction of the cut portion is caused by adhesion to the

external tissues divided, and it lessens future contraction."[1] If dilatation fails in the case of a stenosis anywhere above the line of the aortic arch, the esophagus may be opened above the stricture (external esophagotomy). If the stricture is below the wound a tenotome may be introduced through the wound, the stricture is cut and well dilated by the passage of instruments. This operation is known as Gussenbauer's combined esophagotomy.

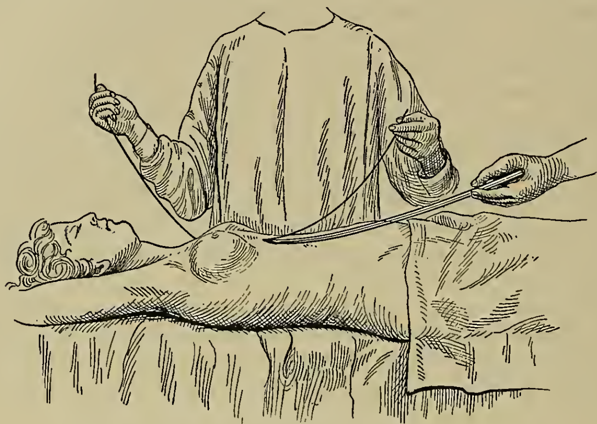

Fig. 593.—Abbe's method of cutting esophageal strictures.

If a stricture is impassable from above, the stomach should be opened and retrograde dilatation be carried out. Billroth showed years ago that a stricture impassable from above may be passable from below. This is because the esophagus above the stricture is basin shaped and immediately below the stricture is funnel shaped (Abbe). If a fine bougie is carried from the stomach to the mouth it is used to carry a piece of string through the same route, and this string is used to pull bougie after bougie through the stricture. A firm, non-dilatable stricture in the thoracic portion of the esophagus can be treated by Abbe's method (Figs. 593, 594). He performs a gastrotomy, sutures the stomach to the abdominal wound to prevent contamination of the peritoneum, and seeks for the esophageal opening by two fingers passed within the stomach. Abbe points out that finding the orifice would seem much more easy than it is. In a recent case I found it only after a prolonged search, the entire esophageal region feeling smooth to the touch. Abbe says that "this surface is maintained by the circular sphincter muscle layers, and it is not until a moment's pressure of the finger at the right place causes them to yield that it slips upward into the esophagus" ("Med. Record," Nov. 30, 1907). Abbe then passes a long filiform whalebone bougie from the stomach into the mouth, ties a piece of braided silk to the bougie, withdraws the instrument, and leaves the silk in place. One end of the silk emerges from the mouth and the other end from the gastrotomy wound. In some cases he opens the stomach and also opens the esophagus above the stricture; one end of the string

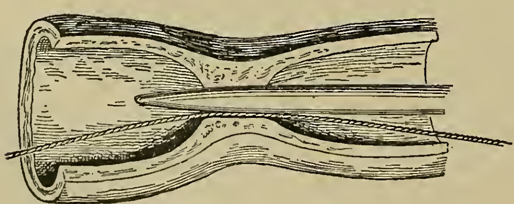

Fig. 594.—The bougie engaged in the stricture while the string-saw is being used.

[1] W. J. Mayo, "Jour. Amer. Med. Assoc.," July 29, 1899.

comes out of the esophagotomy wound and the other end out of the gastrotomy wound. A large dilating bougie is then passed from the stomach into the esophagus and pushed as forcibly as is safe into the lumen of the stricture. The string is used as a string- or bow-saw, and the stricture is divided, the dilating bougie being pushed firmly upward while the saw is being used. If this is not done the saw will not cut. Only stretched tissue will be divided. When the stricture has been divided the silk is withdrawn, full-sized bougies are passed, a temporary gastrostomy is usually made, and the wound or wounds are sutured.

An operation devised by A. J. Ochsner is thus described by Mayo[1]: "The anterior wall of the stomach is drawn out of a left oblique incision through the abdominal coverings; a small opening is made into the stomach sufficient in size to introduce the finger. A whalebone probe, to the tip of which a silk string guide has been tied, is now passed through the esophagus either from above or retrograde, as in the Abbe method. With this guide a loop of silk is drawn out of the gastric incision in such manner as to leave the guide as a third string. Into this loop a small soft-rubber drainage-tube 3 feet or more in length is caught in the middle by traction on the ends of the doubled thread through the mouth; this loop of rubber tube is drawn through the stomach and made to engage in the stricture.

"The greater the amount of traction, the smaller the stretched rubber tube, until it is sufficiently reduced in size to enter the stenosed portion; by alternating the direction of the pull the tube is drawn out by its free ends and in by the silk loop. Increasing sizes of tubes can be employed, and if necessary the third string can be used as a string-saw, after the Abbe plan of procedure." In a very severe case of stenosis gastrostomy is performed to keep the patient from starving. In a case of fibrous stenosis in charge of the author it was found impossible to insert any instrument from above or from below. Gastrostomy was performed by Kader's method. The patient was fed through the artificial opening and the esophagus was thus put at rest. Two weeks after the operation it became possible to pass a bougie from the mouth. The gullet was gradually dilated to its normal caliber and the gastrostomy wound was closed. This case demonstrates that a stricture of the esophagus, like a stricture of the urethra, may become temporarily impassable from inflammation, edema, and spasm; but, after the part is put at rest, may again permit the passage of an instrument.

In some cases of incurable stricture *cervical esophagostomy* is performed below the stenosis, and the patient is fed permanently through the opening. The operation is performed like esophagotomy, except that the mucous membrane is sutured to the skin.

Carcinoma of the Esophagus.—Cancer causes obstruction of the esophagus. It arises in those beyond middle life, and is far more common in men than in women. The disease may begin at any portion of the gullet, but is least often met with in the central portion (Maylard, Butlin). Epithelioma is the usual form, but scirrhus or encephaloid may occur. Cancer soon ulcerates, involves adjacent parts, and affects the deep cervical and posterior mediastinal glands. In at least 75 per cent. of cases of chronic obstruction of the esophagus cancer is the cause.

Symptoms of Cancerous Stenosis.—The patient is over forty years of age, is usually a male, and presents the same difficulty of swallowing met with in cicatricial stenosis. Regurgitation is common. The regurgitated matter is alkaline and is apt to contain blood. There is generally decided pain and very rapid and great emaciation occurs. The seat of obstruction may be located by the very gentle use of a soft or semisolid bougie, but it is wiser to use no bougie

[1] "Jour. Amer. Med. Assoc.," July 29, 1899.

and to rely on the *x*-rays and the esophagoscope. In a very recent case diagnosis is possible only by esophagoscopy. The stomach is the seat of pain; the mouth is dry, and there is often great thirst. As the disease infiltrates, the involvement of adjacent regions produces other symptoms. Dyspnea may result from tracheal pressure. Pleuritis, pericarditis, or pneumonia may arise. There may be paralysis of the sympathetic or recurrent laryngeal nerves.

In suspected cases of cancer never try to pass unguided bougies or sounds through the constriction. In a cancer case dilating instruments are weapons rather than tools. If a bougie is used to locate the constriction it will probably start bleeding and be bloody when withdrawn. A solid instrument might perforate the esophagus. If it does, death will follow. The *x*-rays should first be used and then the esophagoscope.

Treatment.—The disease is, of necessity, fatal, and treatment is only palliative. Complete excision of the cancer is scarcely feasible even in the cervical region. I know of but one successful resection of the thoracic esophagus, which was the case reported by Torek. At present the justifiability of such an operation has not yet been conclusively demonstrated. The patient should be put upon a soft, bland diet, small quantities being given frequently. When trouble is experienced in swallowing the bland and soft food, pass a soft bougie every third or fourth day. When the patient becomes entirely unable to swallow soft food, we may insert a Symonds tube (see Fig. 592) or do an esophagostomy (if this can be performed below the stricture), or perform gastrostomy. In every doubtful case of esophageal stricture give a course of iodid of potassium before performing any operation.

Spasmodic Stricture of the Esophagus (*Esophagismus; Hysterical Stricture*).—By this term is meant a spasm of the circular muscular fibers of the gullet, which is most common near the larynx or the cardia. This condition not unusually arises in a hysterical individual, in which case it will be associated with the stigmata of hysteria, especially globus hystericus. In some cases evidences of hysteria are wanting, although the patient is neurotic and ill-nourished, the condition being due to a reflex irritation. A spasm of the muscular fibers of the esophagus may be clonic or may be tonic. A clonic spasm may arise during vomiting or from some reflex cause; it may affect one part of the tube for a time and then shift to another, or may develop only in one particular region. Globus is a spasm which moves upward. Tonic spasm is in one fixed place. Most reflex spasms are tonic and result from cancer of the liver, cancer of the stomach, tonsillitis, glossitis, pharyngitis, or inflammation of the epiglottis (A. L. Benedict, in "Am. Jour. Med. Sci.," Aug., 1904). It occasionally occurs in tetanus, sometimes in epilepsy. Spasmodic stricture may also arise during pregnancy and as a result of laryngeal ulceration. I have seen several instances due to cancer of the stomach. In 1 of these cases the esophageal spasm entirely disappeared after the performance of pylorectomy.

Symptoms of Spasmodic Stenosis.—It arises suddenly in a hysterical or neurotic individual. It may last for a time and suddenly pass away, or may persist for a considerable time. The difficulty in swallowing is irregular, rarely interfering seriously with nourishment. Usually fluids are taken more easily than solids, but sometimes solids are taken more readily than fluids.

There may be regurgitation; but in recent cases, if it occurs, it does so at once on swallowing food. Examination with a bougie detects the obstruction. If the bougie is held firmly against it, in most cases the spasm will, after a time, relax suddenly or gradually and let the instrument pass. A medium-sized instrument or a large one may not pass until the patient has been anesthetized, but in every case a bougie can be passed after an anesthetic has been given.

Treatment of Spasmodic Stenosis Above the Cardia.—The systematic passage of bougies. Occasionally the passage of an instrument but once will cure a

case. The general health must be improved, and in persistent cases it may be necessary to use electricity within the esophagus, employ cold locally, and administer the bromids.

Cardiospasm.—When the cardiac sphincter contracts the condition is known as cardiospasm. It may or may not be associated with cancer, ulcer, or some other disease of the stomach, with gall-bladder disease or cancer of the liver. The attacks are periodic, with a variable time between them, but sooner or later diffuse dilatation occurs. Before dilatation the patient has periodic attacks of difficulty in swallowing, being perfectly well between the attacks. One of Plummer's cases had periodical attacks of dysphagia lasting from three to fourteen days, and during these attacks it was impossible to swallow either solids or liquids. In many cases the attacks are neither so severe nor prolonged. They usually begin suddenly while swallowing, but may begin at a time when no food is being taken. The attack is a feeling of choking or obstruction felt in the cardiac region and the back. Soon after these attacks originate the patient begins to suffer very soon after eating from regurgitation into the mouth. As the esophagus dilates the regurgitation is postponed longer and longer after eating, until finally the gullet is never completely empty (Plummer, "Northwestern Lancet," Oct. 1, 1906). The matter which is regurgitated is not sour, because it contains no gastric elements. Plummer points out that a stomach-tube cannot be passed, but a large-sized sound can be passed easily. The fact that a large sound can be passed proves that there is no organic stricture. When external causes of pressure are excluded the diagnosis rests between diverticulum and dilatation of the esophagus (Plummer, Ibid.). The *x*-rays aid in diagnosis. Plummer gives methods in detail (Ibid.).

Treatment.—Russell's plan is to dilate the cardia with a silk-covered balloon of rubber. Plummer describes how to construct it ("Collected Papers of the Staff of St. Mary's Hospital, Mayo Clinic, 1905–1909"). The distention is to be gradual, and at once suspended if there is violent pain indicating laceration. Mikulicz and others have performed gastrotomy and dilated the cardia. Willy Meyer ("Am. Jour. Surg.," June, 1912) has opened the thorax under positive pressure, plicated the dilated portion of the esophagus into two longitudinal double folds, and separated the pneumogastric nerves, tearing off the minute esophageal branches (*esophagoplication* and *vagolysis*). This patient was cured. This operation was attempted on 2 other patients. One was improved. The other turned out to have organic stricture. In another case Wendel performed cardioplasty in the same manner as pyloroplasty is done. He did it by the abdominal route. Meyer suggests that it may be done transthoracically.

Diverticula of the Esophagus.—Rokitansky in 1849 described traction diverticula and pressure diverticula. Maylard tells us that these pouches may be due to one of four causes: they may be congenital; may be due to stricture; may be caused by pressure from within upon a weak spot of the wall; may be due to traction from without by the healing and contraction of an area of inflammation. To these another cause should be added, muscular weakness resulting in dilatation. The usual situation for such a pouch is on the posterior wall of the gullet on a level with the cricoid cartilage. At this point there is a space devoid or nearly devoid of muscle, called the *Lannier-Hackerman area* (Charles H. Mayo, "Jour. Am. Med. Assoc.," July 22, 1912). As the pouch enlarges the fundus comes toward the side, usually the left side. Pouches are rare in the thoracic esophagus.

Symptoms.—In spite of the statement that a diverticulum may be congenital, we encounter the condition clinically only in adults. The first symptom is difficulty in swallowing, like that in cancer. There may be cough from nerve irritation and dyspnea from pressure on the trachea (Chas. H. Mayo, "Annals of Surgery," June, 1910). Regurgitation may occur, the regurgitated matter

being free from gastric juice. As the opening of the sac is usually a prolongation of the esophageal canal a sound or bougie tends to enter the sac. When the diverticulum is in the neck a lump forms during deglutition, and this lump may be obliterated by pressure. Food will pass into the stomach only when the diverticulum is full. A bougie can seldom be passed unless the pouch is full of food, at which time it may pass or may not. Sometimes it enters the pouch. This striking symptom, the variability in the passage of the bougie, is evidence suggesting the diagnosis of intrathoracic diverticulum. By listening through a stethoscope fluid may be heard to pass into the pouch. The diverticulum causes obstruction. "The depth of the obstruction can be measured with a stomach-tube, bougie, or acorn probe, but, as a matter of fact, these procedures do not differentiate between diverticula and strictures which are pervious to liquids and yet impassable to sounds" (Charles H. Mayo, "Annals of Surgery," June, 1910). After a patient swallows an emulsion of bismuth or food mixed with a salt of bismuth a diverticulum may be skiagraphed. When a bougie is passed as far as it will go a skiagraph should be taken with the bougie in position. The plate may show that the instrument is so much deviated to the side that it must be in a pouch. If a fine gold chain is swallowed it may fill up the pouch, and if it does, a skiagraph will indicate the diverticulum. The opening of the pouch may be seen by means of an esophagoscope. Plummer's test is valuable. He has the patient swallow a string guide, as described on page 935. The thread is passed through the eye of an olive tip set on a whalebone stem. The instrument is passed onward until it meets an obstruction. "Should the trouble be due to stricture the tip will not change its level when the thread is tightened, but if there is a diverticulum the probe will be elevated to the level of the opening in the lower esophagus, proving at once the existence of a pocket and also its depth by the amount of elevation of the probe upon tightening the thread" (Charles H. Mayo, Ibid.).

Treatment.—In very early cases dilatation may cure. In advanced cases in the cervical esophagus we must perform extirpation and suture, as done by von Bergmann, Hearn, the author, and others. For five days after operation no food is given by the mouth. No attempt should be made to extirpate a pouch in the thoracic esophagus. In such a case gastrostomy may be necessary.

Injuries of the Esophagus from Within.—Injuries of the internal surface are more common than injuries from without. Burns and scalds are among these injuries. Wounds may be inflicted by foreign bodies. Injuries of the gullet cause pain on swallowing, and a wound induces bleeding, the blood being both coughed up and vomited. A severe wound may involve a large vessel and cause violent or even fatal hemorrhage. If the bronchus or trachea is involved, there will be "cough and expectoration of blood, mucus, and food" (Maylard). The pleural or pericardiac sacs may be perforated.

Treatment.—Feed only by the rectum. Give morphin hypodermatically. Do not feed by the mouth for ten days, and even then give only fluid food and jelly. Symptoms are met as they arise. After burns by caustic, administer the antidote; give large drafts of water and wash out the stomach. From two to four weeks after a caustic has been swallowed and after a burn or scald the use of sounds should be begun (provided there is no raw surface), and sounding should be persisted in for a considerable time to prevent contraction.

Injuries of the Esophagus from Without, Other Structures Not Being Seriously Involved.—Such injuries are rare. Esophageal injuries, as a rule, are associated with serious damage to adjacent structures. Injuries may be due to stabs or to bullets. Besides the obvious external signs of the injury there will be difficulty in swallowing, cough, bloody expectoration, or vomiting; and mucus or the contents of the stomach may run out of the wound.

Treatment.—Suture the wound, and feed by the rectum for ten days.

Foreign Bodies Lodged in the Esophagus.—These accidents occur especially in children and lunatics, and women are more apt to suffer from them than men. A list of various bodies which have been swallowed will be found in Poulet's elaborate treatise. There are three regions where a foreign body is especially apt to lodge—viz., opposite the cricoid cartilage, at the level of the diaphragm, and at the point where the left bronchus crosses the gullet. Small and sharp bodies may lodge anywhere.

Fig. 595.—Author's case of whistle in esophagus, removed by external esophagotomy.

The *symptoms* are variable; if the body is large, there will be pain and difficulty in swallowing, and, in many cases, dyspnea from pressure upon the trachea or bronchus. Occasionally the dyspnea is such a prominent feature that it misleads the physician into the belief that the foreign body is lodged in the air-passages. Death may actually result from asphyxia. In some other cases the symptoms are very slight. If the body is sharp, there will be hemorrhage and severe pain. The blood may be hawked up, or may

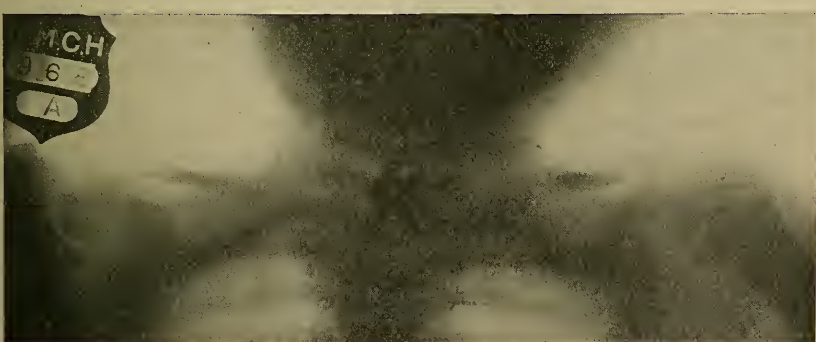

Fig. 596.—Author's case of jackstone in esophagus, removed by external esophagotomy.

be swallowed and vomited. In rare cases a patient grows accustomed to a foreign body and ceases to notice it; but, more often, the foreign body produces inflammation. It may even ulcerate into the wind-pipe, the pleura, the pericardium, or the aorta. In many cases of impaction a patient makes violent efforts to hawk up the foreign body and so produces aphonia. There may be violent retching. Even after a foreign body has been removed by swallowing, by vomiting, or by surgical extraction a sensation is apt to remain as

if the body were still lodged. The diagnosis is made by the history, the detection of the body by external manipulation, by feeling it with an esophageal bougie, by esophagoscopy, and, if bone or metal, seeing it with the fluoroscope or obtaining a skiagraph.

Treatment.—The surgeon should learn, if possible, the size, shape, weight, and nature of the foreign body, and should locate its point of impaction. The exact point of lodgment of bone or a metallic body is determined by the *x*-rays. An anesthetic is given before manipulating a child, a nervous woman, or a lunatic, and is *sometimes* necessary for a man. If the foreign body is soft, external manipulation may succeed in altering its shape, so that it may be swallowed or ejected. If the foreign body is hard, external manipulation may shift its position. It is usually impossible to reach the foreign body through the mouth by means of the fingers (when the body is in the rear of the pharynx it may be pulled forward or pushed down). Sharp foreign bodies may be entangled and carried down when the patient eats mush, bread, or boiled potatoes. The administration of emetics is an old plan which occasionally succeeds, but which is too unsafe to be employed. The esophagoscope is of immense value in many cases. By its aid foreign bodies may frequently be removed which without it could only be removed by the performance of a grave operation (see page 943). Nevertheless I believe, with E. Fletcher Ingalls, that the esophagoscope "cannot entirely supplant the older methods" ("Amer. Jour. of Surg.," Jan., 1912). The instrument is not always at hand, and to use it successfully and safely one must be well trained in its management. Maylard says that when a mass of food is impacted it is occasionally possible to soften and disintegrate the mass by administering a mixture containing pepsin. The bristle probang (Fig. 597, C) is a very useful instrument for the removal of fishbones, pins, and other small objects. It may be used to push a body downward into the stomach, or to catch the body and pull it up. When this instrument is withdrawn it opens like an umbrella. It has been shown that in an adult the cardiac opening is from 14 to 16 inches from the incisor teeth, a point to be remembered in deciding whether to push down or pull up the impacted article. Esophageal forceps (Fig. 597 A, B) are valuable in some cases. The coin-catcher (Fig. 597, D) is a useful instrument. Créquy's plan of removal is to take a tangled mass of threads, tie a stout piece of string about the middle of it, coat it with sugar, and have the patient swallow it. It may pass the foreign body; if it does so, on withdrawal it may entangle the object and extract it. To remove a fish-hook with line attached the following plan may prove successful; stick the line which projects from the mouth into a metal catheter, carry the catheter down to the hook, and push the hook out. It is not proper to allow a foreign body to remain in the

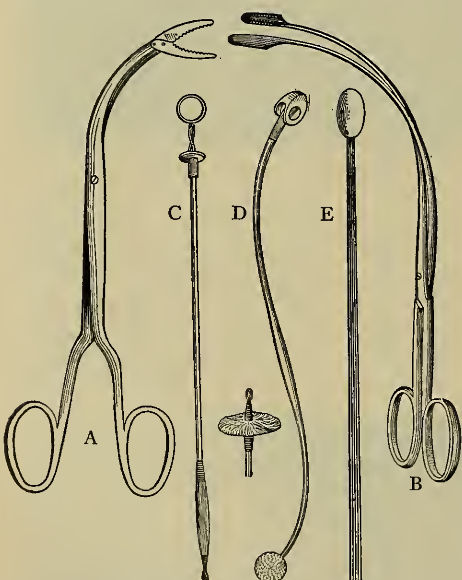

Fig. 597.—Esophageal instruments: A, B, Forceps; C, Gross's bristle probang; D, coin-catcher; E, bulbous esophageal sound.

esophagus until it causes ulceration. Neither is it proper to make prolonged efforts to extract it through the mouth. Such efforts may do great harm, and if one careful and consistent effort fails, and the esophagoscope is not suited to the case, fails, or is unobtainable, or if there is no skilled man to use it, an operation should be performed. If the body is lodged anywhere above the lower third of the esophagus, *external esophagotomy* is performed, and usually on the left side. Through this wound the foreign body is extracted. The cut is made on the left side, between the trachea and larynx in front and the carotid sheath behind, the center of the incision being opposite the cricoid cartilage. After the foreign body has been extracted the mucous membrane is sutured with chromicized catgut, and the superficial structures are closed with silkworm-gut after a drainage-tube has been inserted. The patient is fed by the rectum for eight or ten days. When a foreign body is lodged in the lower portion of the tube the stomach is opened and the body extracted by this route. In White's case of jackstone in the gullet gastrotomy was performed. A string was tied about some rolls of gauze, the string was passed by means of a whalebone from the stomach into the mouth, and the body was entangled and drawn out.

Surgical Invasion of the Mediastinum.—The posterior mediastinum has been entered in order to remove a foreign body from the bronchus and to extract a set of false teeth wedged in the esophagus. The same method can be followed to reach suppurative processes in the mediastinum, abscesses of the lung otherwise inaccessible, and diverticula and carcinomata of the lower end of the gullet. Nassilov resects ribs close to the spine. The portion of the esophagus above the aortic arch can be reached after partial resection of the third, fourth, fifth, and sixth ribs of the left side. The inferior portion of the esophagus can be reached after resecting portions of the lower third or fourth ribs on the right side (Binnie's "Operative Surgery"). Willy Meyer has made four heroic attempts to resect cancers of the esophagus. All the patients perished. He does it under positive pressure ("Surg., Gynec., and Obstet.," Dec., 1912). Out of 35 known operations 1 recovered and 1 lived two weeks after operation. The anterior mediastinum may be entered to remove a bullet, to drain an abscess, to reach a wound of the heart or lung, and to explore for the cause of symptoms. I explored the anterior mediastinum after rib resection, found a bullet embedded in the aorta, and allowed it to remain. The patient recovered. M. H. Milton[1] splits the sternum and separates the two pieces.

Invasion of the mediastinum is much safer if the operation is performed in the Sauerbruch chamber or with the aid of positive pressure within the bronchi. Either of these plans will prevent pulmonary collapse if the pleura is opened.

XXVIII. DISEASES AND INJURIES OF THE ABDOMEN

Diagnosis of Intra-abdominal Emergencies.—The exact diagnosis is always difficult and in many cases is impossible. What a surgeon must try to determine, and what he usually can determine, is whether he is dealing with a trivial and temporary derangement for the relief of which an operation is entirely unnecessary, or whether he is confronted by a grave calamity which imperatively demands immediate surgical aid. We can decide that a calamity exists, but the exact nature of the lesion is often doubtful until operation is performed. Every operation in such a case is exploratory. Before the diagnosis of a calamity is made morphin should not be given, because it allays the pain, relieves the anxiety, causes the disappearance of rigidity, lowers the pulse, abates mental shock, and hence veils the real situation, so that the most discerning surgeon will probably be misled. If

[1] "Lancet," March 27, 1897.

shock is profound, diagnosis is usually impossible, unless shock is due to hemorrhage, and immediate operation during shock is not to be thought of except for a perforation or to arrest bleeding. If excessive and continued hemorrhage is suspected, immediate operation is indicated. If it is not suspected, the patient should be covered with blankets and surrounded with hot-water bags, atropin should be given hypodermatically, and hot salt solution should be administered by rectum, subcutaneously, or intravenously. When the patient reacts, and he usually will react, an attempt is made to make a diagnosis. If a patient must be moved to a hospital it is perfectly proper to give a single hypodermatic injection of morphin ($\frac{1}{3}$ gr.) after the effort has been made to diagnosticate the condition. The danger of deluding the surgeon is past, and the drug abates pain, lessens peristalsis, relieves mental anxiety, and is distinctly beneficial. Before the morphin was given the surgeon came to a conclusion as to the necessity for operation. After the morphin has been given, if an operation is indicated, it is performed as promptly as circumstances admit. Whenever it is consistent with safety, the patient ought to be removed to a hospital for operation.

Foreign Bodies in the Abdomen.—Now and then a sponge, a pad, or an instrument is left in the abdominal cavity during an operation—left, not because of the surgeon's carelessness, but in spite of the most painstaking precautions. Instruments and sponges are counted before and after the operation. A miscount means calamity. The surgeon does not and cannot make the count himself. He has not time. He is doing a more difficult thing which he is trained to do and which the patient expects him to do, that is, operating, closing the wound, and dressing it. The surgeon must delegate this duty, and he delegates it to assistants or nurses, who do it with as much certainty of accuracy as he could have were he to do it. At least *two* people count sponges, pads, and instruments at least *twice* before and *twice* after the operation. If the count is short, and the missing instrument or material is not discovered on the floor, in a bucket, on or under the table, the abdomen must be opened and the lost object sought for and found.

A great safeguard is to use no small sponge or pad unless it has a bit of tape sewed to it. The tapes stick out of the wound and on each one a forceps is clamped. The safest way of all is to use rolls of gauze (Halsted's packs). To do so means a long broad end sticking out of the wound so that it cannot be lost in the belly.

If a septic body of any sort is left in the abdomen it at once produces acute disturbances.

If an aseptic gauze pad or sponge is left it may become encapsuled and cause no trouble for months or years. Sooner or later it will be apt to cause trouble or even death. The sufferer may become a chronic invalid. The object may make its way into the intestine or into the bladder. It may even pass out through the rectum. Usually a piece of retained aseptic gauze or an aseptic instrument produces abdominal pain and a tendency to intestinal obstruction. Sooner or later an abscess forms and the symptoms of an acute septic condition arise.

Schachner says the mortality in reported cases is about 50 per cent. Many fatal cases have not been reported. If we suspect the presence of a metal instrument the x-rays will show it.

Treatment.—Laparotomy (which is often exploratory) and removal of the offending material.

Simple Contusion of the Abdominal Wall Without Injury of Viscera.—In some cases of contusion of the abdominal wall only the parietes are damaged; in other cases the viscera or the abdominal tissues are injured. Contusion may involve the skin alone, or may involve the skin, muscles, and peritoneum. In *simple contusion* there is considerable shock if the injury

is severe. There is pain, increased by respiration, motion, pressure, and attempts at urination or defecation. When tenderness appears some days after the accident there is usually deep-seated injury. Extensive ecchymosis may appear. Even after a severe contusing force has been applied there may be no discoloration, and it may happen that after a slight force there is much discoloration. There is great ecchymosis in anemic persons, victims of hemiplegia, obese individuals, opium-eaters, and drunkards. In severe cases the tissues are pulpified and sloughing inevitably ensues. Abscess occasionally follows contusion. The prognosis after abdominal contusion is always uncertain.

Treatment of Simple Contusion.—In treating simple contusion place the patient at rest in a supine position, with the thighs flexed over a pillow. Obtain reaction from the shock. If pain is severe, and we are certain there is no visceral injury and no internal hemorrhage, give morphin. After shock has passed off it is advisable to place an ice-bag over the seat of injury. If much blood is extravasated into the abdominal wall, aspirate and apply a binder. After twenty-four hours apply local heat by means of the hot-water bag, employ an ointment of ichthyol, and move the bowels, if necessary, by salines. Regard every contusion as serious, and watch carefully for the development of signs of internal hemorrhage or visceral injury.

Muscular Rupture from Contusion.—In this injury there are severe shock, and pain (increased by respiration and movement). Separation between the fibers of the muscle is distinct at first, but it is soon masked by effusion of blood. Such injuries may cause death or may lead to hernia. The rectus is the muscle most apt to rupture. The rupture is due to sudden contraction rather than to the direct effect of a blow.

The *treatment* is the same as for simple contusion. Always apply a binder. If a hernia exists it is returned and a compress is applied over the opening through which it emerged. Later operation is performed. If strangulation occurs, operate at once.

Injuries With Damage to the Peritoneum or the Viscera.—

Rupture of the Peritoneum.—The peritoneum may be involved in an abdominal contusion. It may rupture even when there is no visceral injury or muscular contusion. The uterine peritoneum, the parietal peritoneum, the visceral peritoneum, or the mesentery may rupture. Rupture of the peritoneum causes intra-abdominal hemorrhage.

The *treatment* consists in opening the abdomen, arresting the hemorrhage, and bringing about reaction.

An injury to the peritoneum creates a point of least resistance, and at such a point peritonitis may develop. The peritonitis is usually local, but may become general. After any severe intra-abdominal injury the symptoms of *peritoneal shock* appear (*peritonism*), and the patient may rapidly die. In the condition of peritoneal shock the temperature is subnormal; the extremities are cold; the face is pallid and sunken; the pulse is small, weak, and very frequent; the respiration is shallow and sighing; there is great thirst; the patient is restless and turns uneasily, and there is rigidity and distention. Vomiting almost always occurs. In some cases there is regurgitation rather than vomiting. The abdomen is the seat of a violent, persistent pain. The patient is fearful of impending death. As the symptoms develop in a grave case they will point to one of two conditions—hemorrhage or peritonitis.

In *intra-abdominal hemorrhage* the subnormal temperature and other evidences of shock persist. Vomiting ceases, but nausea exists. The patient is uncontrollably restless and tosses about in bed. The thirst is great. The abdomen is rarely rigid. Fainting-spells occur. Blood examination shows a marked fall in the percentage of hemoglobin. Percussion demonstrates the

existence of an effusion which alters its position as the patient's position is altered, and which gradually increases in amount. Dulness is first met with in the loins. Digital examination of the rectum or vagina may aid in diagnosis, because in hemorrhage blood gathers in the rectovesical pouch. If peritonitis develops, the vomiting is aggravated, the pain is intensified, and the abdomen grows rigid and distended.

Rupture of the Stomach Without External Wound.—The usual cause of rupture is a violent blow, although the accident may happen while washing out the stomach. Rupture is more apt to occur when the stomach is distended with food than when it is empty. The rupture may be partial, the peritoneal coat not being torn. The rupture may be complete. Either the anterior or the posterior wall may suffer. The region of the pylorus is most apt to be lacerated. The symptoms of rupture are collapse, severe pain over the entire abdomen, great thirst, excessive tenderness, especially over the epigastric region, occasionally vomiting, the vomited matter being usually, but not invariably, bloody; tympanitic distention and muscular rigidity coming on after a few hours. Austin Flint pointed out years ago that after complete rupture or perforation gas may enter the abdominal cavity and cause the diminution or disappearance of liver-dulness, but the area of liver-dulness can be lessened by great intestinal distention, and I have seen cases of perforation of the stomach and intestine in which it was not lessened at all. (See article on Perforating Ulcer of the Stomach.) After *incomplete* rupture local peritonitis is frequent; in *complete* rupture the escape of stomach contents into the peritoneal cavity causes general peritonitis. The contents of the stomach are not so liable to escape after rupture of that viscus as are the contents of the intestine after rupture of the gut, because of the thickness of the stomach wall and the tendency of the mucous membrane to evert and block the opening. Perforations of the anterior wall are most apt to lead to extravasation and general peritonitis. Posterior laceration may cause subphrenic abscess. To diagnosticate between complete and incomplete rupture, Senn endeavors to distend the viscus with hydrogen gas; in incomplete rupture the contour of the dilated stomach can be made out upon the surface; in complete rupture the viscus cannot be distended, and the gas passes into the peritoneal cavity, producing the physical signs of tympanites. This maneuver is open to the objection that it may increase extravasation in a complete rupture.

The **treatment** for complete rupture is immediate operation. Treatment for shock is at once instituted and an intravenous infusion of salt solution is given before or during operation. In doubtful cases endeavor to bring about reaction and explore. Open the abdomen. Note if gas emerges from the wound or if stomach fluid appears. Search for the rupture in the same manner as we would search for the opening of a perforated ulcer. When the rupture is discovered, flush out the stomach and the peritoneal cavity with hot salt solution; sew up the stomach wound with a double row of silk sutures, the first row being buried and including the muscular coat and mucous coat, the second row being Halsted sutures; drain the abdomen; close the wound in the parietes; place the patient in Fowler's position; let salt water at low pressure flow continuously into the rectum; feed by the rectum for four days, and then begin the administration of a very little food by the mouth. In incomplete rupture the danger is perforation. The patient is put to bed, and after reaction has taken place is fed by the rectum for several days. Cases of complete rupture not operated upon occasionally recover, adhesions arising and perigastric suppuration taking place. The mortality is extremely large. In 1896 Petry collected 23 cases in which operation was not performed. The mortality was 59 per cent. This mortality is not so large as one would

anticipate. It is quite possible that some of the cases were not genuine instances of rupture. Many fatal cases have not been reported. Nevertheless, the lesion, for reasons previously stated, is not nearly so dangerous as rupture of the intestine. Another reason for the greater danger of intestinal rupture is that fecal matter is much more poisonous than the gastric contents. Laparotomy has lessened the mortality of rupture of the stomach. Petry and also Eisendrath mass together operations for rupture of the stomach and rupture of the intestine. Petry finds the group mortality to be 52.3 per cent., and Eisendrath finds it to be 52.5 per cent. Statistics referring to the stomach alone should show a much lower death-rate.

Rupture of the Intestine Without External Wound.—In the great majority of cases the damage is produced by direct violence. In some few cases the force is indirect (falls on the feet or buttocks, blows on the back or loin). The injury may result from *oscillation* or from *compression* (the younger Senn). The common cause is undoubtedly compression of the gut against the pelvis or vertebral column, but it is certain that a gut containing fluid may be ruptured purely by violent shaking or oscillation. If oscillation produces the damage, the rupture is on the portion of gut furthest from the mesentery; if compression is the cause, any part of the bowel may suffer. Rupture is most apt to occur if the belly is relaxed. It is predisposed to by adhesions, disease of the wall of the bowel, and irreducible hernia. Most ruptures are complete. In a very few cases the tear extends only through one or two of the coats and the rupture is incomplete. A contusion of the gut may be followed by rupture several days after the injury. A complete rupture usually permits leaking of feces, but in very rare cases a small opening is closely plugged by pouting mucous membrane. Leaking from a rupture may be delayed because intra-abdominal pressure may for a time keep the opening pressed against a section of sound gut (the younger Senn). The amount of damage to the belly wall does not convey any notion of the extent of visceral injury. The belly wall may be severely injured and the viscera escape. With only slight contusion of the wall there may be extensive visceral injury. Homer Gage[1] collected 85 cases; in 75 the injury was due to direct force, and in 32 of these the force was inflicted by the kick of a horse or of a man. In 1 of my cases it was due to the kick of a horse, in 1 to the kick of a man, and in 1 to a crush inflicted by a cart-wheel. The victims in the majority of reported cases were young men, probably because young men are most apt to be exposed to violence. In 78 collected cases (Gage) the situation of the injury was specified: The duodenum, 10; jejunum, 20; ileum, 42; large intestine, 6. Curtis found the large intestine injured in 4 cases out of 113, and Poland, in 5 cases out of 64. In many cases there is more than one tear, and sometimes many tears exist. Both the large and small intestines may suffer. Chavasse collected 106 cases in which the ileum or jejunum suffered, 19 in which the large intestine did, 7 in which the duodenum did, 7 in which both the large and small intestine were involved, and 1 case in which the rectum was ruptured (quoted by the younger Senn, in "Am. Jour. Med. Sciences," June, 1904). As Makins points out, the portion of gut most apt to be injured is a portion hanging low in the pelvis, because a loop in this situation is most easily squeezed against bone by a blow on the belly. The mesentery may be lacerated (it is in 7 per cent. of cases, according to Gage; in 16 per cent., according to Curtis). The symptoms of rupture of the intestine are profound shock, tympanites, abdominal pain, and rigidity, rapidly followed by peritonitis if the patient survives. In some cases pain is referred to the back. Vomiting comes on soon after the accident, the vomited matter being possibly at first bloody and later ster-

[1] "Annals of Surgery," March, 1902.

coraceous. The respiration is thoracic, the tongue is dry, and great thirst exists. The pulse, which may be slow at first, soon becomes small, rapid, and of high tension. Blood in the stools rarely appears early enough to be of diagnostic value, and there may be diarrhea or constipation. The respiration is costal. Dyspnea exists. There may be no marked symptoms for an hour or two or for many hours. Cases are on record of people with ruptured intestine returning to work perhaps for hours. Holland's patient had no symptoms for twenty-four hours, although the jejunum was ruptured. Poland's patient ruptured the duodenum, but walked one mile in spite of it. The escape of gas into the peritoneal cavity may cause the diminution or disappearance of liver dulness. After anesthetizing the patient, hydrogen gas insufflated into the rectum will come from the mouth if there is no perforation in the stomach or the intestine; if a perforation exists, tympanites is much increased and the area of liver dulness may disappear. To apply *rectal insufflation of hydrogen*, generate the gas in a bottle by means of zinc and sulphuric acid, catch the gas in a large rubber bag, and attach the tube from the gas reservoir to a tip which is inserted in the rectum. Give the patient ether to relax the abdominal muscles, direct an assistant to press the anal margins against the rectal tip, and when the patient is unconscious turn on the stopcock and press upon the reservoir (the elder Senn).

It has been suggested that ether vapor, mixed with air, can be used instead of hydrogen gas.[1] In this method a little ether is poured into the bottle of an aspirator, the valves are opened, one tube is carried into the rectum, the other tube is attached to a bicycle pump, and by working the pump the ether vapor is driven into the bowel. If there is perforation, tympanites is notably increased. Most surgeons regard the rectal insufflation test as unsatisfactory and often dangerous. Personally, I am not inclined to use it. Its application requires considerable time; it must, of necessity, increase fecal extravasation. If we operate after insufflation the gaseous distention is an embarrassment to the surgeon; as Le Conte[2] says, it "so distends the intestines that it may be impossible to return them to the abdominal cavity until they have been emptied of gas."

Treatment for Rupture of Intestine.—After an abdominal injury, if symptoms point to dangerous hemorrhage, and in any case in which the patient does not seem to be reacting, but is rather getting worse, operate at once. If in doubt as to whether or not rupture exists, make every endeavor to bring about reaction and explore. Reaction is brought about as previously directed. Asepticize and anesthetize. Perform a laparotomy, making the incision in the middle line and below the umbilicus; observe if gas escapes when the peritoneum is opened or if fecal material or an inflammatory exudate flows out; check hemorrhage; start at a fixed point and conduct a careful search to find the rent. When the rent is found, it should be closed by Halsted sutures if possible, but only a small rupture can be so treated. A large tear makes resection necessary. Because of the frequency of multiple lesions the surgeon must not be sure he has finished his work when he finds and closes one tear, but he must determine by careful search that no other tears exist. The surgeon notes if there is injury of the mesentery and if the circulation of any portion of the bowel is interfered with. If there is serious impairment of circulation in any part of the bowel wall, perform intestinal resection, followed by end-to-end approximation or lateral anastomosis. In some cases of rupture the patient is so severely shocked that it is impossible to do a resection with any hope of his living. In such a case stitch the ruptured portion of gut to the belly wall. The opening in the gut be-

[1] Emerson M. Sutton, of Geneva, in "Jour. Am. Med. Assoc.," July 23, 1898.
[2] "Jour. Am. Med. Sciences," Dec., 1901.

comes a fecal fistula, and if the patient survives, can be subsequently closed. The same procedure is proper if the bowel is distended and paralyzed. After closing the opening in the bowel or resecting, flush the abdominal cavity with hot saline solution, and wipe the peritoneal fossæ and the space between the liver and diaphragm with gauze. Finney eviscerates, wipes out the abdominal cavity, and wipes the intestines as he restores them. This is justifiable if the operation is done soon after the rupture, but not in later cases, in which the lymph has gathered on the bowel. Whatever method is used to cleanse the abdomen, remember that infectious material is apt to accumulate between the liver and diaphragm and in Douglas's pouch. Drainage is to be used. Suprapubic drainage is most advantageous. Place the patient semi-erect and employ continuous proctoclysis of normal salt solution as directed for peritonitis. The value of operation for intestinal rupture is conclusively demonstrated. Curtis collected 116 cases which occurred before 1887. Not a case was operated upon, and every patient died. Homer Gage collected 85 cases since 1887: 45 were not operated upon and every one died; 40 were operated upon and 17 recovered. Eisendrath collected 40 cases operated upon: 19 recovered and 21 died (52.5 per cent.). The mortality of cases not operated upon is, according to Eisendrath, at least 93 per cent. The sooner after the injury operation is performed, the greater the chance for success. The younger Senn points out that in operations done within four hours the mortality is 15.2 per cent.; in those done between five and eight hours it is 44.4 per cent.; in those done between nine and twelve hours it is 63.6 per cent., and in those done later it is 70 per cent.

Identification of the Small Intestine and of the Large Intestine.—"In abdominal operations it is frequently imperatively necessary that the large intestine be recognized with certainty or the small bowel be positively identified. The size of the tube will not always aid in this recognition, as a small intestine may be distended enormously, and a large intestine may be contracted to the size of a finger because of obstruction above. The longitudinal muscular fibers of the large bowel are accentuated in three portions; these accentuations constitute the three longitudinal bands which begin at the cecum and terminate at the end of the sigmoid flexure of the colon. Each band is composed of a number of shorter bands, the shortness of these constituent bands permitting the sacculation of the large intestine. Longitudinal bands and sacculation are not met with in the small gut, their presence or absence being a means of identification in many cases; but when the colon is much distended the bands cannot be seen distinctly and the sacculation disappears. From the large intestine only spring the appendices epiploicæ (small overgrowths of fat in pouches of peritoneum), but they are sometimes not well marked except upon the transverse colon, and when emaciation exists they may almost entirely disappear. The relatively fixed position of the large intestine and the free mobility of the small bowel are important points of distinction. The foregoing indicates that it is not always easy to distinguish between colon and small gut, and that, according to old rules, it may be often necessary to make large incisions, to see as well as feel, and to handle a large extent of the bowel. Any scrap of knowledge that will shorten an abdominal operation, that will permit of as certain work through a smaller incision, and that will diminish handling of intraperitoneal structures tends to increase the chances of recovery. For these reasons the writer suggests a method of bowel identification which rests upon the facts that each bowel has a posterior attachment, that the origin of the attachment differs according to the bowel it supports, that a single finger can detect the origin of the peritoneal support of any section of the bowel, and, this origin being known, the portion of the bowel it supports is with certainty deducible. In an exploratory operation, for instance,

the finger comes in contact with the bowel: to determine whether it is a large or a small bowel, note first if the structure is movable or is firmly fixed; next,

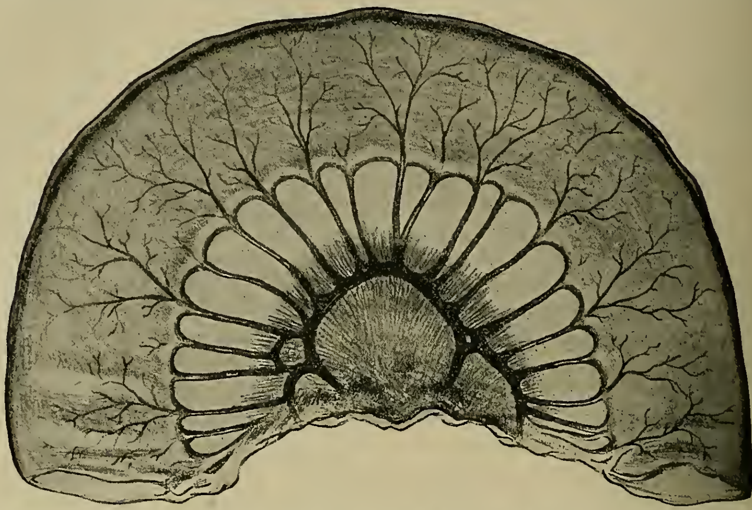

Fig. 598.—A loop of intestine, the middle of which is exactly 3 feet from the end of the duodenum. The gut is of large size. The mesenteric loops are primary, and the vasa recta large, long, and regular in distribution. The translucent spaces (lunettes) between the vessels are extensive. Below, the mesentery is streaked with fat. The veins, which had a distribution similar to the arteries, are for simplicity omitted from this and from the subsequent drawings. The subject from which the specimen was taken was a male of forty years, with rather less than the usual amount of fat. The entire length of the intestine was 23 feet (Monks).

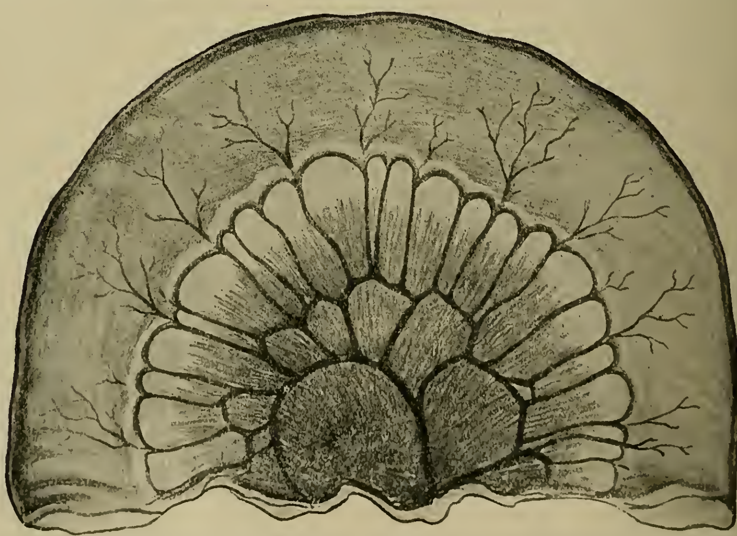

Fig. 599.—A loop of intestine at 6 feet. As compared with Fig. 598 the gut is somewhat smaller. The vascularity of the intestine and mesentery is less. Secondary loops are a prominent feature. The vasa recta are smaller. The lunettes are also present, but are not so large as in Fig. 598. The subject was a male of about thirty-five years, with an average amount of fat. The entire length of the intestine was 20 feet (Monks).

pass the finger over the bowel and let it find its way posteriorly. If dealing with a small bowel, the finger will reach the origin of the mesentery between the left side of the second lumbar vertebra and the right sacro-iliac joint; if dealing

with the large bowel, the finger will reach the origin of the mesocolon, or the point where the colon is fixed posteriorly and to the side."[1]

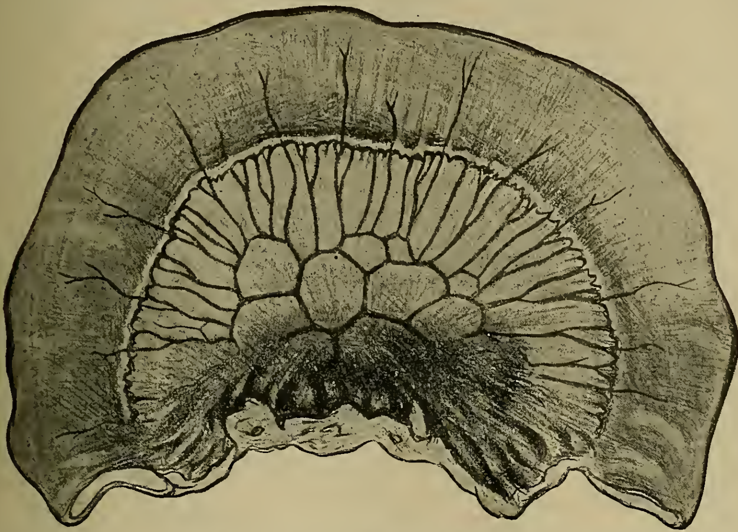

Fig. 600.—A loop of intestine at 12 feet. The vessels are smaller. The primary loops are lost in the fat, but secondary and even tertiary loops are visible. The vasa recta are shorter, more irregular, and branching. The specimen came from the same subject which furnished Figs. 598 and 599 (Monks).

Fig. 601.—A loop of intestine at 20 feet. The gut appears to be thick and large. The mesentery is quite fat and opaque, and large and numerous fat tabs are present. The vessels, which are complicated, are seen with difficulty, and are represented by mere grooves in the fat. The subject was a stout woman, and the entire length of the gut was 21 feet (Monks).

Location of a Loop of Small Intestine (Figs. 598–601).—Monks points out a plan by which, in most instances, we can learn with approximate accuracy what portion of the small intestine we may have hold of ("Annals

[1] The author, in "Medical News," June 9, 1894.

of Surg.," Oct., 1903). He learns first by observation of the mesenteric vessels. Opposite the upper portion of the bowel there are primary vascular loops only with perhaps an occasional small secondary loop. As we descend "secondary loops become more numerous, larger, and approach nearer to the bowel than the primary loops in the upper part," and about the fourth foot these secondary loops first become a "prominent feature." As we descend primary loops become smaller, secondary loops become more numerous and nearer the bowel, and possibly tertiary loops appear. Opposite the lower portion of the ileum the loops are not definite in arrangement, but are simply a network. Monks points out that opposite the upper bowel the vasa recta, when put gently on the stretch, "are straight, large, and regular, and rarely give off branches to the mesentery," and are about 5 cm. long. In the lower third they are usually less than 1 cm. long, are smaller, are not quite so straight, are not so regular, and give off numerous mesenteric branches. Monks further shows that fat impairs the translucency of the mesentery. The thinnest mesentery is that connected with the upper gut. As we descend the mesentery becomes thicker and thicker because of fibrous tissue, unstriated muscle, and fat. Translucency varies greatly. If a loop of upper intestine is raised against the light, one notices close to the gut and between the vasa recta transparent lunettes. The lunettes become smaller and fatty as we descend, and disappear at the eighth foot. In an incision in the median line, if the loop of intestine is pulled downward, we can determine if "the line of resistance from above is from the median line of the body or from the left or right of it." This resistance of the mesentery indicates to which point the loop is attached, and hence what portion of bowel the loop comprises. I have used these observations of Monks repeatedly to great advantage.

Rupture of the Liver.—(See page 1032.)

Rupture of the gall-bladder and the bile-ducts (see page 1032) is most apt to happen from injury when gall-stones exist. Peritonitis, general or local, is almost certain to follow such a rupture. Besides those symptoms common to all severe abdominal injuries there may be intense jaundice.

Treatment.—Suture the laceration or make a biliary fistula.

Rupture of the Pancreas.—(See page 1054.)

Rupture of the Spleen.—(See page 1063.)

Rupture of Mesenteric Arteries.—The symptoms are those of hemorrhage. The superior mesenteric artery, the inferior mesenteric artery, or branches of either or both may be damaged. If branches of the superior mesenteric artery are divided near the bowel, gangrene of the bowel will result, but wound of a branch far from the intestine does not cause gangrene. The branches near the gut are terminal arteries, hence the gangrene. The branches of the artery divide and form arcades arranged concentrically and the terminal arteries come from the peripheral arcades. In wounds of the vessels far removed from the gut anastomosis prevents gangrene (Labastie, in "Archives Générales de Chirurgie," Jan. 25, 1908). In most cases in which there has been rupture of mesenteric arteries death from hemorrhage rapidly occurs. If the victim should not die of hemorrhage he is in danger of gangrene and peritonitis. Aldrich[1] reported a case in which death was deferred until the seventh day. The treatment is immediate laparotomy. If the wound is found close to the gut, the portion of gut supplied by the cut vessel should be resected. If well removed from the gut, simply ligate the vessel (Labastie, Ibid.). In a wound near the root of the mesentery perform extensive resection of the gut and remove also a portion of the mesentery.

Rupture of the Kidney.—(See page 1280.)

Rupture of the Ureter.—(See page 1282.)

[1] "Annals of Surgery," March, 1902.

Wounds of the Abdominal Wall.—**Non-penetrating wounds** are to be treated on general principles. They are sutured with great care and are firmly supported externally. Ventral hernia may follow a large wound.

Penetrating Wounds.—The *symptoms* of penetrating wounds of the abdominal wall are usually those of shock and hemorrhage, and later of septic peritonitis. Emphysema is apt to occur and viscera may protrude, and often do in the case of a large incised or lacerated wound. Extravasation of contents of intra-abdominal viscera is very apt to occur, and is sure to occur if the viscus was distended when injured. Normal urine and normal bile may do little harm, but if either excretion is septic, disastrous consequences are certain to ensue. If intestinal contents escape, septic peritonitis is sure to arise. Bleeding is usually profuse and prolonged, because spontaneous arrest of hemorrhage from any vessel of considerable size will seldom take place within an unopened abdomen.

Treatment.—The surgeon endeavors to promptly discover if a wound of the abdominal wall is or is not penetrating in character. This fact may be proved by protrusion of viscera, by the appearance of stomach contents in the wound, or by a flow of bile, urine, or feces from the wound. If none of the above indications exists, and if there are no signs of serious hemorrhage, the wound should be irrigated with hot salt solution, and should be dressed with gauze, and every effort should be made to bring about reaction; otherwise operation should be immediate.

When reaction is obtained, the wound should be enlarged layer by layer until it becomes obvious whether or not the peritoneum is open. Madelung,[1] of Strassburg, points out that incision layer by layer will be of no use in settling the question of penetration if the wound is in the chest, the buttock, the perineum, or the back of a fat individual. If after incision layer by layer it becomes evident that penetration has not occurred, the wound should be closed and treated on general principles. If it becomes evident that it has occurred, the abdomen should be opened at the point of penetration, and a thorough exploration of intra-abdominal structures should be made in order to locate injury and be able to treat it properly.

In a case still doubtful after incision by layers, do an exploratory laparotomy in the middle line. It is impossible from the appearance of the wound and it may be impossible from the symptoms to affirm that visceral injury has not occurred; hence in every case in civil practice in which it is evident that penetration has occurred, laparotomy is necessary in order to detect and correct intra-abdominal injury, and to clean the peritoneum by flushing with hot salt solution. If viscera protrude, they must be washed off with hot salt solution and covered with hot sterile pads, and after the patient has reacted the wound should be enlarged, the condition of the contents of the abdomen investigated, hemorrhage arrested, wounds properly treated, and the viscera returned.

It is customary to flush the belly with hot salt solution, some of the fluid being allowed to remain. This procedure mechanically cleanses the peritoneum, removes blood-clots, strongly combats shock, and antagonizes infection. It is not absolutely necessary to flush out the belly unless a considerable hemorrhage has occurred or feces or stomach contents have been extravasated. If extravasation of stomach contents or feces has occurred, not only should flushing be practised, but evisceration should be carried out; the fouled intestine should be wiped off with gauze pads wet with hot salt solution, and while extruded should be kept wrapped in hot moist towels; the peritoneal fossæ should be rubbed with gauze pads and the space between the liver and the diaphragm should be carefully wiped.

[1] "Annals of Surgery," Sept., 1897.

A wound of the stomach should be sutured; a wound of the bowel may be sutured, or resection and anastomosis or resection and end-to-end suturing may be required. Visceral injuries are treated by appropriate means. In a punctured wound or a gunshot-wound of the intestine rectal insufflation of hydrogen gas when the abdomen is open may disclose the situation of the injury, but evisceration is usually practised instead and is preferable.

After the completion of intra-abdominal manipulations the surgeon restores any protruding bowel.

Drainage is required if the contents of the stomach or the intestines escaped, if hemorrhage was severe, or if the liver, pancreas, kidney, or spleen were found to have been damaged. The peritoneum may be sutured with a continuous suture of catgut; the muscles and fascia, with continuous or interrupted sutures of catgut, and the skin, with interrupted sutures of fine silk or of sikworm-gut. If there is need of haste, through-and-through sutures of silkworm-gut may be used. Active stimulation and artificial heat are needed immediately after the operation to combat shock. In many cases intravenous infusion of hot normal salt solution is given. It is of great value. It may be given both during and after operation. Enteroclysis, or high rectal injection of hot saline fluid, is useful. So is hypodermoclysis, or the subcutaneous injection of hot salt solution. The usual after-treatment consists of the semi-erect position, continuous proctoclysis of salt solution, avoidance of food by the stomach for forty-eight hours, and the administration of brandy and water from time to time. For two days the patient should be fed by the rectum. On the appearance of flatulent distention, forty-eight hours or more after the operation, give a saline cathartic. It is not wise to purge during the first forty-eight hours after the operation unless a Murphy button was used. When there is no sign of peritonitis a purge should not be given until the fourth day. After forty-eight hours liquid food can usually be given by the stomach. Solid food may be given after seven or eight days, but the patient must not leave his bed until the abdominal wound is firmly united because of the danger of ventral hernia. A support should be worn for a long time. E. D. Fenner[1] reports 39 stab-wounds of the abdomen operated upon in the Charity Hospital of New Orleans. There were 9 deaths (23.07 per cent.).

Gunshot-wounds of the Abdomen.—The bullet may penetrate from the front, the side, the back, the chest, or the perineum. If a bullet has penetrated, it may or it may not have produced visceral damage; a pistol-bullet or the bullet of a sporting-rifle almost invariably does. A projectile of a modern military rifle may not or may produce wounds which can be recovered from without operation. A urinary examination should be made promptly to see if blood is present.

In gunshot-wounds of the belly shock is usually greatly added to by hemorrhage, and in civil practice prompt operation is certainly indicated. The incision is made through the belly even when the shot entered the back. In some cases the opening is made through the wound; in others it is not; but in every case the wound made by the bullet is explored and disinfected. The incision should be long enough to permit of thorough work. After opening the abdomen our first duty is to arrest hemorrhage, our next is to look for perforations of the viscera and mesentery and close them. If the anterior wall of the stomach is perforated, close the opening and examine the posterior wall through an opening made in the gastrocolic omentum. If a posterior perforation is found, close it, and insert posterior drainage into the lesser peritoneal cavity. As a rule, an intestinal perforation can be closed, but occasionally a portion of the intestine

[1] "Annals of Surgery," January, 1902.

requires resection. If the bullet is encountered it is removed, but a prolonged search for it should never be made. Finally, the abdominal cavity is cleansed, drainage is provided for, and the abdominal wound is closed. In one of my fatal cases the bullet entered the rectum low down and was not found. In a case of mine with 6 perforations of the small intestine recovery followed operation.

E. D. Fenner[1] reports 113 gunshot-wounds of the abdomen operated upon in the Charity Hospital of New Orleans; there were 78 deaths (69 per cent.). In a series of 14 cases operated upon by Vaughan the mortality was 64 per cent. ("Am. Jour. Med. Sciences," Feb., 1906).

Military surgeons have shown that wounds inflicted by the modern hard-jacketed projectile are not so apt to involve fatal hemorrhage and disastrous complications; in fact, such wounds are often recovered from without operation, and sometimes with an entire absence of serious symptoms. Again, it is difficult or impossible to treat such cases as in civil practice, even were it desirable. In fact, in military practice the results are slightly better from expectant treatment, whereas in civil practice expectant treatment is a ghastly failure. Still, even in war, if conditions permit, operation should be performed if there is hemorrhage or obvious visceral injury, or if septic peritonitis develops. Treves says that in the Boer War only 40 per cent. of cases of gunshot-wounds of the abdomen not operated upon died, but, as pointed out by Hildebrandt, many cases die on the battlefield and while being taken to the hospital, hence the real mortality of these injuries is much more than 40 per cent. In the war between China and Japan the mortality from gunshot-wounds of the abdomen is said to have been about 77 per cent.

Gunshot-wounds of the Pregnant Uterus.—It is rarely that both walls are perforated, as the force of the bullet is greatly lessened by the uterine contents. There are severe shock and hemorrhage, and occasionally amniotic fluid flows from the wound of entrance. The intestine may also be injured. As a rule, labor-pains come on soon after the injury. The proper treatment early in pregnancy, if the wound is small, consists in emptying the uterus and closing the wound. In Albarran's case the fetus was expelled forty-eight hours after operation. A large wound, or any wound late in pregnancy, demands the Porro operation—removal of the uterus, ovaries, and tubes. Gellhorn[2] has collected 18 cases. In this series there were 12 recoveries. Russell Fowler reports a case of a patient eight months pregnant who was shot twice in the abdomen. There were two wounds in the uterus. Fowler did a Cesarean operation. The cut in the uterus was carried through one of the bullet wounds. The other bullet wound was sutured. The baby was wounded on the fingers of the right hand. Both mother and baby recovered ("New York State Jour. of Med.," Nov., 1911). In Judge's case ("Jour. Am. Med. Assoc.," vol. i, 1912), a girl of sixteen, nearly at full term, was shot with a Winchester rifle. The child was in the abdominal cavity and dead. The mother recovered. Tucker, of Shanghai (Ibid.), did a Cesarean operation for gunshot-wound of the uterus. The mother died and the child survived.

Omental Cysts.—Cysts may spring from the outer surface of the omentum (escaped ovarian cysts, lymphatic cysts, dermoids).

True omental cysts arise within the cavity of the great omentum. In 50 per cent. of cases the patient is an adult, but in half of the reported cases the patients were under ten years of age. Some of the cysts are probably of embryonic origin. Dowd is inclined to think that the cyst he removed resulted from omental hematoma ("Annals of Surgery," Nov., 1911). In this case there was torsion of the pedicle of the cyst. Dowd (Ibid.) reports 1 case of omental cyst and collected 37 from literature. Hasbrouck ("Annals of Surgery," August,

[1] "Annals of Surgery," January, 1902.
[2] "St. Louis Med. Review," Dec. 2 and 9, 1901.

1908) points out that the condition is much more common in females than in males, that there are no characteristic symptoms, that the condition begins as omental endothelioma between the two surfaces of omentum which fuse because of inflammation and form a closed sac, that hemorrhages are apt to occur into the cyst, and that operation shows a mortality of 6 per cent. The operation performed is extirpation.

Mesenteric Cysts.—These rare cysts are divided into (1) embryonic, (2) hydatid, (3) cystic malignant disease (Dowd, "Annals of Surgery," 1910). A great majority of mesenteric cysts are embryonic. Moynihan believes that embryonic cysts arise in "rests" from "the Müllerian or Wolfflan organs or ducts, or from the ovary," which are included between the folds of mesentery. These rests undergo cystic degeneration. Mesenteric cysts grow and pass along between the layers of mesentery until they reach the gut and then compress the gut and push its wall ahead of them.

Such a cyst may contain embryonal material, bloody fluid, serous fluid, chylous fluid, or lymph. In Harry C. Deaver's report of a case ("Annals of Surgery," May, 1909) it is shown that in 40 cases there were 25 females and 15 males; that the size varies from that of a split pea to enormous dimensions; that there may be a pedicle form in front of the vertebral column or from the intestinal wall; that the sac wall may be exceedingly thin or as much as 1 cm. in thickness; that in some cases large veins are present on the surface of the cyst; that adhesions to the abdominal viscera are common; that intestinal obstruction may occur (kinks, volvulus, intussusception); that cysts are most commonly found in relation with the lower end of the ileum; and that there are no characteristic symptoms except perhaps the rapid body wasting mentioned by Moynihan. Moynihan also points out that the cyst fluctuates and is most prominent toward the navel, that it is very mobile, especially transversely (we should add if not anchored by adhesions), and that the cyst is surrounded by a resonant zone and crossed by a resonant band.

Treatment.—Incision and drainage if there are numerous and firm adhesions. Enucleation whenever possible. Resection of the involved portion of gut with the cyst in some cases of multiple cyst (Harry C. Deaver, Ibid.).

Torsion of the great omentum is usually caused by a fall or strain or attempts to reduce a hernia. In nearly all cases a hernia is present. Hedley ("Brit. Med. Jour.," Nov. 11, 1911) studied records of 73 cases. In 60 there was or had been a hernia. In 5 cases without a hernia there were adhesions. In 48 of the hernia cases the omentum was attached in the sac, in 4 it was anchored near the sac, in 3 to the bowel, and in 1 to the Fallopian tube.

Symptoms are like those of a strangulated omental hernia or of appendicitis.

The **treatment** is by laparotomy.

Stomach and Intestines

Foreign Bodies in the Stomach and Intestines.—Foreign bodies of considerable size are rarely taken into the alimentary canal except by children, insane people, or drunkards. Small bodies (bits of straw, fragments of bone, etc.) are frequently swallowed. Most foreign bodies swallowed are passed with the feces, but some lodge. Any body which can pass the esophagus is not too large to pass through the intestines. Lodgment is an accident, not an inevitable consequence—an accident which is due to the shape and size of the body. A foreign body may lodge in the stomach. In some cases there are no symptoms. In other cases symptoms are violent. The severity of the symptoms depends upon the shape and character of the body.

In some cases it is possible to feel the body from without. A metal body in the stomach will deflect a magnetic needle held over the viscus (Polaillon). Many foreign materials can be skiagraphed. A body of small size may pass through the entire canal and emerge without having done any harm, but it may lodge and may cause perforation. If perforation occurs, the foreign matter may become encysted, for instance, in the mesentery; may cause an abscess or may cause general peritonitis. A fish-bone may cause an anal abscess. An epiploic appendix may cause sacculation of the bowel, perforation by a foreign body may take place in this sac, an *epiploic abscess* resulting, which may attain considerable size and may be mistaken for carcinoma (Sir J. Bland-Sutton, in "Lancet," Oct. 24, 1903). It is not wise to attempt to recover a foreign body from the stomach by inducing vomiting. In some cases gastrotomy is necessary. When a small or sharp foreign body has been swallowed and has not caused perforation, abscess, or obstruction, the usual treatment is as follows: a purgative should *never* be given to expedite the passage of a foreign body, because increased peristalsis increases the danger of impaction or of perforation. Endeavor to encrust the foreign body, and thus lessen the danger of perforation, by feeding with bread and milk only for several days, and at the end of this period give a mild laxative. An exclusive diet of mush or of mashed potatoes has been suggested. Suet dumplings may be given. Pain is relieved by opium. A foreign body rarely lodges in the duodenum, but may lodge lower down, and may cause ulceration, perforation, abscess, or intestinal obstruction. Operation is necessary in such cases.

Volvulus of the Stomach.—This condition is very unusual. Ten cases are on record (Streit, in "Am. Jour. Med. Sciences," June, 1906). One-third of the cases are associated with diaphragmatic hernia. The symptoms come on suddenly. There is violent abdominal pain. Distention and collapse are early. There is nausea, but the patient can neither vomit nor belch. In the upper left abdomen there is a tender, tense, and tympanitic area. The rotation of the stomach may be on its vertical or on its longitudinal axis. An hourglass stomach may undergo twisting on its vertical or longitudinal axis. Berg operated successfully for volvulus of the stomach. He opened the abdomen, relieved distention by tapping the stomach with a trocar, and then easily corrected the twist. The gastrohepatic omentum should be shortened by Beyea's operation (see page 1104).

Fibromatosis of the Stomach.—This condition was long ago described by Brinton as cirrhosis of the stomach. Alexis Thomson has recently published an admirable description containing many new things ("Annals of Surgery," July, 1913). He shows that ulceration of some form is the cause (simple ulceration or cancerous ulceration). The condition may be and commonly is localized, but it may involve the entire stomach ("leather-bottle stomach"). There may be glandular enlargement. The local form starts at the pylorus and resembles cancer, but is not nodular. There may or may not be adhesions. There is no "cicatricial stenosis of the pylorus," but the canal of the pylorus is narrowed by submucous thickening. The thickening is not scar-tissue, but is more like a fibroma (Ibid.). It is probably a reaction against infection. Thomson proves that there is an innocent form of fibromatosis, and thinks it probable that there may even be an innocent form of leather-bottle stomach (Ibid.).

The **symptoms** suggest ulcer, cancer, or some sequel of ulcer. It is often possible to be mistaken as to the nature of the mass even when it is exposed by exploratory incision. The cases of "pyloric cancer" which have recovered after gastro-enterostomy and some of the cures of gastric cancer by gastrectomy are explained when we know how easy it is to mistake innocent fibromatosis for cancer.

Treatment.—Thomson always insists on an immediate microscopical examination of a portion of the tumor or, better, of an enlarged lymph-gland. He advocates resection for local fibromatosis because he believes cancer is liable to arise. In some cases gastro-enterostomy is performed; in some, jejunostomy.

Carcinoma of the Stomach.—Innocent tumors and sarcomata occasionally attack the stomach, but they are infinitely rare in comparison with primary cancer. This disease is unusual before the age of forty, and is very seldom seen before the age of thirty. I operated upon a man of twenty-three for gastric cancer. It is more common in men than in women, the proportion being as 5 to 4. Beyond question, in some cases cancer arises from the margins of an ulcer. The forms of cancer which may arise in the stomach are the spheroidal cell growth (either the hard form known as scirrhus or the soft form known as medullary or encephaloid), the cylindrical cell growth or adenocarcinoma, and colloid (due to the myxomatous degeneration of either a spheroidal cell or a cylindrical cell carcinoma). Scirrhus more than any other form produces constriction of the pylorus and more seldom than any other form produces hemorrhage. It may spread for a considerable distance along the submucous coat, muscular coat, and subserous coat without apparent involvement of the mucous membrane wide of the primary focus of disease. Fibromatosis may develop about it. In some cases scirrhus is limited to the pyloric region, in others it is a limited tumor of some other part of the wall of the stomach. In the condition known as malignant "leather-bottle stomach" a scirrhus has invaded the entire stomach wall, or fibromatosis has developed with the cancer and the wall of the viscus is thick and rigid.

Medullary cancer and adenocarcinoma produce hemorrhage. Both of these forms most often arise in the pyloric region. Medullary cancer may remain limited, but, as a rule, a cauliflower growth arises and eventually fills the stomach and portions of the mass may slough away.

Adenocarcinoma is apt to spread along the mucous membrane instead of "infiltrating the deeper layers," as other forms are prone to do ("Cancer and Tumors of the Stomach," by Samuel Fenwick and W. Soltau Fenwick). Spheroidal celled carcinomata are twice as common as cylindrical celled, and medullary cancer is about as common as scirrhus. Any cancer may be accompanied by fibromatosis.

Cancer may be limited to the body of the stomach (either curvature or either wall), the pyloric end or the cardiac end, but it may involve two of these regions or almost the entire stomach, or, being multiple, may be found in many parts. Sometimes there is a primary cancer on one wall, and another growth, due to contact, on a corresponding point of the opposite wall (*contact cancer*). All forms of carcinoma most frequently begin in the region of the pylorus. In many cases of gastric carcinoma adhesions form between the stomach and the liver, colon, or diaphragm. Even in cancer of the pylorus the duodenum is seldom invaded. Medullary cancer not unusually passes into the esophagus. Gastric cancer is usually fatal in from four months to two years, and most patients die within one year. In 60 per cent. of cases the pylorus is involved. In over half of the cases of cancer of the pylorus there is no important lymphatic involvement (McArdle). In investigating any gastric disorder follow the advice of the Mayo brothers and study the history of the case, the size and situation of the stomach, the existence and situation of pain and tenderness, the presence of a tumor, and if the passage of food is interfered with.

Symptoms.—Examine with care a patient in whom cancer is suspected. In unusual cases it produces no symptoms until it has lasted for some time and has attained a large size (latent cancer). In nearly all cases it does produce symptoms. The disease comes on gradually, usually with indigestion and physi-

cal weakness. The patient has persistent dragging pain, which is increased by eating and pressure, and attacks of vomiting are frequent. After a short time he becomes very weak and exceedingly anemic, and it is often possible to feel a tumor in the stomach. Blood examination shows diminution of red corpuscles and hemoglobin and perhaps absence of any increase of leukocytes after a full meal. The vomiting of a patient with gastric cancer is at first only occasional, but as the case progresses it becomes more and more frequent. Vomiting soon after eating occurs when the cardiac region is involved; vomiting an hour or so after eating occurs when the pyloric end is involved. When the body of the organ is the seat of disease, vomiting may be absent. The vomited matter is often mixed with a small amount of altered blood (*coffee-ground vomit*). In most cases occult blood is found in the feces, especially if hydrochloric acid is absent from the stomach contents. These symptoms above cited associated with "coffee-ground vomit" and lactic acid in the stomach contents are strongly indicative of cancer (Wm. J. Mayo, in "Surg., Gynec., and Obstet.," May, 1908). A *test-meal* is given, and important conclusions are sometimes derived from the presence or absence of hydrochloric acid and lactic acid. It is my custom to have the stomach washed out and then have Ewald's test-breakfast given. This consists of one roll of white bread (35 gm.), 400 gm. of H_2O, and 400 gm. of tea without milk or sugar. In one hour the stomach is emptied by means of a tube and a pump or a tube and abdominal compression, and the material is examined. If the result of the test seems out of accord with the other symptoms, repeat the process (L. Boas, in "Berlin. klin. Woch.," No. 440, 1905). In most cases free hydrochloric acid is not found in the stomach contents, but lactic acid is found and Oppler's bacillus can often be detected. There may be red blood-corpuscles in the fluid. If the cancer is not ulcerated, free hydrochloric acid will probably be found; if it is ulcerated, it will usually be absent.[1] Free hydrochloric acid may be absent from the stomach because of atrophy of glands, cessation of secretion, or neutralization by the products of the cancerous area. Free hydrochloric acid may be absent in individuals in whom cancer does not exist. I have noted its absence in several cases of cicatricial stenosis of the pylorus.

It may be absent in cancer of the esophagus, advanced Bright's disease, cancer of the duodenum, distant cancer, febrile conditions, and amyloid disease. The constant presence of considerable quantities of hydrochloric acid is strong evidence against the existence of cancer of the stomach. If cancer arises from ulcer, free hydrochloric acid is apt to be present for a considerable time after the cancer has begun.

Distend the stomach with gas or fluid and map out its outlines. Feel for a tumor. A tumor can usually be felt if it involves the greater curvature or anterior wall, and a large tumor of the pylorus can be palpated, but in other regions the tumor can rarely be felt.

Cancer of the cardiac end interferes with the entrance of food into the stomach, and in such a case the stomach is shrunken and the esophagus is dilated immediately above the growth. In cancer of the pylorus the food is partially or completely arrested as it passes to emerge from the stomach, and the stomach becomes much dilated. The vomited matter in a case of cancer rarely contains recognizable fragments of the growth, but fluid with which the stomach has been irrigated may contain pieces which can be identified as cancer (Rosenbach).

In cancer of the stomach the general course of the temperature is normal, but there are occasional deviations to below or above normal. In many cases the urine contains albumin, indican, acetone, and casts. Occasionally cancer of the stomach produces spasm of the esophagus. I have seen this in several cases.

[1] Reissner, in "München. med. Woch.," Dec. 3, 1901.

Cancer of the stomach is apt to involve secondarily adjacent lymph-glands, or organs or other structures, especially the liver; in fact, the liver is involved in 30 per cent. of the cases (Welch). Occasionally there is enlargement of the supraclavicular glands of the left side. Metastases are usual and early, but in cancer of the pylorus 60 per cent. of the cases show no distinct lymphatic involvement. In many doubtful cases exploratory incision is imperatively required.

Treatment.—The *medical* treatment consists in milk-diet, the use of morphin, and of *lavage* if the pylorus or body of the stomach is diseased. Perform lavage as follows: The tube for lavage should be long enough to extend about 3 feet out of the mouth when the other end is in the stomach, it should be flexible, should have an opening in the stomach end and another opening on the side about 1 inch above the stomach end. The tube should be greased with glycerin. The patient sits down, throws the head back, opens the mouth widely, and is directed to take deep breaths, at regular intervals. The tube is carried into the pharynx, the patient is ordered to make efforts to swallow it, and the tube is thus taken into the stomach. About 1 quart of fluid is poured into the funnel-like end of the tube, and just before the tube empties itself of the last of the water the funnel is lowered and the fluid runs out. This proceeding is repeated until the fluid becomes clear. The best fluid to use is a solution of bicarbonate of sodium, a teaspoonful of the salt to a quart of warm water. Lavage should be practised before breakfast, and sometimes also at bed-time.

The *indications for operation* are well set forth by Macdonald[1]: They are progressive aggravation of symptoms in spite of a rigid diet and medical treatment, loss of gastric mobility, progressive diminution of gastric peristalsis, progressive diminution of free hydrochloric acid, emaciation even under forced feeding, progressive reduction of hemoglobin to 65 per cent. or under, and moderate leukocytosis.

Surgical treatment aims to remove the growth or to obviate the effect of obstruction at one of the orifices of the stomach.

In cancer of the body of the stomach, if the growth is not extensive, excision of the growth may be performed; if it is extensive, it is useless to attempt it unless the growth is absolutely non-adherent. Conner, of Cincinnati, attempted total excision of the stomach in 1883, but the patient died on the table. In 1897 Schlatter, of Zurich, successfully removed the entire stomach. Brigham, Richardson, Macdonald, Boeckel, De Carvalho, Bardeleben, Haine, Gallet, Dollinger, Ferry, Ribera, and others have successfully removed the entire stomach and attached the esophagus to the small intestine (*complete* or *total gastrectomy*). In the successful cases digestion was satisfactorily performed after removal of the stomach. Very rarely will cases be found suitable for such a radical proceeding. The case suitable for this treatment is one in which the entire stomach is involved in the growth, in which there is no obvious glandular involvement, and in which the stomach is not adherent, but is freely movable. Herbert J. Paterson ("The Hunterian Lectures for 1906") collected 27 cases of total gastrectomy for cancer: 10 died and 17 recovered. If a small portion of the fundus is left the operation is called *subtotal gastrectomy.* H. J. Paterson (Ibid.) collected 20 cases of subtotal gastrectomy for cancer with 6 deaths. In limited cancer of the body of the stomach perform *partial gastrectomy.* In cancer of the cardiac orifice of the stomach the surgeon usually keeps the passage open as long as possible by the frequent passage of a tube, and through this tube introduces liquid food. Sometimes a small tube is introduced and permanently retained. When it becomes difficult to introduce a tube, *gastrostomy, duodenostomy*, or *jejunostomy* may be performed. As a matter of fact, in most

[1] John B. Murphy, in "Chicago Med. Recorder," June 15, 1902.

cases gastrostomy is done as a last resort, and it is scarcely worth doing in cancer of the cardiac end of the stomach. It is far more useful in cancer of the esophagus. In cancer of the pylorus, limited in extent and without lymphatic involvement, *pylorectomy* may be performed; but in cancer which has widely infiltrated the coats of the stomach and has involved the lymphatic glands, *gastro-enterostomy* is performed as a palliative measure, the patient during the rest of his life subsisting upon liquid or semiliquid foods and submitting to frequent irrigation of the stomach to remove food residue. In cases of irremovable and far-advanced cancer it is often best to refuse to operate and to deliberately create the opium-habit in the patient, although, in some cases, duodenostomy or jejunostomy may be performed.

The most successful of all the above operations are pylorectomy and partial gastrectomy. The mortality is large. In H. J. Paterson's series of cases the mortality was 28 per cent. There are in literature many cases which have survived three years or over. Mayo reported 21 gastro-enterostomies for cancer, with 4 deaths. The greatest prolongation of life was nineteen months. His experience makes him question if the operation is worth doing in malignant disease.

Sarcoma of the Stomach.—Of recent years it has been proved that sarcoma is more common than was once supposed. There are over 60 cases on record. It can occur at any age, but is more usual in early life than carcinoma. It has been estimated by Wm. T. Howard[1] that 37.7 per cent. of cases are under the age of forty, and 11.44 per cent. are under the age of twenty. The pylorus is involved in about one-fourth of the cases. In most cases the posterior wall and greater curvature are involved. Howard says there is a diffuse growth in 21.31 per cent. of cases and that the cardiac end is involved in only 4.9 per cent. of cases. Sarcoma arises in the submucous coat. Any form of sarcoma may arise. It causes stenosis in less than one-tenth of the cases. There is no sex predisposition in sarcoma. The growth may attain a great size.

Symptoms.—A tumor forms, grows rapidly, and often attains a large size, and not unusually actually causes a projection of the abdominal wall. If it ulcerates there will be hematemesis, but it often does not ulcerate, and bleeding is much rarer than in carcinoma. Not unusually this growth arises in a person under forty, and sometimes in one of less than twenty years of age. Stenosis is uncommon. The liver is involved secondarily in only 11.47 per cent. of cases (Howard), metastases are more rare than in carcinoma, free hydrochloric acid is usually absent from the gastric contents, and microscopical examination of washings from the stomach may detect fragments of sarcoma. Certain diagnosis is impossible without exploratory incision. Howard estimates the average duration of life to be from nine to ten months.

Treatment.—If the liver is free and if there are no metastases, partial gastrectomy or complete gastrectomy may be advisable. If pyloric stenosis should arise, gastro-enterostomy may be performed. Scudder ("Annals of Surgery," August, 1913) reports a case. He performed jejunostomy. Six weeks later he removed the tumor by partial gastrectomy, closed the jejunal opening, and did anterior gastro-enterostomy. A year later the man remained well.

Ulcer of the Stomach (Peptic Ulcer of the Stomach).—Ulcer of the stomach is a condition due to digestion of a portion of the stomach wall by very acid gastric juice, the destroyed portion having been the seat of lowered vitality. The reason for the lowered vitality of the gastric mucous membrane is uncertain. Thrombosis has been suggested as a cause, but it is rare in gastric ulcer. Embolism is assigned by some as a cause, but emboli are seldom found on pathological examination. It has been asserted that

[1] "Jour. Am. Med. Assoc.," Feb. 8, 1902.

menstrual disorders may be responsible for ulcer, that tight lacing may be, and that habitually bending over (as in making shoes) may be a cause. The Mayos are of the opinion that the grinding action of the pyloric portion of the stomach may be a traumatic exciting cause of ulcer of that region. Some assert that mental anxiety, alcoholism, and syphilis may be causal (Alderson). Thirty-two per cent. of the cases in the Mayo Clinic used alcohol. Ulcers due to syphilis and tuberculosis are not peptic ulcers.

Robson believes that gastric ulcer is septic in origin, and that oral sepsis is responsible for its origin in most cases. "Mild sepsis leads to gastritis and hyperchlorhydria, which in its turn provokes and keeps up ulceration" (A. W. Mayo Robson, in "Keen's Surgery," vol. iii). In 140 cases studied by Smithies in the Mayo clinic ("Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912) 26 had had enteric fever, 6 pneumonia, 5 syphilis, 8 malaria, and 27 some other general infection. Twelve had previously been operated upon for appendicitis and 2 for gall-stones. Some observers blame direct damage to the mucous membrane by traumatism or the swallowing of corrosive liquid. The question of cause is involved in uncertainty. What does seem to be certain is that anemia predisposes to the formation of very acid gastric juice (*hyperchlorhydria*) and to ulceration. In some cases chlorosis is associated with ulcer. According to Wm. J. Mayo there are three known causal factors of the first importance, viz., anemia, hyperchlorhydria, and traumatism (April 16, 1904).

It used to be stated that ulcers are far more common in females than in males. This statement is not correct. It applies to acute ulcers, but not to chronic ulcers. Up to July 1, 1912, the Mayos had operated on 404 proved ulcers of the stomach, and over 70 per cent. of these patients were males (Smithies, in "Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912). The acute round ulcer is vastly more common in women, and in young women rather than in those of middle or advanced age. The chronic indurated ulcer is most frequent in men. Men about forty, and women between twenty and thirty are particularly liable. Between thirty and forty is the period of greatest liability. I have only once found ulcer in a person under twenty. There is usually a single ulcer, but in one-fifth of all cases there are two or more, and when there is an ulcer on the anterior wall, it is not uncommon to find one exactly opposite on the posterior wall (*a kissing ulcer* Moynihan calls it). The Mayos divide ulcers into two clinical forms—the *indurated* and the *non-indurated*. In the indurated ulcer all the coats of the stomach are involved, and the mass of scar tissue indicates an effort at repair. The most common situation for this form of ulcer is the region of the pylorus (Wm. J. Mayo, in "Jour. Am. Med. Assoc.," Oct. 21, 1905). The non-indurated ulcer involves the mucous coat only and may be of microscopical size, and even a microscopical ulcer may cause death from hemorrhage. These non-indurated ulcers exhibit no sign, or almost no sign, on the outer surface of the stomach, and may not be detected even when the stomach is opened by the surgeon. The non-indurated ulcers are divided into the *mucous erosions* of Dieulafoy, in which the superficial epithelium only is involved, and the true round fissured *peptic ulcers* (Wm. J. Mayo, in "Jour. Am. Med. Assoc.," Oct. 21, 1905). Both conditions are rare. Ulcers are also divided into *acute ulcers*, which progress rapidly and produce definite symptoms, and *chronic ulcers*, which are usually chronic from the beginning, but which may exhibit acute exacerbations, and may have periods of great relief or apparent cure (Wm. J. Mayo, in "Med. Record," August 6, 1904). The most common seats of ulcers are the posterior wall and lesser curvature, especially in the pyloric region; in fact, 80 per cent. occur in the pyloric region. An ulcer may heal or may perforate. Only 1 or 2 per cent. of ulcers on the posterior wall perforate, as they tend to form adhesions to adjacent structures. Ulcers on

the anterior wall are unusual, do not tend to form adhesions, and are apt to perforate. It is not uncommon to have ulcer of the first portion of the duodenum associated with gastric ulcer. An ulcer may be accompanied or followed by fibromatosis which gives a deceptive likeness of cancer (see page 957). Gastric ulcer is at least four times as frequent in England as in the United States. In 2830 autopsies made in the Philadelphia Hospital there were 40 gastric ulcers, and in 3763 autopsies made in four Philadelphia institutions there were 51 gastric ulcers—a percentage of 1.35. (See A. P. Francine, in "Proceedings Phila. County Med. Soc.," March 31, 1905.)

Symptoms.—In an acute ulcer the symptoms are often typical; there are pain, tenderness on pressure, slight or distinct unilateral muscular rigidity, vomiting, hemorrhage, and hyperchlorhydria. In a chronic ulcer the symptoms may be clear, may be misleading, may be variable, and in some cases even absent (*latent ulcer*). In ulcer dyspepsia usually exists. It is usually but not always acid dyspepsia, and is associated with much flatulence. In most cases, though not in all, food promptly causes pain. There is a gnawing sensation (*hunger-pain*) when the stomach is empty, and may be actual pain. The taking of food may *temporarily* relieve pain, but as gastric peristalsis arises and perhaps as quantities of gastric juice are poured out to digest the food the pain increases. If hyperchlorhydria disappears (as it may do from chronic gastritis and does from gastric dilatation following pyloric obstruction), pain may not be increased during digestion. In ulcers of the cardiac end and lesser curvature gnawing uneasiness is but briefly or not at all relieved by taking food and pain develops immediately or almost at once after eating. In ulcer of the pyloric region the gnawing uneasiness may be distinctly relieved by taking food, but in an hour or two hours pain is apt to become severe. The time after eating when pain occurs may not be constant in a case. In ulcer the pain is paroxysmal. It is at times very violent in the epigastric region, and may pass to the back, being located between the eighth and ninth dorsal vertebræ to one side of the back (the right most often), into the esophagus, into the chest, or to the top of the ensiform process.

In gastric ulcer it is usual to find distinct or severe tenderness developed by epigastric pressure, and tenderness is associated with more or less rigidity. In ulcer of the lesser curvature pain and tenderness are in the neighborhood of the left costal margin. In ulcer of the pylorus they are above the umbilicus in or to the right of the midline. Vomiting usually relieves the pain, so does lavage, so does the administration of an alkali. In ulcers of the anterior wall tenderness is most acute. In many of these patients vomiting occurs about two hours after eating. The vomited matter, as a rule, contains much hydrochloric acid and the vomiting usually relieves the pain. Examination of the gastric contents after the administration of a test-meal shows in about 80 per cent. of the cases hyperacidity. Obvious hemorrhage from the stomach occurs in less than one-half of the cases, and from 3 to 8 per cent. of cases actually die of hemorrhage. Wm. J. Mayo states that "more than 90 per cent. of hemorrhages from the stomach are from chronic ulcers with a well-marked ulcer history" ("Surg., Gynec., and Obstet.," May, 1908). The blood may be brought up with food, and is then black and clotted, or may be vomited clear and in large amount. Blood may be present in vomited matter or stools in such small amount that its presence is observed only by the microscope. The demonstration in the feces of minute quantities of blood (occult blood) is important diagnostically. It may be demonstrated by the guaiacum test or the aloin test. For two days before this test the patient must not eat rare meat, sausages, or fish. Blood in the stools does not prove the existence of gastric ulcer. The blood may have come from any spot from the mouth to the anus.

As Wm. J. Mayo ("Surg. Gynec., and Obstet.," May, 1908) says: "Visible or occult blood in the stool affords proof as to the fact that there is blood, but it should never be lost sight of that it bears with it no evidence as to its exact gastro-intestinal origin. The patient may have bleeding gums or hemorrhage from some slight abrasion in any part of the many feet of mucous membrane which exist between the lips and the anus. If occult blood is found by one chemical test, it must be corroborated by others, as some unsuspected food or drug may give rise to the reaction.

"As a matter of fact, hemorrhage from ulcer is by no means of frequent occurrence. The base of the ulcer is clean and free from granulation tissue, so that bleeding may be infrequent. Careful examination of the stools for many days may be necessary to detect its presence."

In hemorrhage from an acute ulcer a pint or two may be ejected in a few minutes, and such a patient presents all the general symptoms of dangerous hemorrhage. When an ulcer bleeds the blood is far more apt to be vomited than passed by the bowels, but in some cases blood from the stomach is passed by the bowels in part or wholly. A very large hemorrhage may occur, and yet the bleeding never be repeated, or a large hemorrhage may be followed by another or be the first of three or of a series. In a great many cases after a large hemorrhage there is no further bleeding or there are subsequently a few small hemorrhages. Small hemorrhages may occur indefinitely, and may after a time eventuate in a large hemorrhage. In chronic ulcer in which small hemorrhages recur over a long period the condition is due to bleeding from congested mucosa, dilated veins, or to the erosion of small vessels which cannot contract or retract because they are embedded in fibrous tissue. A large hemorrhage may be due to the erosion of a large vessel, but is often produced by the existence of a great number of erosions of the mucous membrane, erosions perhaps so numerous that blood seems to pour from every portion of the mucous surface. It is usually stated that in a sudden acute violent hemorrhage there will probably be no history of antecedent stomach trouble, but Wm. J. Mayo is of the opinion that "a single hemorrhage from a patient who has not had previous gastric symptoms is probably not due to ulcer" (Ibid.). It may arise from rupture of veins about the cardia or from blood from hemoptysis being swallowed.

In a chronic ulcer it is sometimes, though seldom, possible to palpate the indurated area.

Constipation exists in at least 90 per cent. of cases. There is often very marked anemia, aggravated and, some think, occasionally caused by continued loss of blood. Indigestion aggravates anemia and also may cause it. Most cases complain of prolonged indigestion. There is often a tender area in the back a little to the side of the eighth and ninth dorsal spines (usually the right side). A triangular area of hyperesthesia may be found in the left epigastric region (Head).

If the ulcer does not cicatrize, but progresses, causing pain and hemorrhage, the patient usually becomes thinner, more anemic, weaker, and even exhausted. In 140 cases in the Mayo clinic studied by Smithies ("Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912) 107 showed loss of weight. The average loss of weight was 20 pounds. The maximum loss observed was 65 pounds in six months. The average hemoglobin finding was 72 per cent.

It is certain that many cases of gastric ulcer are unrecognized; in fact, as Habershon says, diagnosis is rarely made unless hemorrhage exists, and in certain latent cases both vomiting and bleeding are absent. It is believed by some that latent ulcers are even more common than are ulcers causing symptoms. Hall ("Am. Jour. of Med. Sciences," May, 1909) says: "Rather than look too narrowly for exactly this or that evidence, we should take the broader ground that ulcer probably exists in most patients complaining of persistent

indigestion, even though not of an acid character, if pain, tenderness, vomiting and rigidity, or two or three of these phenomena be present, and even though hyperacidity be not proved." A bleeding ulcer with palpable thickening of the pylorus, especially if there is anemia and loss of weight, is frequently mistaken for cancer. *Fibromatosis* of the stomach with or without ulcer is usually diagnosticated as cancer. This condition was fully described by Alexis Thomson at the 1913 meeting of the American Surgical Association. The entire stomach may be indurated. It is cases like the above that may get well after gastro-enterostomy and thus furnish the first obtained proof that the condition was not cancerous (see page 957). The diagnosis of ulcer is far less difficult when there is food retention than when there is not.

The fluoroscope may aid in the diagnosis. Skiagraphs after a bismuth meal give highly important information as to the existence of scars, contraction of the pylorus, dilated stomach, and hour-glass stomach. In many cases it is impossible to make a differential diagnosis between pyloric ulcer and duodenal ulcer. In duodenal ulcer the pain and tenderness are above the umbilicus and in the midline or to the right, and if the duodenal ulcer bleeds the blood is most apt to pass by the bowel, but vomiting of blood is not unusual. A small percentage of duodenal ulcers also involve the pylorus.

A gastric ulcer may cicatrize and thus be cured, but the cure of the ulcer may prove the ruin of the stomach by producing stenosis of one of the stomach orifices or hour-glass contraction of the body of the stomach. An ulcer may perforate. Perforation occurs in about 15 per cent. of cases (Robson). A *perforation* may be *acute;* that is, the ulcer suddenly breaks open when the stomach contains food or liquid, and the contents of the stomach are poured into the free peritoneal cavity. A *subacute* perforation occurs when the stomach is empty or nearly empty. The opening is small in size, there is no escape of stomach contents or the escape of only a small amount, and the opening may be quickly closed by adhesion to an adjacent surface of peritoneum or a piece of omentum. If a certain amount of stomach contents is extravasated, it is usually surrounded by adhesions or tracks slowly toward the pelvis. In what is known as a *chronic* perforation the break takes place usually in the posterior wall into a box of preformed adhesions, the extruded gastric contents are circumscribed by these adhesions, the general peritoneal cavity is not invaded, but circumscribed suppuration is inaugurated.[1] This condition is known as *perigastric abscess*, and the subphrenic form is the commonest. In such a case the abscess may break into the pleural cavity or even into the lung. I operated on a girl of sixteen and found a perigastric abscess and a perforation of the anterior wall near the pylorus, and this condition was tuberculous. A fistula persisted for months, but finally healed.

Perforation is generally preceded by a history of indigestion, but it may come on without a suggestion of antecedent stomach trouble, is usually brought about by muscular effort, and is most common after a full meal, but it may occur when the patient is perfectly quiet and has not eaten for some time. The real cause is spasm of the pylorus, which causes tension of the stomach walls and keeps the viscus from emptying. Pyloric spasm is very common in sufferers from ulcers. In acute perforation food is the most active cause; in chronic perforation, muscular effort. "The severity of the symptoms depends upon several conditions: the previous state of health, the size and number of the perforations, the condition of the stomach, whether full or almost empty, the bacterial virulence of its contents, and the occurrence of vomiting."[2] The situation of the ulcer has some influence on the symptoms. "If in the fundus, at the cardiac end, or in the body of the stomach, an acute infection of the whole

[1] See paper by B. G. A. Moynihan, "Brit. Med. Jour.," Jan. 31, 1903.
[2] Moynihan, in "Brit. Med. Jour.," Jan. 31, 1903.

peritoneal cavity rapidly follows; if the ulcer be at the pylorus or in the first portion of the duodenum, the fluid is directed down the right side of the abdomen, owing to the hillock formed by the transverse mesocolon at the pyloric end of the stomach".[1] In such a case the fluid may gravitate toward the right iliac region and the condition may be mistaken for appendicitis. In a case of subacute perforation I operated, believing that appendicitis existed. Alderson calls attention to the fact that the sudden perforation of an ulcer may be mistaken for poisoning, and he cites the death of Henrietta, Duchess of Orleans, in 1670.

Acute perforation can be certainly diagnosticated if the case is seen early. Such an emergency has usually, but not invariably, been preceded by positive and prolonged symptoms of gastric disorder. It causes sudden and intensely violent epigastric pain, greatly increased by swallowing fluids, by vomiting, by turning the body, by cough, by inspiration, and by pressure. This pain may radiate throughout the abdomen, but the chief tenderness is in the region of the stomach. The seat of the pain after perforation does not, of necessity, correspond to the seat of perforation. Vomiting occurs in about half the cases after rupture. When it does occur it comes on soon after the pain, may recur again and again, and does much harm by increasing shock and by ejecting gastric contents into the peritoneal cavity. Vomiting of blood is very unusual. In many cases there is, singularly, little shock. Even when severe shock exists its duration is usually temporary. This important fact is insisted on by Eliot ("Annals of Surgery," May, 1912). Board-like rigidity exists, and it is most marked in the upper portion of the abdomen. The area of liver dulness is in some cases diminished and in exceptional cases obliterated. This symptom is due to gas passing into the peritoneal cavity and getting between the liver and the parietal peritoneum. It is seldom present after pyloric perforation or when the stomach at the time of the perforation contained very little food. It is when perforation is far from the pylorus and when the stomach contains fermenting food that enough gas escapes to diminish liver dulness (Eliot, Ibid.). There may be dulness in one flank or both flanks due to fluid. Eliot (Ibid.) lauds auscultation as an aid to detecting small amounts of fluid, and calls attention to *Shoemaker's symptom*, that is, a dull note on light percussion giving way to a tympanitic note when the percussed finger is pressed firmly against the abdominal wall, thus coming nearer to the intestine by pushing fluid away. The pulse may be very rapid, but often shows curiously little disturbance. Some few cases die rapidly in shock, but, as a rule, reaction occurs and, if operation is delayed, peritonitis arises. Acute perforation of the stomach may be in certain cases mistaken for appendicitis, cholecystitis, or hemorrhagic pancreatitis. If a patient with acute perforation is not promptly operated upon, he will soon exhibit the symptoms of general peritonitis. Subacute perforation causes less violent symptoms and they come on more gradually. There is in the beginning severe but not agonizing pain, which gradually abates. Moynihan points out that there is gastric uneasiness for several days before the perforation. Peritonitis develops slowly and the chief symptoms are often pelvic. *Chronic perforation* gives the signs and symptoms of perigastric abscess.

Treatment.—*Medical Treatment of Non-perforated Ulcer.*—Rest in bed. It is necessary to abandon stomach feeding for a time. For seven to ten days give nothing whatever by the mouth and give an enema of 10 oz. of normal salt solution every sixth hour. This is preferable to a nutritive enema because every time a nutritive enema is given a flow of gastric juice takes place into the stomach. (See W. Pasteur, in "Lancet," May 21, 1904; Seymour J. Sharkey, in "Lancet," Nov. 10, 1906.) During this treatment the patient is usually comfortable and is not unbearably disturbed by hunger and thirst. At the

[1] See paper by B. G. A. Moynihan, in "Brit. Med. Jour.," Jan. 31, 1903.

end of a week or ten days pancreatinized or peptonized milk is cautiously given by the mouth. According to some, nutritive enemata should now be substituted for saline enemata and be given for a few days before stomach feeding is instituted. After rectal enemata (saline and nutritive) have been abandoned the patient is placed on a very bland diet, preferably pancreatinized milk, and lavage is given twice a day. The value of introducing food into the rectum is, to say the least, doubtful. Saline fluid and certain drugs are absorbed from the rectum, but little if any protein matter is absorbed. Investigators are now seeking for some form of digested protein matter that will be absorbed. Protein material when in the rectum is not acted upon by the enzymes necessary for its absorption, it undergoes putrefaction, causes irritation, and sets free toxic alkaloids which are absorbed. It is suggested that digested albumin and fat and grape-sugar may be absorbed. In some cases of ulcer Carlsbad salts are given by the mouth (Ziemssen); in others, silver nitrate with extract of belladonna, bismuth subnitrate, or oxalate of cerium. If pain is severe, opium may be required. Many cases are apparently cured by medical treatment. Russel's statistics show that 40 per cent. of cases were reported cured under medical treatment, but no one knows how many of those reported cured again gave evidence of the disease or later perished because of hemorrhage or perforation. Further, 18 per cent. of the 500 London Hospital cases under medical treatment died and 42 per cent. were not cured when discharged. Out of the supposed 40 per cent. of cures many later undoubtedly developed or will develop renewed symptoms and perhaps fatal conditions.

Surgical.—The exact curative value of operation is not settled. Kronlein's clinic claims 85 per cent. cures, Von Eiselsberg's clinic but 52 per cent. of cures and 15 per cent. of improvements. The nearer the ulcer is to the pylorus, the better the chance of cure. Following the Mayos, we would not advise surgical treatment in acute ulcer unless complicated by hemorrhage, perforation, or obstruction; or in chronic ulcer, until careful medical treatment has failed. Operation is indicated for chronic ulcer when a mechanical cause is responsible for retention and stagnation of stomach contents, and in certain cases of hemorrhage. Operation is also indicated in chronic ulcer with frequent exacerbations, but the surgeon should be very chary of operating upon neurotic women with gastroptosis unless, of course, there is a positive indication (Wm. J. Mayo, in "Jour. Am. Med. Assoc.," Oct. 21, 1905).

In a chronic ulcer if the patient grows worse in spite of careful dietetic and medical treatment, if hemorrhage has been profuse or if there have been frequent distinct hemorrhages, if the pain is violent, or if tenderness is marked, open the abdomen and inspect the stomach. An ulcer with indurated edges is easily found. The form, called by the Mayos the non-indurated ulcer, gives no evidence or little evidence of its existence when the outer coat of the stomach is felt and inspected (Wm. J. Mayo, Ibid.). Even when the stomach is opened, no ulcer may be found. According to Mikulicz, in some mucous ulcers there is a very little thickening, and, according to Moynihan, the mucous coat may be a little adherent to the muscular coat, so that it does not slide easily. An enlarged gland in a portion of the omentum may be a sign of ulcer (Lund). An indurated ulcer may be removed by an elliptical incision in the long axis of the stomach, the coats being sutured by the usual method, and gastro-enterostomy being also performed. In ulcer of the pylorus with great thickening we may excise the pylorus, close both the duodenal and stomach openings, and perform posterior gastro-enterostomy. In some cases gastro-enterostomy alone leads to the cure of chronic ulcer. The Heineke-Mikulicz operation is not satisfactory in ulcer. Finney's gastroduodenostomy is not advisable if there is an unhealed ulcer, because food still passes over the ulcer after its performance.

Wm. J. Mayo ("Annals of Surgery," 1910) has described a transgastric method for excising ulcers of the posterior wall which are adherent to the pancreas. The excision passes through pancreatic tissue. Bleeding is arrested by suture-ligatures. The wound in the pancreas is not sutured, but is closed by a mobilized portion of gastrohepatic or of gastrocolic omentum.

Operation for Gastrorrhagia (*Hemorrhage from the Stomach*).—Rydygier proposed in 1882 to operate for hemorrhage. The first operation was done by Mikulicz in 1887, and the first successful operation was reported by Roux in 1893.

In acute and violent hemorrhage threatening life the proper course to pursue is somewhat uncertain. It is not proper to operate if there has been but one hemorrhage, because the chances are that the bleeding will not be repeated. Again, the chance of arresting such a hemorrhage by operation is, on the whole, poor. The danger of waiting after one hemorrhage is not so great as the danger of immediately operating, because collapse antagonizes renewed hemorrhage, but adds enormously to the risk of an operation. In over 90 per cent. of cases the hemorrhage ceases spontaneously. In over 18 per cent. of those dying of hemorrhage death is so rapid that operation is impossible (Savariaud). If the bleeding is from a distinct ulcer, we may succeed in excising the ulcer or in ligating the bleeding-point. Roux, of Lausanne, saved a patient by excising an ulcer and ligating the bleeding coronary artery on each side of it. As a rule, however, the bleeding is not from a distinct point, but from a multitude of excoriations. In the light of our present knowledge we may lay down the following rule: Do not operate for one acute hemorrhage. Simply bring about reaction by gentle means, let the patient take bits of ice, and give suprarenal extract by the stomach. If the bleeding recurs once or twice in comparatively trivial amounts, do not operate; but if it recurs violently, we should advise operation. In cases of ulcer in which bleeding in small amounts persists, operation is indicated. In operating for a severe hemorrhage the surgeon opens the abdomen while hot salt solution is being thrown into a vein, The stomach is opened, the clots washed out, and a search made for the source of the blood. If it is found that the blood comes from an area of ulceration, this area may be extirpated, ligated, or cauterized with the thermocautery. Some advise surrounding it with a purse-string suture. Others, notably Moynihan, simply perform gastro-enterostomy, which is of service by draining and giving rest to the dilated stomach, the hemorrhage being perhaps arrested by contraction of the gastric walls and the rest secured preventing the detachment of hemostatic clot. Gastro-enterostomy is of most service in ulcer near the pylorus and in duodenal ulcer. If the ulcer is well above the pylorus it should be excised if possible. As a rule, it will be found that the vessels entering the ulcer are varicose. Excision is indicated because of this varicosity. If excision is impossible "the main blood-vessels leading into the ulcer should be ligated and the peritoneum and muscular coats drawn over it" (Wm. J. Mayo, in "Surg., Gynec., and Obstet.," May, 1908). If it is found that the bleeding comes from a multitude of excoriations and that the stomach is, as Moynihan expresses it, "weeping blood," we can do nothing but gastro-enterostomy, which in such a condition is of uncertain value.

Operation for Perforation.—In acute and subacute perforation operate at once, having all proper means taken to bring about reaction from shock, while the abdomen is being sterilized and while ether is being administered (hot saline enemata, external heat, atropin hypodermatically, etc.). As a matter of fact, shock is seldom so profound as to cause us to hesitate about operating. I formerly advised to wait until reaction was established before operating. I now believe such advice erroneous. To delay after an acute perforation is to wait for what may never come. Open the abdomen at the point of greatest

tenderness, or, if there is no such point, open it in the epigastric region, a little to the right of the midline. When the abdomen is opened there may be an escape of odorless gas, and food or fluid may be discovered in the peritoneal cavity. The perforation is sought for and is usually found in the anterior wall. When found, it should be buried and overlaid by stomach wall, a portion of which must be inverted by two layers of Halsted sutures. I do not believe that excision or paring the edges is necessary or desirable in a case of perforated ulcer. If it is too large to close, stitch a plug of omentum into the opening or insert a tube and create a temporary gastrostomy. If no perforation is found on the anterior wall, make an opening into the lesser peritoneal cavity through the gastrocolic omentum, explore the posterior wall, and close and cover any perforation found. In addition to closing the perforation, gastro-enterostomy is theoretically indicated in order to drain the viscus, give it rest, and lessen the tendency to recurrence of ulceration. But, as a matter of fact, such ulcers seldom return. By the time the perforation has been closed the patient is perhaps too severely shocked to render such an additional operation justifiable, and I agree with Gibbon that such an operation should be performed only when there are multiple ulcers or when there is pyloric constriction (John H. Gibbon, in paper before the Tri-State Med. Assoc. of Virginia and the Carolinas, Feb. 23, 24, 1904). After closing the perforation the abdominal cavity is irrigated with hot salt solution, and the space between the liver and diaphragm is sponged out with a gauze pad wet with hot salt solution. If the case is operated on many hours after the perforation, or if the peritoneum was badly soiled, drainage *must* be used, but even in other cases it is safest to use it. Drainage is obtained by means of a cigarette drain or a piece of gauze passed to the suture line in the stomach. In cases with much extravasation, especially if the extravasation has reached the pelvis, a suprapubic opening is made and a tube inserted. After the patient has reacted from the shock of the operation he should be placed in a semi-erect position to direct the flow of infective material to the pelvis, and continuous proctoclysis should be employed as in peritonitis (see page 1024). The treatment of chronic perforation is the treatment of perigastric abscess, and consists of incision and drainage. Of late, a number of cases of acute and subacute perforation have been successfully operated upon. Moynihan estimates that 35–40 per cent. of acute perforations recover after operation. T. Crisp English ("Lancet," Nov. 28, 1903) reported 42 consecutive gastric perforations operated on in St. George's Hospital; 22 recovered.

Cicatricial stenosis of the orifices of the stomach results from the healing of an ulcer, the swallowing of a corrosive substance, or traumatism from a foreign body. Constriction of the *cardiac orifice* is indicated by gradually increasing difficulty in swallowing. After a time the esophagus above the stricture dilates or pouches; the fluid food passes into the stomach, but the solid food lodges in the esophageal pouch and is soon regurgitated. The site of the stricture is located by a bougie, and by having the patient swallow while auscultating over the esophagus and cardiac end of the stomach. If the constriction be malignant, the patient will be found to be beyond middle life, the vomit is occasionally bloody, emaciation is rapid and decided, and occasionally the supraclavicular glands are enlarged. A tumor of the cardiac end of the stomach can seldom be palpated. If the constriction be cicatricial, the history will indicate the cause. Constriction of the *pyloric orifice* causes retention of food and dilatation of the stomach. Dyspeptic symptoms will be found to have been long present. A tube passed into the stomach permits of the injection of fluid so as to fill the stomach. When the fluid runs out it contains portions of undigested food, which was perhaps eaten days before, and measurement of the liquid shows that the capacity of the stomach is enormously in-

creased. If hydrogen be forced through the tube, the outline of the distended stomach is at once made clear. The usual method of distending the stomach is by a Seidlitz powder: two solutions are made; the bicarbonate solution is swallowed at once, and the tartaric solution is taken afterward in small amounts at a time. Percussion over the distended stomach indicates the size of the viscus. It is well to remember that when gastric ulcer exists dilatation of the stomach can occur without cicatricial stenosis. The cause in such a case is pyloric spasm, or perhaps the atonic condition which may result from anemia and neurasthenia.

In malignant disease of the pylorus a tumor may often be palpated; there are tenderness and considerable persistent pain, great cachexia and emaciation, absence of free hydrochloric acid from the gastric juice, diminution of red corpuscles and hemoglobin, and perhaps no increase of white corpuscles after a full meal. There is sometimes enlargement of the supraclavicular glands. Vomiting of bloody fluid occurs in 40 per cent. of the malignant cases. The use of the x-rays after a bismuth meal is a valuable aid in diagnosticating pyloric constriction. The diagnosis of cardiac constriction is discussed in the section on Stricture of the Esophagus. In cicatricial stenosis of the pylorus there may be paroxysms of pain, there is no tenderness, emaciation is not so early in onset or so rapid in progress, and the supraclavicular glands are never enlarged. Vomiting occurs, but the ejected matter is not bloody.

Treatment.—Cicatricial cardiac stenosis requires dilatation with bougies and the maintenance of the restored caliber. If dilatation from above is unsatisfactory, perform gastrotomy, push a small bougie from the mouth into the stomach, tie a string to the bougie, draw the string through the stricture, use the string as a saw to cut the fibrous bands, pass a full-sized bougie, close the wound in the stomach, and maintain the caliber of the cardiac orifice by the repeated passage of dilating instruments. If no instrument can be passed through the stricture from above, perform a gastrotomy, introduce an instrument from below and pass it into the mouth, tie a string to it, draw the string into the stomach, and use Abbe's string-saw (see page 936). If no instrument can be passed from below, convert the gastrotomy into a gastrostomy. In malignant stenosis of the cardia, gastrostomy, if performed at all, should be performed early. Jejunostomy is a better operation. Cicatricial pyloric stenosis was formerly treated by gastrotomy and digital divulsion of the stricture (*Loreta's operation*); but this operation is obsolete, experience having shown that recontraction is inevitable. Pyloroplasty was until recently advocated by many surgeons. This is known as the Heineke-Mikulicz operation. In 30 per cent. of the cases the symptoms are not relieved by pyloroplasty, a condition which renders gastro-enterostomy necessary. Mayo points out that in such cases pyloroplasty fails because the pylorus is on a higher level than the gastric pouch, the degenerated muscle of the stomach is unable to lift the food from the pouch to the pylorus, and the symptoms of gastric dilatation and retardation of the passage of food into the duodenum are not relieved. The operation has been generally abandoned. Finney's method of gastroduodenostomy (Figs. 645–648) is a great improvement on pyloroplasty. The opening is large and in a proper position to afford satisfactory drainage. Gastro-enterostomy is the most satisfactory operation in most cases and usually effects a cure. Malignant stenosis is treated by pylorectomy or gastro-enterostomy. (See under these heads respectively.)

Congenital or Infantile Hypertrophic Stenosis of the Pylorus.—Osler tells us that the first case was published by an American, Hezekiah Beardsley, in 1778. Hirschsprung, of Denmark, in 1887 published the first modern case (Bunts, "Am. Jour. Med. Sciences," Jan., 1912). Stenosis in adults is almost invariably due to cancer or to ulcer, but in very young children one occa-

sionally meets with a form that is congenital. The history of such a case is that during the first two or three days after birth the child seems in every way normal, but that after several or a number of days or perhaps weeks vomiting suddenly begins—vomiting for which no dietary cause seems responsible, and which persists irrespective of medication. After the stomach has been emptied by vomiting the child seems much relieved, but when, after a time, food is administered, vomiting will begin again, either in a very short time or after an hour or so. It has been noted that the vomited matter in congenital stenosis of the pylorus never contains any bile whatever, for obvious reasons—the pylorus is shut and the bile cannot enter the stomach. A child in this condition receives little or no nourishment, becomes quickly emaciated, and soon dies. Some of these children die in a month; others, in several months, and a few may live for five or six months. It may be possible, in these cases, to palpate a thickened pylorus, and the outlines of the dilated stomach may be made out. Regurgitant vomiting by keeping the stomach empty may prevent dilatation. The most common symptom is gastric peristalsis. In Bunts's table gastric peristalsis was present in 84 per cent., and tumor in 69 per cent. of cases. In true congenital stenosis there is hypertrophy. The circular muscular fiber undergoes great increase from hypertrophy, perhaps with some fibrosis. The mucous mmbrane is hypertrophied and thrown into folds. The opening into the duodenum may be no larger in diameter than a pin and may be totally blocked by folds of mucous membrane. Even when there is comparatively little or no hypertrophy the lumen of the pylorus may be closed by spasm. It is these latter cases which are benefited by medical treatment. Such cases are not instances of congenital hypertrophy and should be classified as pyloric spasm. In congenital hypertrophic stenosis the intestines are very much collapsed, and the child is, of course, much constipated. Cases of pyloric closure have recovered after lavage carried out daily for some weeks and careful breast feeding. Such cases are probably instances of spasm. This plan is only permissible if there is no palpable thickening at the pylorus. A trial should be given this method unless the condition of the patient demands immediate relief. If there is palpable thickening of the pylorus, operation is called for imperatively. The delay in employing surgery in hopes of lavage succeeding must never be so long that the patient emaciates. If the condition does not soon show signs of improvement, operation is indicated. Cases reported cured by medical means may have been instances of pyloric spasm. The operation for this condition is usually gastro-enterostomy. The mortality after the operation is apparently over 50 per cent. It is superior to pyloroplasty because it enables us to at once feed the exhausted child. Bunts ("Amer. Jour. Med. Sci.," Jan., 1912) operated on 7 cases and 4 recovered. Gastro-enterostomy saves the child from starvation and restores the function of the intestinal canal, but the pyloric tumor remains permanently (Scudder, in "Surg., Gynec., and Obstet.," Sept., 1910).

Perigastric Adhesions.—That perigastric adhesions are frequently responsible for stomach pain and digestive difficulty is undoubted. Such adhesions often arise in cases of protracted ulceration of the stomach or duodenum. A common cause of perigastric adhesions is gall-stone disease. Tuberculous peritonitis causes dense adhesions. In some cases adhesions are traumatic, in some are due to syphilis, in many the cause is uncertain (Fred. D. Bird, "Intercolonial Med. Jour. of Australia," Dec. 20, 1900). Adhesions may cause blocking or kinking of the pylorus, or may glue the stomach to the parietal peritoneum or to some adjacent viscus. In Fenwick's table of 123 cases he finds that the adhesions usually cause the stomach to adhere to the pancreas or to the liver. The formation of adhesions in cases of gastric ulcer is, in many instances, conservative, serv-

ing to prevent perforation or to limit extravasation if perforation of the stomach wall occurs.

The **symptoms** are variable. In some cases the adhesions produce little or no trouble; but in the majority of cases they cause definite symptoms, and sometimes the condition becomes one of absolute disablement. The symptoms may be due to blocking of the pylorus, a condition that is followed by gastric dilatation. They may be due to dragging upon the adhesions when the stomach contracts during digestion, or when peristalsis occurs in an adherent piece of intestine.

The usual symptom is pain, frequently of a violent character. The pain comes on in paroxysms, and recurs over and over again, it may be during years. H. Hale White[1] points out that in these cases there is usually some pain persisting, which is now and then increased into violent paroxysms; and that the only other condition that produces persistent pain with violent exacerbations is cancer. In *adhesion-dyspepsia*, however, there is no distinct loss of weight; the condition may exist in youth, as well as in middle age or old age; it is not always increased by taking food, and it very rarely causes death. If there is a history of antecedent gall-stone disease or of ulcer of the stomach, it is possible to make the diagnosis without exploratory operation. Even in other cases the condition may sometimes be diagnosticated, because, although there are these attacks of violent pain, there is no tenderness. In rare cases the adhering and matting together with inflammatory exudate produces a palpable mass. In doubtful cases of chronic and disabling stomach disease an exploratory operation should be performed; if adhesions exist, they will then become manifest.

Treatment.—In some cases simply dividing an adhesion effects a cure; in other cases it is necessary to make extensive separation of adherent structures, covering the raw surfaces with omental grafts. In serious adhesions about the pylorus gastro-enterostomy is usually the proper operation.

Bilocular Stomach (Hour-glass Stomach).—It is usually stated that some cases are congenital, but the writings of Mayo Robson, Moynihan, and H. L. Paterson cause us to doubt if the condition is ever congenital. Even in the so-called congenital cases ulcers are found, or ulcer scars exist, or ulcer adhesions are demonstrable. The advocates of a congenital origin say that the ulcers are secondary to the narrowing, and that ulceration tends to occur, particularly at the seat of constriction. Beyond doubt, a very great majority, at least, of cases of bilocular stomach result from adhesions produced by the healing of an ulcer. In hour-glass stomach with a large opening between the two sacs there may be no symptoms. When the opening is small the symptoms resemble those of pyloric stenosis. The sac toward the cardia is frequently much dilated.

Symptoms.—The diagnosis of cancer is often made. The protracted gastritis may have caused free hydrochloric acid to disappear and acids of fermentation are usually found. The patient vomits from time to time, bringing up food which was eaten a day or two before, proof that food is retained in the stomach and not digested. Occasionally, perhaps, blood is vomited. There is pain and the patient is harassed by foul-smelling eructations. Emaciation becomes pronounced. Cumstom[2] points out that in a thin belly distention of the stomach may make the condition evident; further, that if water is thrown into the stomach, only a part returns, and when the stomach is emptied as much as possible by a tube, a splashing sound can still be elicited in the stomach because the pyloric pouch is not empty. One cause of death is torsion on the axis. A skiagraph taken after a bismuth meal gives diagnostic information of the first importance.

[1] "Lancet," Nov. 30, 1901. [2] "Med. News," Dec., 1901.

Treatment.—The diagnosis becomes certain after exploratory operation, and exploration also enables the surgeon to decide with certainty as to what operation should be performed. Cumstom[1] gives us the following suggestions:

1. In rare cases resect the stricture and suture the pouches.
2. If there is trivial ulceration or a slight scar, do gastroplasty, an operation upon the constriction exactly similar to pyloroplasty.
3. The best operation in most cases is gastrogastrostomy—that is, anastomosis of the cardiac pouch to the pyloric pouch; but this cannot be done if the pyloric pouch is small. Then do gastro-enterostomy.

Other operations are:

4. Gastroduodenostomy.
5. Gastrojejunostomy.
6. Gastrolysis.

In malignant disease resection (partial gastrectomy) is indicated. After gastroplasty recontraction is common, and I do not believe in the operation. Gastro-enterostomy is unsatisfactory. The ordinary operation drains but one pouch. Weir and Foote advised a double gastro-enterostomy, tapping each sac. In most cases gastrogastrostomy followed by gastro-enterostomy is the best procedure.

Chronic Dilatation of the Stomach.—A dilated stomach, roughly speaking, is one which can contain more than 1.5 quarts (Ewald). Some few cases of dilatation result directly from atrophy of the muscular coat brought about by drinking quantities of liquid, especially beer; chronic catarrh of the stomach; and conditions such as cancer, tuberculosis, diabetes, etc. The common cause of dilatation is constriction of the pylorus. In order to force food through the pyloric narrowing more force is necessary than is required in a normal state of affairs to cause the food to enter the duodenum, hence the stomach muscle hypertrophies. This muscular hypertrophy is compensatory, and dilatation does not occur so long as the muscle is efficient. But finally the pyloric opening becomes so narrow that compensation fails, the stomach contents accumulate, and the stomach dilates.

Symptoms of Dilated Stomach.—There is annoying hunger unless cancer exists. Thirst is complained of. At intervals of a day or two the patient vomits enormous quantities, and portions of food may be identified which were eaten one or more days before. The vomited matter is sour and foul smelling, contains numbers of yeasts, and much fermentative acid. Free hydrochloric acid is often absent. In some cases vomiting occurs two or three hours after each meal. The patient suffers from foul gaseous eructations. There are progressive emaciation, constipation, scantiness of urine; sometimes cramp in the legs, belly, and arms; tetany may occur (see Parathyroid Tetany, page 1244) insomnia is the rule; cardiac palpitation occurs, and there is dyspnea, particularly at night.

Physical Signs of Dilated Stomach.—The epigastric region is hollow and the left side of the abdomen is more prominent than the right. The outline of the greater curvature of the stomach can be distinguished. If the stomach contains air, percussion gives a tympanitic note; if it contains fluid, a dull note. When it is partly full of fluid, by altering the position of the patient we can show by percussion that the fluid changes its position. In a doubtful case give a light meal in the evening, and in the morning, before the patient has eaten, introduce a tube and remove any material contained in the stomach. The presence of undigested food points to dilatation.

To Test the Motor Power of the Stomach.—*Klemperer's Test.*—Wash out the stomach. Introduce 100 c.c. of olive oil by means of the tube. After two hours withdraw the oil. The stomach cannot absorb oil, and if the

[1] "Med. News," Dec. 7, 1902.

amount withdrawn is subtracted from the amount introduced the difference is the amount which passed the pylorus. If the condition is normal, not more than from 20 to 40 c.c. should be found in the stomach after two hours.

The Salol Test of Ewald.—Salol is not decomposed in the stomach, but in the intestine is broken up into phenol and salicylic acid. Salicylic acid is absorbed and salicyluric acid soon appears in the urine. If salol cannot reach the intestine, salicyluric acid will not appear in the urine. If salol reaches the intestine more slowly than normal, salicyluric acid will appear after a longer interval than when there is no pyloric block to retard the emptying of the stomach. In a normal person salicyluric acid is found in the urine in from three-fourths of an hour to an hour after swallowing a dose of salol. In stenosis of the pylorus it appears much later. The test is made as follows: The bladder is emptied and the patient is given three capsules, each containing 5 gr. of salol. The patient is directed to pass water every half-hour until he has done so four times. Each sample voided is examined for salicyluric acid by adding neutral chlorid of iron. If salicyluric acid is present, a violet color is noted.

To Test the Absorptive Power of the Stomach.—The absorptive power of the stomach can be tested by giving the patient a capsule containing $1\frac{1}{2}$ gr. of iodid of potassium. Normally the drug should be found in the saliva in from ten to fifteen minutes. When absorption is deficient, it may not appear for an hour or longer. In order to test for it, moisten starch paper with the saliva and touch the moist paper with a drop of fuming nitric acid. If iodin is present, a blue color develops.

While the diagnosis of dilatation of the stomach can be certainly made, the determination of the cause may require an exploratory operation.

Treatment.—Cases not due to pyloric obstruction are much improved by lavage, regulated diet, use of an abdominal belt, electricity, aperients, and other agents called for by symptoms.

In all cases in which there is pyloric obstruction, in many doubtful cases, and in cases in which medical treatment fails, exploratory operation is indicated. In dilatation without pyloric obstruction some surgeons advocate gastroplication. If pyloric obstruction exists, the surgeon may elect to do pylorectomy, pyloroplasty, or gastro-enterostomy, the method selected depending on the condition discovered. If gastroptosis exists, gastropexy or Beyea's operation may be performed.

Acute Dilatation of the Stomach.[1]—This condition may suddenly arise in the course of chronic dilatation or when no previous dilatation existed. Its clinical features were described by Brinton in 1859. Hilton Fagge in 1873 furnished us with the first comprehensive description of the signs and symptoms. The cause is uncertain, and is a subject of active investigation at the present time. It is said to be due to degeneration of the gastric muscle in the course of specific fevers, to paresis arising in the course of chronic gastritis, and to the drinking of a quantity of effervescing liquid. If is occasionally a fatal sequence of abdominal operations, particularly operations upon the gall-bladder and bile-ducts. The surgeon sees it in the course of sepsis and during shock from operations in which a general anesthetic was used, and occasionally in cases of spinal curvature.

One set of observers maintains that the condition is brought about by actual constriction of the duodenum, the constricting cause being the root of the mesentery and the superior mesenteric artery and the duodenum being squeezed against the vertebral column (Rokitansky, Albrecht, Robinson, and Kundrat).

[1] See Kelling, in "Archiv. f. klin. Chir.," 1901, lxiv; Albrecht, in "Virchow's Archiv.," 1899, clvi; Conner, in "Am. Jour. Med. Sciences," March, 1907.

Codman believes that normally in man there is more or less tendency to such constriction on standing erect or lying down, and that a trivial increase of the constriction which may be brought about by various causes may completely obstruct the duodenum ("Boston Med. and Surg. Jour.," 1908). Lewis A. Conner collected 18 fatal cases shown by necropsy to be due to mesenteric obstruction ("Am. Jour. Med. Sciences," March, 1907).

Another set of observers asserts that acute dilatation is due to lesion of the nerve-trunks or nerve-centers, resulting in paresis of the muscle of the stomach wall and spasm of the pylorus. The cause of the nerve lesion is variously held to be hyperacidity of gastric secretion, the absorption of the toxins of fermentation, the secretion of chloroform into the stomach, the overdistention of the viscus with ether vapor, or an enormously great secretion of fluid into the stomach.

As Conner (Ibid.) says, the theory of pyloric spasm being causative is untenable because in most cases vomited matter contains bile, and in two-thirds of the cases the duodenum is involved in dilatation.

It seems certain that some cases of gastric dilatation are associated with mesenteric constriction of the duodenum, brought about by the intestines descending into the pelvis. The constriction inaugurates the dilatation and is aggravated by the dilatation. Conner points out that the intestines enter the pelvis as a result of dorsal decubitus, a long mesentery, and a gut nearly empty of gas and feces, and is favored by relaxation of the belly wall ("Jour. Am. Med. Assoc.," March, 1907).

Symptoms.—The most frequent and prominent is violent vomiting, usually inaugurating the symptoms and continuing throughout the illness, although occasionally it ceases for some time before death. The amounts vomited are always large and often enormous. The vomitus is thin and of a green or black hue, usually contains bile and sometimes a little blood, but very seldom feces.

In most cases, but not in all, there is epigastric or umbilical pain and tenderness. Distention is the rule. Rigidity is rare. In many cases there is no passage of gas or feces, but in some diarrhea exists. There is great thirst, there may be hiccup, and delirium may arise before death. The temperature is nearly always normal or below normal. There is seldom visible gastric peristalsis (Conner, Ibid.), and splashing sounds are obtainable over the stomach.

Collapse arises early and quickly becomes profound. Tetany occasionally occurs. A case of my own died of acute gastric dilatation after an operation for stone in the kidney. He suddenly developed attacks of violent and profuse vomiting, rapidly went into collapse, lividity developed and hiccup arose, and he died in forty-eight hours.

A case may die in less than twenty-four hours or may die after ten days or more. Conner's group of cases shows a mortality of 72.5 per cent. Fluid cannot reach the small intestine, and as none is absorbed from the stomach and little from the duodenum, the tissues starve for the want of it (Laffer, in "Annals of Surgery," April, 1908). The condition is frequently diagnosticated acute intestinal obstruction or peritonitis from perforation.

Treatment.—When the stomach has dilated greatly and when collapse is profound, treatment is usually of no avail. When an early diagnosis is made treatment is often of the greatest value. The stomach must be at once emptied by the use of a tube and the treatment be repeated at intervals of a few hours. Neither food nor drink should be given by the mouth. Saline enemata and perhaps nutritive and stimulating enemata should be given. The patient should at once be placed upon the belly and kept there until the condition abates, in the hope that this posture will relieve duodenal constriction.

Gastro-enterostomy has been employed, and is advocated by Mayo Robson. Byron Robinson had a successful case. I would be disposed to employ it in spite of the reported failures. In a number of cases the stomach has been opened and washed out without benefit. Petit opened the abdomen and discovered a kink at the junction of the duodenum and jejunum; he raised the jejunum and sutured it to the transverse colon and the patient recovered (Conner, "Jour. Amer. Med. Assoc.," March, 1907).

Not until we know definitely the cause or causes of acute dilatation of the stomach will we be able to lay down with precision and accuracy the treatment which is indicated. There is much difference of opinion as to the causation of the condition, and widely different methods of treatment are advocated by various surgeons.

Fig. 602.—Gastroptosis (shown by a skiagraph).

Gastroptosis (Fig. 602).—In this condition the stomach has undergone displacement downward, the greater curvature in many cases being but little above the pubic symphysis and the lesser curvature being between the ensiform cartilage and the umbilicus. This condition is far more common in women than in men, and is especially common in women who have had many children. It may be produced by tight lacing and may follow movability of the right kidney, of the liver, or of the spleen. It is often associated with enteroptosis, mobile cecum, and prolapse of the colon, and is particularly prone to arise in the anemic and tuberculous.

Symptoms.—There may be no symptoms for a long time, but sooner or later dyspepsia arises because the stomach cannot empty itself. The stomach becomes atonic, its secretions are scanty and altered, and while the viscus may be normal in size or even shrunken, it is usually dilated. The malposition can be made out by percussion when the stomach is distended with air or with fluid, and by the *x*-rays after the patient has drunk a pint of a solution of mucilage of acacia containing subnitrate of bismuth. The bismuth lines the stomach and intercepts the *x*-rays and a radiograph shows the outlines of the stomach and hence its size and position. The pylorus descends to the umbilical region, which it does not do in plain dilatation. In dilatation the pylorus is but slightly lower than normal, but the lower border of the stomach

is notably depressed. In gastroptosis there is often a constriction a short distance from the pylorus due to a kink produced by the sagging.

When a patient with gastroptosis stands erect the bulging is most prominent in the region of the umbilicus and the epigastrium is deepened.

Gastroptosis is not infrequently associated with chlorosis and commonly with neurasthenia.

Treatment.—Lavage, regulation of diet, improvement of the general health, the wearing of an abdominal binder, and placing the patient supine for a time after each meal. If medical treatment fails and the condition is producing grave impairment of the general health, it may be necessary to perform a surgical operation. Gastro-enterostomy is advocated by some on the ground that the unpleasant symptoms result from stagnation of gastric contents. Good results have been reported by this plan. The operation of Depage is unphilosophical. Duret's operation is objectionable (see page 1104). Beyea's operation or Ransohoff's method are preferred (see page 1104).

Chronic Intestinal Stasis.—This is a term employed by Mr. Arbuthnot Lane to designate such a delay in the passage of material along the gastro-intestinal tract as to permit of the absorption of so much toxin that the body cannot successfully deal with it (Lane's paper before the Derby Med. Soc., Oct. 17, 1911). Defective drainage permits absorption of poison, and absorption of poison is responsible for ill health and the lowering of vital resistance to various bacteria. Lane and his followers are of the opinion that toxemia so induced may cause chronic mastitis, rheumatoid arthritis, gastric ulcer, duodenal ulcer, appendicitis, and, by lowering resistance, may be responsible for progressive tuberculous disease. They believe that the block to drainage is brought about by kinks, and that the kinks, which tend to form in certain situations, are due to bands; in other words, the condition is due to a mechanical cause (Lane, Ibid.). Mayo regards such bands as congenital. Lane holds that faulty feeding in early life causes abnormal distention and pull on the gut, that when the erect posture is assumed the condition is exaggerated by the formation of new peritoneal bands which are formed to resist the dropping of the intestine.

In 1909 Jabez Jackson described a pseudomembrane sometimes seen over the peritoneum of the lower ileum and colon and loosely attached to it. Sometimes it is also attached to parietal peritoneum and thus limits movements of the gut. This thin membrane is known as *Jackson's veil,* and it is probably identical with Lane's bands. Some observers regard Jackson's veil as the result of pericolitis, some as due to infantile colitis, some to chronic colitis, some to appendit𝑖tis. Isaacs ("New York Med. Jour.," Oct. 26, 1912) points out that this pseudo-membrane may be found in other regions than over the colon, and suggests calling the condition *membranous perienteritis.* He believes the membrane is formed because of ulceration or inflammation of the gastro-intestinal tract.

The large intestine plays such a prominent part in toxin absorption that Barclay Smith (quoted in "Brit. Med. Jour.," Dec. 7, 1912), Metchnikoff, Lane, and others put under ban that portion of the gut, regard it as a useless and dangerous encumberance, and would take it out and cast it away.

Treatment.—If a band or membrane exists, remove it, and if a raw surface is left, cover it over with peritoneum.

In partial blocking of the beginning of the large intestine or of the lower ileum some perform ileocolostomy. Lane extirpates the colon and fastens the upper end of the divided ileum to the rectum. He does the same operation for rheumatoid arthritis, tuberculous joints, and other conditions—radical steps on a road where so far few have gone more than a short distance.

Intestinal obstruction (**ileus** or **enterostenosis**) is a condition in which fecal movement is mechanically impeded or prevented. It may be

either *partial* or *complete, acute* or *gradual*. *Acute obstruction* is due to a sudden narrowing or occlusion of the lumen of a portion of the intestine. *Chronic obstruction* is due to a gradual narrowing of the lumen of a portion of the intestine, and it may at any time become acute. If there is not only interference with the passage of the fecal current, but is also obstruction to the blood-current in the wall of the bowel, the condition becomes *strangulation*. The primal cause is mechanical in nature, in most cases a mechanical block. In paralysis of the bowel from peritonitis there is inability of the bowel wall to contract and force the feces onward. In all cases of unrelieved obstruction the nerves are sooner or later damaged and paralysis occurs. In acute obstruction the stagnated intestinal contents become charged with powerful poisons which act most harmfully on the musculature of the intestinal wall, and, after absorption, attack the heart and nervous system. The inaugural shock is due to the production of the block; later the increasing depression is due to absorption of poisons. Gas forms in great amount in the intestine and produces distention. Distention impairs the circulation in the wall of the intestine and embarrasses respiration by pushing up the diaphragm.

Acute Obstruction.—The worst forms of this grave condition are due to sudden and absolute blocking of the bowel with strangulation, as when a portion of bowel is caught under a band or in a hernial aperture.

As soon as strangulation occurs there is violent peristalsis. The bowel above the strangulation for a short time vainly lashes itself into effort to force intestinal material by the obstruction. The peristalsis below empties the bowel below the obstruction, leaving it empty and contracted, but not paralyzed.

Peristalsis above the obstruction soon ceases, and the bowel in this region becomes greatly distended with bloody fecal fluid and gas. The putrefaction of the intestinal contents forms great quantities of gas: none of it can pass the obstruction and none of it can be absorbed because of circulatory disturbance in the bowel wall. It is only early in an acute obstruction that the distended bowel above the block is thin. It soon becomes congested and edematous, bleeding may occur from the mucous membrane, and that structure desquamates and may be eroded. When the mucous membrane is desquamated, bacteria pass through the bowel wall and cause peritonitis, or erosions may perforate. Miles ("A System of Surgery," edited by C. C. Choyce) points out that swelling of the gut is greatest when obstruction is in the small intestine because "secretion of a considerable amount of fluid is reflexly stimulated." The distention may ascend all the way to the stomach.

In most cases strangulation at first blocks veins; later, in severe cases, it also blocks arteries. In a very sudden and complete strangulation both arteries and veins are shut off simultaneously. Early in the case, when the veins only are obstructed, the coil of gut is purple, edematous and distended, and bloody serum may pass into the lumen of the bowel and also into the cavity of the peritoneum. Later the arteries are blocked and then gangrene soon occurs. In very acute cases when the arteries and veins are blocked simultaneously gangrene arises promptly. In such a case the strangulated coil is not distended and is gray or greenish in color. When strangulation occurs bacteria soon begin to pass through the walls of the strangulated coil and cause peritonitis. Perforations may take place in the coil, at the seat of constriction, or even in the gut above the block.

Chronic Obstruction.—This comes on gradually. A tumor may slowly fill up the lumen of the bowel or a cicatrix or tumor in the bowel wall may constrict more and more. Pressure outside the bowel may be responsible. In regions where the feces are fluid great narrowing can occur without symptoms. When fecal passage is seriously hindered the bowel above the obstruction becomes distended and its muscular wall undergoes hypertrophy. The hyper-

trophy depends on the exercise of greater and greater effort to overcome the obstruction. Miles ("A System of Surgery," edited by C. C. Choyce) states that above the obstruction the bowel becomes thick, "elongated, and tortuous"; that in the small intestine hypertrophy exceeds dilatation, and in the large intestine dilatation exceeds hypertrophy.

The mucous membrane is inflamed because of irritation of retained decomposed material and ulceration may occur. Peri-intestinal suppuration may arise. Gas does not gather above the obstruction because the circulation is still active in the bowel wall and because some gas can still pass naturally. When the narrowed channel in a partially obstructed bowel suddenly and completely closes, acute obstruction arises. When it does the bowel above becomes congested and distended. An active purgative or indigestible food may be responsible for acute obstruction.

Various Causes of Intestinal Obstruction.—**Obstruction by Adhesions** (Fig. 603).—Adhesions result from previous peritonitis. There may be a few adhesions or a multitude of them. A portion of bowel may be bent or twisted by the traction of adhesions or gaseous movement may twist a coil or bend it above an adhesion. The obstruction may be acute or chronic. Even when acute, strangulation is unusual.

Volvulus (Fig. 604).—By this term we mean twisting of a loop of bowel upon its mesenteric axis. It is true that under peculiar circumstances the bowel may twist on its own long axis because of adhesions, but such a twist is not a true volvulus. Volvulus may occur in a hernial sac. In rare cases two coils of intestine twist together. Volvulus is not limited to the pelvic colon, but in a very large majority of cases it is that portion of bowel which suffers. The twist may be partial, a complete turn, or even two or three complete turns. This very dangerous condition occurs particularly in adults. A colon loaded with feces predisposes; so does a long mesocolon and a mesocolon with a narrow base, and so may adhesions. Rotation may be caused by straining at stool, by a sudden shift in position, by lifting, by a blow upon the abdomen, or by peristalsis induced by an active purgative. In most cases the twist is tight enough to occlude the blood-supply of the loop. The loop becomes plum colored and edematous, bloody serum flows into the bowel and into the peritoneal cavity, and immense distention of the loop occurs. The colon above the obstruction also distends. Peritonitis occurs early. Perforation may occur and is most apt to take place above the loop.

Intussusception (Figs. 605, 606).—By this term we mean the invagination of a portion of bowel wall into the lumen of an adjacent part of the gut. In nearly all cases an upper segment invaginates into the lower. One-third of all cases of obstruction are due to this cause (Treves). In young children it usually causes acute obstruction; in an adult, chronic obstruction, ending perhaps in an acute attack. Most cases of obstruction in children are due to intussusception. Pitt reports that in St. Thomas's Hospital, from 1875 to 1900 inclusive, there were 115 cases of intussusception, and every patient was under fifty years of age. Gibbon's patient was fifty-eight. Rutherford Morrison had a case due to polypus, and the patient was sixty-two years of age. Males are twice as liable as females. During the performance of peristalsis a localized circular constriction forms and the invagination takes place through the constricted area. The great relative frequency of intussusseption in childhood is due to the greater mobility and irritability of the child's bowel (Treves). The irregular and localized spasm is due to bulky or irritant material within the gut, and, according to Rushmore ("Annals of Surgery," August, 1907), the starting-point of invagination is obstruction. Were peristalsis alone the cause the condition would be far more common than it is in the diarrhea of children. There are four chief varieties: the *ileocecal*, in which the ileum and the ileocecal valve pass into the

cecum and colon; the *colic*, in which the large intestine is prolapsed into itself; the *ileal*, in which the small intestine alone is involved; and the *ileocolic*, in which the ileum prolapses through the ileocecal valve. Other forms are *diverticular* (with a diverticulum), *retrograde* (due to reversed peristalsis), *of Meckel's diverticulum*, *ileo-appendiceal*, and *cecal*. The first variety is vastly the most common. In Rushmore's table ("Annals of Surgery," August, 1907) the location was definitely stated in 237 cases: 140 of these were ileocecal and 31 were ileocolic.

The *intussusceptum* consists of the entering tube and the returning layer. The *intussuscipiens* is the sheath or receiving tube. As the intussusceptum grows longer and longer the mesentery is drawn between the entering tube and the sheath. The mesentery becomes curved and draws the involved intestine toward the back and left side. The dragging, twisting, and squeezing of the mesentery impairs the blood-supply of the intussusception. The invaginated portion, especially the returning tube and apex, becomes congested and swollen, the mucous membrane secretes profusely, and blood passes into the bowel. From this source come the blood and mucus passed by the bowel. An intussusception tends to become irreducible by adhesion of its walls and by engorgement, particularly of the apex. Any intussusception may eventually cause complete obstruction, strangulation may take place, gangrene may occur, peritonitis may arise.

Foreign Bodies, Gall-stones, and Enteroliths (Fig. 607).—Foreign bodies include, besides certain substances that have been swallowed, gall-stones and enteroliths or intestinal calculi. Foreign bodies are apt to lodge in the lower portion of the ileum or in the cecum, and they may cause ulceration at the seat of lodgment. If a gall-stone is sufficiently large to cause obstruction, it cannot have passed the duct, but must have ulcerated into the bowel from the gall-bladder. About three-fourths of the cases of gall-stone intestinal obstruction occur in women. The stone is arrested at some point because either local spasm or paralysis of the bowel has developed. It may be arrested high up, but is most apt to be in the lower ileum. A stone under 1 inch in diameter ought to pass. A. W. Mayo Robson ("Brit. Med. Jour.," May 1, 1909) points out that all cases of obstruction due to gall-stones are not the result of mechanical obstruction by a large stone which entered the intestinal canal by ulceration, but that there are three other possible conditions, viz.: Local peritonitis in the gall-bladder region causing paralysis of the bowel; volvulus of the small intestine due to biliary colic or to ulceration of a gall-stone into the gut; obstruction coming on "after the original cause has disappeared" and due to adhesions without or obstruction within the gut.

Enteroliths (fecal concretions) are usually deposits of salts from the feces, especially apt to be formed when the patient has long suffered from catarrhal inflammation of the bowel. The nucleus may be a hair-ball in woman who swallows hair, or the stone of a fruit. A gall-stone may have a concretion form about it. Food residues mixed with salts may constitute concretions. So may insoluble materials taken frequently as medicine or from habit (chalk, bismuth, magnesia). An enterolith increases in size up to a certain point, but seldom becomes enormous.

Internal Herniæ (Fig. 609).—These include: (1) retroperitoneal hernia, (2) diaphragmatic hernia.

A hernia may pass into one of the fossæ about the duodenum, one of the fossæ about the cecum, the intersigmoid fossæ, or through the foramen of Winslow into the lesser peritoneal cavity. The appendix may be strangulated in a pericecal fossa and cause obstruction. Diaphragmatic hernia is described on page 1164. An internal hernia may become strangulated just as does an external hernia.

Obstruction by Bands and Abnormal Openings (Fig. 610).—The band may be a portion of the great omentum which has taken on an unnatural attachment, a Meckel's diverticulum, an appendix attached at its tip, a broad band or cord-like peritoneal adhesion. The obstruction in these cases is apt to be acute and is commonly accompanied by strangulation. It usually involves the ileum, sometimes the colon. There may be an abnormal opening, congenital or acquired, in the omentum, the mesentery, or the mesocolon. The bowel may slip through such an opening and be caught and strangulated.

Obstruction may take place by *Meckel's diverticulum* (Fig 608) (see page 988), a structure due to persistence of the vitelline or omphalomesenteric duct, coming off from the ileum from 12 to 36 inches above the ileocecal valve, and present in about 2 per cent. of persons. The vitelline duct should be obliterated in the eighth week of fetal life. If it persists the individual possessing it is in constant and serious danger. The mortality of a series of cases of obstruction due to Meckel's diverticulum is enormous. A Meckel's diverticulum usually has no mesentery, is from 3 to 10 inches long, and arises from the convex side of the gut. It may hang free or may be attached to the umbilicus by its tip or by a fibrous cord formed by the obliterated tip. In some cases it remains open at the umbilicus (see page 402). In other cases a cord runs from the umbilicus to the gut or the tip of the diverticulum or is adherent to another portion of the intestine. The diverticulum may become strangulated, may enter a hernial sac, may ulcerate or perforate like an appendix. (W. Sheen, in "Bristol Medico-Chir. Jour.," Dec., 1901, gives an admirable account of "Some Surgical Aspects of Meckel's Diverticulum"; see also article on "Obstruction of the Bowels by Meckel's Diverticulum," by James E. Moore, in "Jour. Am. Med. Assoc.," Oct. 4, 1902, and on "Abdominal Crises Caused by Meckel's Diverticulum," by Miles F. Porter, in "Jour. Am. Med. Assoc.," Sept. 23, 1905.) Strangulation of the diverticulum may take place beneath an adherent appendix, a Fallopian tube, a portion of mesentery, or the pedicle of an ovarian tumor, or it may take place in an omental or a mesenteric aperture. Gangrene, inflammation, or twisting may occur. Obstruction may be due to invagination of the diverticulum into the bowel. H. Tyrrell Gray collected 39 cases of invagination and added 1 of his own, 40 in all ("Annals of Surgery," Dec., 1908).

Cicatricial Stricture.—This is not a common cause. I have operated on 1 case due to the scar of a typhoid ulcer. The obstruction occurred gradually and became acute years after the fever. Any healed ulcer may be responsible. Tuberculosis is the most common cause. Syphilis or dysentery may be responsible. A contusion or wound of the bowel may be causal.

Tumors of the Bowel.—They are uncommon in the small intestine. Adenoma, lipoma, fibroma, and myoma may occur. They may cause obstruction from blocking or may be responsible for intussusception. Sarcoma is seldom met with, but more often in the small bowel than in the large gut. The patient's general health is much impaired, and a tumor can be palpated before obstruction occurs, and obstruction may never occur. Cancer of the small bowel is more common than benign tumors and sarcoma, but less common than cancer of the large bowel. Cancer of the small intestine is most common in the lower ileum, and arises from columnar cells. It causes constriction and stenosis and usually ulcerates. In the large intestine fibroma, lipoma, adenoma, or myoma may arise. I removed an adenoma from the sigmoid which had produced obstruction. Apparently it has not recurred after four years. A great number of adenomata may be present (*multiple adenoma of Virchow*). Obstruction is rare from innocent tumors. The colon is a common site for cancer. It is usually primary, but may be secondary. It produces chronic

obstruction. The growth is columnar celled, and may be scirrhus, encephaloid, or colloid.

Obstruction by Tumors, Etc., Outside the Bowel.—Among the causes of such obstruction are retroflexion or retroversion of the womb, especially in pregnancy, cysts or tumors of the kidneys, ovaries, uterus, etc., movable kidney, and enlarged spleen. Obstruction from any of the above causes takes place in the rectum, the sigmoid flexure, or the colon above the sigmoid.

Obstruction from Fecal Accumulation.—Fecal impaction resulting from prolonged constipation is quite common. Obstruction sometimes, but seldom, occurs. When obstruction follows upon impaction it is usually brought about by rotation of a loop of bowel (volvulus) or angulation of a segment, but may be due to abolition of peristalsis because of paralysis. In impaction the fecal mass is usually soft, but may be hard. There may be one large mass or numerous smaller ones. The mass may reach from the rectum even into the transverse colon. It usually begins to form in the pelvic colon (Miles, "A System of Surgery," edited by C. C. Choyce). The weight of such a quantity of feces may cause a packed loop of gut to sink into the pelvis and may stretch and narrow the mesocolon. Ulcerations of the mucous membrane may form (*stercoral ulcers*).

Postoperative Obstruction.—Obstruction may come on a day or two after, several or many days after, or weeks or even months after an abdominal operation. We deal here with early obstruction.

Obstruction may be due to a mechanical cause at the seat of operation (adhesion of the bowel to a raw surface, volvulus, catching of the gut under a band, etc.). It may be due to a mechanical cause distant from the seat of operation (bands, adhesions, displacement of the intestine, etc.). It may be due to thrombosis of the mesenteric vessels. Although any one of the above conditions may arise after an operation, there is nothing special and peculiar in it when it does. Such conditions are considered under special headings (bands, adhesions, etc.). Again, postoperative obstruction may be due to the pressure upon the gut of gauze-packing or of a drainage-tube. It may be due to paralysis of a loop of gut because of local sepsis (as after an operation for appendicitis), or paralysis of the intestine from widespread sepsis (general peritonitis).

What we really mean by postoperative obstruction is a condition arising from gaseous distention. Gas begins to accumulate soon after the operation. The patient cannot expel it. He tries, but the straining efforts fail and may burst the belly wound. More and more gas gathers and annoyance becomes torture. The overdistended bowel finally becomes paralyzed and paralytic obstruction occurs. This true postoperative obstruction is particularly apt to arise if evisceration has been practised, if the intestines have been squeezed and handled and not protected from chill, and if the operation were prolonged.

Embolism or Thrombosis of the Mesenteric Vessels.—The arteries may be the seat of embolism or thrombosis; the veins, of thrombosis. The section of bowel, large or small, from which the blood is kept undergoes paralysis. Gangrene and peritonitis soon follow. This very fatal condition is one of suddenly arising paralytic obstruction in an individual who has cirrhosis of the liver or valvular disease of the heart, or who has had ulcerative endocarditis.

Pseudo-obstruction or Spasm of the Intestine.—In this condition a limited portion of the bowel undergoes spasmodic contraction, which lasts for several hours or even for a day and then passes quickly away. This contraction is usually in the pelvic colon. In many cases a swelling can be made out. It is due to a loop of distended gut and disappears when the patient is under ether. Such a swelling is known as a *phantom tumor*. These attacks occur in neurotic women, especially those with catarrh of the colon. Besides the causes of obstruction above mentioned we should refer to shrinking of the mesentery.

Symptoms of Acute Obstruction.—The onset is marked by pain, shock, and vomiting. The tighter the constriction, the more sudden is the attack; the more bowel there is involved, the greater the shock. This element of shock often makes the diagnosis uncertain, and we may suspect abdominal hemorrhage or perforation when the real lesion is strangulation. The pain is violent and continuous, with fierce exacerbations. The continuous pain is due to the constriction; the exacerbations, to the colic of peristalsis. If the small intestine is involved the continuous pain is about the umbilicus. If the large intestine or duodenum is the seat of trouble the continuous pain is located about the lesion. The pains of peristalsis are generalized throughout the abdomen. The higher up the constriction, the tighter it is, and the more bowel there is caught, the greater the pain. Later, when paralysis of the gut occurs or perforation takes place, the pain for a time abates, to recur again with peritonitis. Early in the case there is neither rigidity nor tenderness; as paralysis begins tenderness develops. Early in the case pressure may actually afford some relief. When tenderness exists tapping is more apt to cause pain than is pressure; in peritonitis pressure causes more pain than tapping (Battle). When peritonitis arises, of course tenderness becomes acute and rigidity develops.

Vomiting comes on soon after the development of pain, but does not give any relief. It is accompanied by nausea and violent retching, continues practically without cessation, and whether food and drink are taken or not.

The vomited matter consists first of the contents of the stomach, next of quantities of bilious matter, and finally of brown or yellow stinking fluid, which was long believed to be feces. Vomiting of this character is called *stercoraceous vomiting.* Vomiting of genuine feces may occur, but is rare. In stercoraceous vomiting the fluid gushes up in quantity and by regurgitation rather than efforts of vomiting. This sort of vomiting can occur even when the obstruction is in the upper jejunum or duodenum.

A notable characteristic of obstruction is total inability to pass gas or feces. It is necessary to remember that in the very beginning of the case there may have been a bowel movement, due to peristalsis emptying the intestine below the seat of lesion. A single movement early is no proof that the condition is not obstruction. It is only in cases of strangulation in the pelvic colon that the patient has a strong desire and makes frequent attempts to move his bowels. If an enema is given it is usually retained, or else leaks away without bringing fecal matter with it. Distention from gas (*tympanites*) is always soon present. The lower the obstruction, the more widespread is the distention. Early in the case the abdomen is flat and relaxed, but this condition is very temporary. We may be able to gain information by studying the distention. If both flanks bulge, the block is in the pelvic colon. If the left flank is flat and the right distended, the block is in the colon well above the pelvic colon. If only the small intestine is distended, the block is on the proximal side of the ileocecal valve. As the case progresses distention increases and causes great embarrassment to respiration by pushing up the diaphragm. In thin patients, early in the case, we may occasionally see waves of peristalsis above the obstruction. We can sometimes feel them even when they are unrecognizable by the eye. In many cases of intussusception and in a number of cases of chronic obstruction which have become acute they can be felt.

Cases of intestinal obstruction tend to pass into collapse. This condition is due to the absorption of poisons from the decomposing matter above the obstruction, and is aggravated by vomiting and sweating which abstract quantities of fluid from the blood. When collapse has come on the temperature is subnormal; the extremities cold; the pulse very rapid and weak, often a mere thread or trickle; the respirations are rapid and shallow, and the face *Hippo-*

cratic (eyes and temples sunken, nostrils thin and drawn, features pinched, lips blue, skin livid or deadly pale). The amount of urine passed is very small. The higher the obstruction, the less the amount passed. During or after the second day indican is usually present in the urine. It results from putrefaction of proteins and the formation of indol in the intestine. There is leukocytosis, the white count being from 15,000 to 30,000 (Bloodgood, in "Johns Hopkins Hospital Reports," vol. vii).

The mortality from acute obstruction is very high. According to Elsberg, gangrene occurs in 13 per cent. of cases. Seldom can a mass be felt. It can often be felt in intussusception; it can sometimes be palpated when there is a fecal concretion or other foreign body.

Symptoms of Chronic Obstruction.—The symptoms come on gradually. There are periods when great constipation exists, alternating with periods of comfort or perhaps with seizures of fluid diarrhea. After a time the attacks of constipation become painful and accompanied, it may be, by vomiting after eating. The patient feels abdominal discomfort most of the time and is much annoyed by gas in the intestine. It is very difficult to expel the gas from below. All the time the constipation is growing more obstinate and the patient is resorting to stronger and stronger purgatives and obtaining less and less response. Finally, a strong purgative may fail utterly, only serving to cause severe colic and perhaps vomiting. It may also cause pain at the seat of the lesion. Patients in this condition may develop attacks of diarrhea, small amounts of feces mixed with mucus being passed. This condition is due to colonic catarrh, is called the "diarrhea of constipation," and affords no mitigation to the discomfort and pain.

During the progress of the case the bowel above the block distends. Because of the hypertrophy of the muscular wall of the gut and of the loss of flesh painful peristalsis (which can be felt and seen) is often noted above the obstruction. This sign is detected far oftener in chronic than in acute obstruction. The distended intestine showing peristaltic contraction is a strong suggestion of chronic obstruction. The painful peristalsis is often productive of rumbling and gurgling noises (*borborygmi*). By noticing the portion of gut distended we may be able to locate the seat of stenosis (see page 984). This method is more valuable in chronic than in acute obstruction. On digital examination of the rectum the rugæ may no longer be felt and the rectum is greatly distended because of paralysis. This is known as *rectal ballooning*.

The above-described condition may cease to intermit or even remit, all the symptoms may grow progressively worse, constant nausea being present, vomiting ensuing on taking food, and the breath being horribly foul. Such a patient is being poisoned to death by putrefactive toxins. He may perish from exhaustion, from perforation, or from peritonitis. At any time during the progress of chronic obstruction acute obstruction may develop. The sudden complete block may be due to a plug of hardened feces or some foreign body. It not unusually follows the taking of a strong purgative. It may be due to volvulus or to bending.

In some cases of chronic obstruction a tumor may be palpated, in some intussusception can be made out, in some there is a history of antecedent peritonitis, in many there are evidences of malignant disease.

Diagnosis.—*The determination of the seat of lesion* requires abdominal and rectal examination. An intussusception may sometimes be felt by a finger in the rectum and can often be felt by palpation of the abdomen. Vaginal examination may be demanded. Pain is apt to arise at the seat of obstruction or to radiate from there. Abdominal palpation may detect a tumor. Rectal insufflation of hydrogen may locate the obstruction by causing great distention below it. Entire suppression of urine, early vomiting, absence of

abdominal distention, and rapid collapse mean obstruction in the duodenum or in the jejunum. Early vomiting, a rapidly progressive case, with great distention of the umbilical region, means obstruction of the ileum or the cecum. Distention of the entire abdomen and of the flanks, linked with tenesmus, with less violent symptoms, less rapidity of progress, and less diminution of urine than in the above-cited forms, means obstruction low down in the colon or in the rectum. An old test for obstruction in the adult large intestine is an injection by a fountain-syringe: if 6 quarts can be introduced, there is no obstruction in the large intestine; if less than 4 quarts can be introduced, there is probably obstruction in the large intestine. This test is unreliable. The passage of a sound in the rectum is generally useless and is often unsafe. In many cases the seat of the lesion and the cause of the obstruction can be determined only by exploratory laparotomy.

The *determination of the causative condition* is always difficult and is often impossible. *Intussusception* may arise in child or adult. It is the common cause in children. Intussusception may induce acute or chronic obstruction. In the child acute obstruction is far more common than chronic obstruction. In most cases the child was previously healthy except for previous constipation or diarrhea. The attack begins with a violent seizure of colicky pain and vomiting, but although the patient is pale, there is seldom shock at this stage. The vomiting may be occasionally repeated, but it is not forcible retching and very rarely becomes stercoraceous. The bowel below the obstruction is often emptied in this stage. After a time pain abates or disappears, to recur again and again. Between the seizures of pain the patient often appears to be in good condition, with a normal temperature and an almost normal pulse. Tenesmus soon arises in most cases, bloody mucus in small quantities being passed frequently. The source of the bloody mucus is the squeezed and congested intussusceptum. A sausage-shaped mass can usually soon be felt somewhere over the large intestine. It may be in the right iliac fossa or in the left iliac fossa, but usually over the region of the transverse colon. Osler reports that a mass was palpable in 66 of 93 cases, and in over one-third of these cases it was noted the first day. It has been felt as early as three hours after the onset of pain. It becomes rigid during a pain. It may shift its position hour by hour, and it may disappear after having been obvious. It may be detected only when an anesthetic is given. Rectal examination gives no information in early cases or cases involving only the small bowel. In late cases a mass may perhaps be felt in the rectum. The abdomen is rarely rigid, distended, or tender until late in the case, and at this period there may be shock or sepsis. In chronic intussusception in a child the condition may progress very slowly. The stools contain bloody mucus, there are attacks of abdominal pain, a lump may be felt along the colon or by the rectum, and peristalsis may be visible. If an abdominal lump is detectable it will harden during colic and will change its position from day to day.

Acute intussusception in the adult seldom presents characteristic features unless the sausage-shaped lump can be detected.

Chronic intussusception in an adult causes sudden attacks of vomiting and of abdominal colic which last a short time and pass away as suddenly as they arose. Later they may linger longer. A lump can usually be made out. There may be constipation or mucous diarrhea, and blood may be passed with the mucus. Acute obstruction usually arises.

Obstruction from adhesions is chronic obstruction which may become acute. There is a history of antecedent peritonitis. A local distention of the intestine is often noted. In *obstruction from bands* there is a record of antecedent peritonitis, of a traumatism, of a violent effort, or of pelvic pain. The attack is sudden in onset, is fierce in character, and is usually excited by violent

exercise or the taking of food. Vomiting is early and intractable, and it soon becomes stercoraceous; pain is violent; peristalsis above the obstruction is forcible for a time; tympanites and abdominal tenderness appear after the attack has lasted for some little time; obstruction is complete, not even gas being passed; collapse soon arises; no tumor can be detected, and rectal examination is negative. *Volvulus,* which is usually located in the pelvic colon, is far commoner in men than in women, in the middle aged than in those at the extremes of life. It is usually preceded by constipation. The symptoms come on with explosive suddenness and rapidly attain great severity. Obstruction is absolute; vomiting is late and is rarely stercoraceous; no tumor can be detected; rectal examination is negative; abdominal distention is early and pronounced, and may become enormous; peristalsis above the volvulus is seldom discovered; collapse is not so rapid nor so grave as in obstruction from bands and internal hernia. There is severe continuous pain with frequent exacerbations. The pain is about the umbilicus and in the left iliac region and left loin. Tenderness is soon manifest and is ominous, as it means peritonitis. If unrelieved, death will occur in from forty-eight to seventy-two hours. Cases of incomplete obstruction by volvulus are rarities. *Obstruction by a foreign body* may sometimes be inferred from the history of some such body having been swallowed. The obstructing body may occasionally be felt during palpation or may be discovered by the *x*-rays. Abdominal distress may exist for days or weeks before obstruction occurs. Vomiting is late and is rarely severe, but pain, tenderness, and distention are marked. In *obstruction from gall-stones* the victim is elderly and usually stout. There may be a history of one or more attacks of hepatic colic, but often the only history is of what was supposed to be painful chronic indigestion. When the stone is ulcerating into the bowel it causes localized pain and tenderness. As it slowly descends along the intestine it may be arrested again and again, causing attack after attack of blocking. When the gut becomes really blocked pain is early and acute, and vomiting is invariable and usually becomes stercoraceous. There is seldom much tenderness. Rigidity is not common. Shock is seldom present at the onset. Distention is not marked. In rare cases the stone can be palpated.

In *obstruction by an enterolith* the patient may give a history of many attacks of supposed enteritis or colitis, followed after some time by temporary attacks of obstruction. The calculus in rare cases can be palpated. The *x*-rays will show it.

In *obstruction from fecal impaction* the subject is usually of advanced years, and more often a woman than a man. There is a long history of constipation, flatulent indigestion, abdominal annoyance, painful straining at stool, and of repeated attacks of the diarrhea of constipation (small fluid movements, which bring no relief because the solid masses remain agglutinated to the wall of the bowel). The colon is distended by a mass of feces, usually dough-like, but sometimes hard, which is appreciable by palpation. Sometimes hardened or putty-like masses can be touched by a finger in the rectum. In such a subject acute obstruction may at any time arise. It is characterized by severe colic, great distention, and often by vomiting, but the vomiting is not violent and is seldom stercoraceous. Collapse soon begins. *Obstruction from stricture* or *from pressure* comes on acutely after a prolonged period of disturbance, during which period attack after attack of temporary obstruction, complete or partial, took place. A history of blood or pus in the stools suggests *tumor of the bowel;* a history of *blood* or pus having been absent would suggest pressure from without. In *pseudo-obstruction* or *spasm of the bowel* there is sudden apparent obstruction occurring in a neurotic subject, especially a female. It is most apt to arise in a victim of old colitis, or in one who has very recently been subjected to an abdominal operation. There is severe pain, vomiting, distention, and

inability to pass gas or fecal matter. The attack is transitory, lasting a few hours or, at most, a day or two, and ceasing as suddenly as it began. Sometimes a limited swelling can be detected. It is due to a loop of distended bowel and results from a contracted segment of gut. It disappears under ether, and is called a *phantom tumor.*

The presence of an *internal hernia* is not thought of until strangulation takes place and seldom then. In duodenal hernia the patient has long suffered from pain of a colicky character. There is "a circumscribed globular swelling, resembling a movable cyst, except that it is resonant on percussion and yields intestinal sounds on auscultation. Owing to the compression of the inferior mesenteric vein at the neck of the fossa, the patient usually suffers from piles which bleed freely" (Alexander Miles, in "A System of Surgery," edited by C. C. Choyce). When strangulation occurs shock is early and overwhelming, and vomiting is early, violent, and persistent. Obstruction from pericecal or intersigmoid hernia is not diagnosticated as to cause.

In hernia into the foramen of Winslow the pain is violent and epigastric, and in this region there is a swelling which gives a dull note on light and a tympanitic note on deep percussion. Diaphragmatic hernia is considered on page 1164.

Obstruction due to embolism or thrombosis of the mesenteric vessels is announced by colicky abdominal pain, but early in the case there is no tenderness, no rigidity, and no distention. Pain in the loin and back is often complained of (McArthur, "Annals of Surg.," vol. xxxiii). Moderate vomiting may occur and there may be blood in the vomitus. There is great restlessness, usually collapse; frequently bloody diarrhea or, at least, bowel washings may be bloody. Cardiac disease can usually be demonstrated and albuminuria is common.

In *true postoperative obstruction* (see page 983) as the pulse mounts the abdomen distends, usually vomiting comes on, and there is an almost continuous regurgitation of brownish putrid fluid. It may cease for an hour or two, when there will be a great gush of the fluid. The regurgitated matter may contain blood. There is seldom pain or rigidity, the temperature is subnormal, the extremities are cold, and the face is Hippocratic (see page 985). The condition resembles acute gastric dilatation. The cause is intestinal paralysis. The symptoms of *postoperative thrombosis of the mesenteric vessels,* according to A. E. Maylard,[1] are as follows: Abdominal pain, perhaps colicky in character, gradual or acute in onset, and, as a rule, constant. Early in the case there is no abdominal tenderness, no distention, and no rigidity. The pulse is rapid, the patient is extremely restless, there may be vomiting, but it is never violent, as in acute obstruction; often there is diarrhea, and sometimes bloody diarrhea. These symptoms become particularly significant if there is cardiac or vascular disease.

Obstruction from Meckel's diverticulum is usually acute, but is sometimes chronic, and occurs particularly in young adults and children. It has been stated that other and visible deformities are usually present, but in a study of 69 cases by A. E. Halstead[2] this was true of but 1 case, in which harelip existed. In obstruction from Meckel's diverticulum there is often a history of former mild attacks (Ibid.). Halstead sums up the symptoms as follows: As the obstruction is high up, the abdomen is the shape of an inverted cone; early in the attack there is often local meteorism, especially under the costal arch of the right side, but there is no distention in the flanks. Early, active peristalsis may be visible. The tenderness is just to the right of the umbilicus, on a level with it or below it. In most cases there is early fecal vomiting. Gray ("Annals of Surgery," Dec., 1908) describes invagination of the diverticulum into the bowel. The average age for those attacked is fifteen years. Such cases give a history of previous abdominal crises due to

[1] "Brit. Med. Jour.," Nov. 16, 1901. [2] "Annals of Surgery," April, 1902.

twisting, inflammation, or slight invagination. The acute attack is apt to begin while the patient is active. Gray says that about 30 per cent. of the patients pass blood; that the pain is umbilical and usually very violent; that tenderness is seldom acute unless there is peritonitis; that there may be an abnormal umbilical cicatrix; that in a minority of cases there is a palpable abdominal mass, and that the mortality after operation in acute cases is nearly 60 per cent.

Differentiation of Intestinal Obstruction from Other Diseases.—Always examine for a strangulated hernia at every hernial outlet. If obstruction is complicated with an irreducible hernia above the seat of lesion, the hernia, if it contains gut, will always enlarge and become tender because of accumulation of feces. Functional obstruction may attend peritonitis or may follow the reduction of a hernia. In this condition, if peritonitis is absent, there is no pain, no tenderness, no tumor, no tendency to collapse, but simply absolute constipation, distention, and perhaps non-stercoraceous vomiting. Appendicitis with peritonitis may cause symptoms similar to those of obstruction; but there is fever, is a history of pain in the right iliac fossa, and the vomiting is not stercoraceous. Acute pancreatitis produces symptoms so similar to those of intestinal obstruction that a diagnosis cannot always be made (see page 1059). We must consider in the diagnosis perforation of a gastric or duodenal ulcer, rupture of an extra-uterine pregnancy or a pus tube, strangulation of the pedicle of an ovarian tumor, renal colic, and hepatic colic. Poisoning by arsenic or by corrosive sublimate should not be confounded with intestinal obstruction.

Prognosis.—Without surgical interference most cases of acute intestinal obstruction die within ten days—usually within seven days. In volvulus death may occur in forty-eight or seventy-two hours. It may occur as early in obstruction by a band, in internal hernia, or mesenteric blocking. Death may be due to shock, to exhaustion, to perforation, to peritonitis, or to obstruction of respiration and circulation by tympanites. Recovery occasionally, but very rarely, happens by the formation of a fistula externally or into another portion of the bowel. In acute obstruction from foreign bodies the obstructing body occasionally passes. Volvulus and strangulation by bands are almost invariably fatal unless an operation is performed. In intussusception recovery occasionally follows the sloughing away of the prolapsed gut, but stricture almost inevitably results from this rare event. Functional obstruction gives a good prognosis. The prognosis of chronic obstruction depends upon the causative lesion. It does not threaten life immediately to anything like the degree that acute obstruction does.

Treatment.—In any abdominal case in which the diagnosis is uncertain and the patient is shocked give an enema of brandy and hot water, wrap the patient in blankets, surround him with hot-water bottles, and study the development of symptoms and signs. In half an hour, as a rule, reaction will be brought about and a probable diagnosis may be made (Greig Smith). In acute obstruction it is usually customary to empty the stomach by lavage and to evacuate the rectum by means of copious injections given while the patient is in the knee-chest position. The emptying of the stomach is imperative if stercoraceous vomiting has been going on, for vomiting of a quantity of such material while a patient is taking ether may cause death by drowning, the fluid flowing in enormous quantity into the bronchi. In very severe cases a general anesthetic cannot be given and the belly must be opened under cocain. Hutchinson's method of taxis and massage is uncertain, and is as liable to inflict harm as to confer benefit. Some surgeons apply constant compression to the abdomen by means of straps of adhesive plaster. Puncture of the intestine by an aseptic hypodermatic needle (introduced obliquely)

to relieve gaseous distention is a decidedly dangerous proceeding. The passage of a small tube from the anus as high as possible will empty the colon of gas if no obstruction intervenes. In intussusception it is the custom of some surgeons to give no food by the stomach; administer opium and belladonna to arrest peristalsis, wash out the rectum with copious injections, give an anesthetic, and insufflate hydrogen gas or carbonic-acid gas in order to distend the bowel. Other surgeons treat intussusception by forcing air into the rectum by means of an ordinary bellows, and others inject water by a fountain-syringe, the reservoir being at a height of 3 feet. D'Arcy Power believes in the value of hydrostatic pressure in intussusception in children. He states that the child should be anesthetized and the large intestine filled *gradually* with hot saline fluid, the reservoir not being raised more than 3 feet above the patient. The fluid should be retained for ten minutes. My own feeling is that whereas it may be justifiable to try to reduce by gaseous or hydrostatic pressure during the first twenty-four hours of the attack, early operation, except in newborn infants, gives a better prognosis and is safer and more certain. Without opening the abdomen it is impossible to know the condition of the intestine. Gangrene may occur early (it has been found in less than four hours after the onset of symptoms), and if gangrene exists gaseous distention or hydrostatic pressure will cause death. Rushmore's reported case shows that there may be "no systemic symptoms to indicate the presence of gangrene" ("Annals of Surgery," August, 1907). Another point against conservative treatment is the common uncertainty as to whether complete reduction has been accomplished. Vomiting may continue for hours after genuine reduction and the bowels may not move for some time. Waiting to be sure reduction was accomplished will probably be responsible for death if reduction was not obtained. After the first twenty-four hours it is never justifiable to use gaseous or hydrostatic pressure because of the great risk that ulcer or gangrene may exist. Pressure cannot be accurately regulated, and if the bowel is much damaged, may lead to rupture. If the case is not seen until after the first day, or if injections have been used and have failed, all surgeons believe that laparotomy should be performed.

Frederick Holme Wiggin has made a study of the reported cases of laparotomy for infantile intussusception, and considers that operation done within the first forty-eight hours will give a mortality of 22.2 per cent.[1] (see Operation for Intussusception). In very young infants the mortality of laparotomy is very high, and it is a fair question if on them immediate laparotomy should be advised without a trial of conservative methods if the case is seen during the first twelve or twenty-four hours. The mortality of operation is very large on those under eighteen months of age. But even in those under six months of age Wiggin thinks the mortality after operation is not above 22.2 per cent. if operation is done within forty-eight hours, and my personal feeling is that operation should be the method of treatment even in the case of a young baby.

I agree with Rushmore that operation done during the first twelve hours would greatly reduce the mortality, perhaps to the figures he expects would come from such a practice, viz., 12.5 per cent.

In obstruction of the main mesenteric vessels operation is of no avail. In obstruction of branches it may be possible to resect the involved region of bowel, a region which is found to be gangrenous or at least is becoming so.

In obstruction from fecal impaction use large rectal injections and give small repeated doses of salines or of castor oil. If there are signs of inflammation, do not give cathartics, even in small doses, but give opium and belladonna to arrest vomiting and to relax spasm. Impactions in the

[1] "Med. Record," Jan. 18, 1896.

rectum can be removed by the use of a spoon. In acute intestinal obstruction do not delay, but open the abdomen, if possible, before collapse comes on, and find the cause of the obstruction. If it is a gall-stone or enterolith, try to crush it without opening the intestine; if this fails, push it up a little distance, incise the bowel, remove the stone, and close the incision with Halsted sutures. Pilcher[1] collected 40 cases operated upon for gall-stone obstruction, with 21 deaths. If there is fecal obstruction, break up the masses by pressure and push the fecal plug down without opening the bowel. If there is intussusception, reduce the prolapse and shorten the mesentery; but if reduction is impossible, perform a resection and enterorrhaphy, or make an artificial anus. In volvulus untwist and shorten the mesentery; but if this is impossible, treat as an irreducible invagination. In obstruction from adhesions try to separate them and straighten out the bowel, stitching healthy peritoneum over each raw spot to prevent recurrence. In obstruction by a band, free the loop and, if it is gangrenous, resect or follow the plan of Mikulicz (see page 992). Anastomosis may be necessary. In flexion separate the intestines, remove the flexion by a V-shaped incision, and suture the wound in the bowel. In chronic obstruction it is often advisable to perform an exploratory laparotomy, discover the condition, and determine what is to be done to correct it. Some tumors external to the bowel may be removed. Growths in the bowel wall may be removed by resection of the involved portion of intestine, or an anastomosis may be performed, or it may be necessary to make an artificial anus. In obstruction from Meckel's diverticulum that structure may be found twisted, the gut near it may be kinked or twisted, or the diverticulum may act as a band, the bowel being caught under it or kinked over it. Intussusception of the gut below it sometimes occurs; so does invagination of the mucous membrane of the diverticulum; so does chronic inflammation and cicatricial narrowing of the diverticulum or gut (Halstead). The diverticulum may be gangrenous, perforated, or cystic. In internal hernia the constriction must be divided and the bowel removed from the fossa. Any gangrenous gut should be resected if the patient's condition justifies it, or Mikulicz's plan should be followed (see page 992).

After opening the abdomen the surgeon must be guided by conditions. The diverticulum should be removed, just as the appendix is removed in appendicitis, and complications relating to the gut must be dealt with.

The mortality after operations for acute intestinal obstruction is very high (from 60 to 75 per cent.). If the diagnosis were made earlier, operations would be done earlier and the mortality would be much less. Nine out of 10 of these cases that I see in hospital work are gravely shocked and practically dying on admission. If a patient with obstruction is very gravely shocked, I usually follow Moynihan's plan, of simply opening the bowel and draining it in its most distended coil without any search being made for the lesion. The object is to drain the poisons from the intestine, poisons which are the active agents in killing the patient. The abdomen is opened under cocain, the incision being small. A distended coil of intestine is sutured to the peritoneum about the abdominal incision, every care being taken that the stitches do not penetrate the mucous membrane of the gut (Moynihan). A purse-string suture is now inserted so as to enclose an area of the exposed gut; an incision is made into the gut in this enclosed area, and gas and feces flow out. Paul's glass tube (see Fig. 718) is passed into the gut and the purse-string suture is tied. Instead of Paul's tube we may use a rubber tube sutured as is the tube in Kader's gastrostomy (Elsberg, in "Annals of Surgery," May, 1908). The obstruction is thus temporarily relieved, and if the patient recovers, the causative lesion may be subsequently sought for and attacked. If a fecal fistula follows the enter-

[1] "Med. News," Feb. 8, 1902.

ostomy and refuses to close, it may be closed by operation. If Elsberg's plan is followed a persisting fecal fistula will be rare. My colleague, Professor Francis T. Stewart, has devised a method by which the bowel can be drained without any risk of infection of the peritoneal cavity, a risk which always exists in using Paul's tube. Stewart places a clamp at either extremity of the loop of bowel and surrounds it with gauze. One half of a Murphy button is inserted into the empty loop through a small incision. The other half of the button is squeezed into a rubber tube the diameter of which is somewhat smaller than the flange of the button. The two parts of the button are then clamped, and the clamps are removed from the loop of bowel. The intestine is sutured to the wound margins and the feces drain into a receptacle on the floor. Fig. 611 shows Stewart's operation. In any case of intestinal obstruction if gangrene exists the temptation to do immediate resection is strong. I have done it a number of times with a very large mortality. Of late I have been following the plan of Mikulicz and results have been far better. The gangrenous loop is brought outside of the abdomen, it is fixed parallel to the wound, and enterostomy is performed above it. The loop is dealt with later. If a fecal fistula forms it is subsequently closed by appropriate methods. Postoperative obstruction coming on soon after a surgical operation is often not recognized for a time, and the surgeon will be in doubt as to whether he is dealing with peritonitis or intestinal paresis. When distention becomes evident after an operation we should wash out the stomach with warm salt solution, administer salines in small doses frequently repeated, and employ enemata. Many surgeons give two or three doses of atropin hypodermatically at intervals of two hours. Each dose should be $\frac{1}{200}$ gr. Atropin is given with the idea that it increases peristalsis and contracts blood-vessels. It is probably merely sedative, relaxes spasm, and is useless if strangulation exists. Eserin stimulates the muscular coat of the intestines. There seems no doubt that eserin given soon after an operation tends to prevent distention. A better plan than the administration of atropin is to give hypodermatically $\frac{1}{30}$ gr. of eserin and $\frac{1}{40}$ gr. of strychnin every hour until four doses have been taken. During fifteen minutes of this period carry the heated Paquelin cautery to and fro over the abdomen, not touching the skin, but near enough to it to

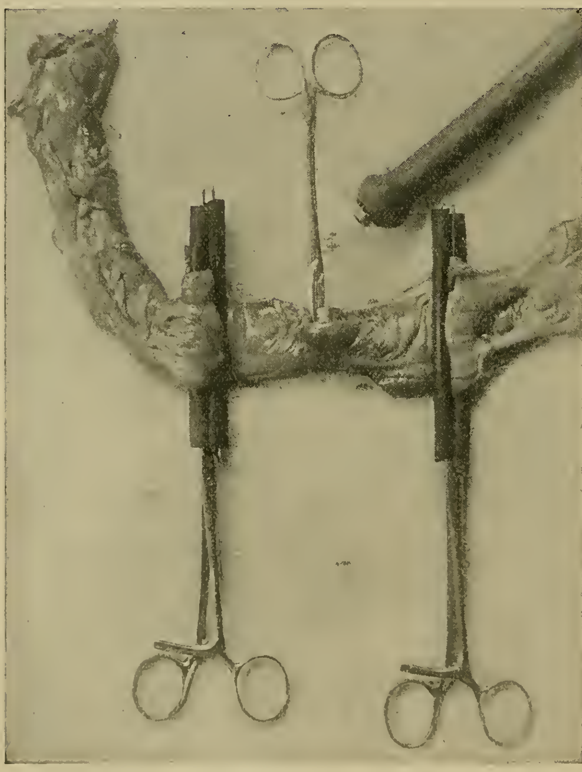

Fig. 611.—Stewart's method of enterostomy.

cause distinct reddening. The intestinal tract should be gone over systematically with the cautery, first, the stomach and small intestine, then the large intestine. Pituitrin is an extract of the posterior lobe of the pituitary gland. When given intravenously or subcutaneously it raises blood-pressure, is a diuretic, and stimulates involuntary muscular fiber. It is useful in cases of flatulent distention. It comes in ampoules each of which contains 1 c.c. The dose is one to two ampoules, repeated in two hours. If these measures are not soon followed by the passage of flatus or feces, open the abdomen; never wait for the advent of stercoraceous vomiting.

Fecal Fistula and Artificial Anus.—A fecal fistula is an abnormal opening in the intestine through which gas or a portion of the feces escape (Fig. 612). If all the intestinal contents escape through the opening, it is called an *artificial anus* (Fig. 613, Senn). A surgeon may make a fistula deliberately (*intentional fistula*). A fistula may be the product of disease or injury (*accidental fistula*). Senn enumerates the following causes of accidental fistula: wounds, injury of the intestines, intestinal ulceration, intestinal strangulation, foreign bodies in the intestinal canal, malignant tumors, actinomycosis, pelvic and abdominal abscess, appendicitis, injury of the bowel during an abdominal operation, the application of ligatures, catching by sutures, and the employment of drainage-tubes.

Treatment.—Many fistulæ close spontaneously. This can be hoped for only if the opening is quite small, if the general health of the patient is good, if the cause has passed away, if the fistula is not lined with mucous membrane, and if there is no spur (spur is shown at *a*, Fig. 613). In most cases

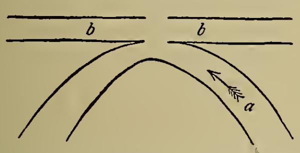

Fig. 612.—Fecal fistula: *a*, Direction of fecal flow; *b*, *b*, belly wall.

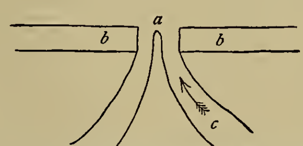

Fig. 613.—Artificial anus, showing spur: *a*, Spur; *b*, *b*, belly wall; *c*, direction of fecal flow.

of fistula not high up it is well to give Nature a chance to effect a cure, and not to be in a hurry to operate. Most fistulæ in the large bowel heal spontaneously. The part is cleansed frequently with peroxid of hydrogen, the patient is kept recumbent, food is given which does not leave much residue, pads of gauze are applied with pressure, and the bowels are kept regular.

If the track is lined with granulations, it may be touched with lunar caustic; if it is lined with mucous membrane, the actual cautery should be applied. Any collection of pus which exists should be drained. If these methods fail, an operation must be performed. The fistula may be sutured by extraperitoneal manipulation (Greig Smith); it may be covered with skin (Dieffenbach); the spur may be removed by means of a clamp, or resection may be performed. In most cases it is best to incise a button of skin around the opening, temporarily suture the fistula, open the peritoneal cavity, deliver the bowel, and suture carefully (Senn's method). In some cases partial exclusion of the fistulous part is necessary, the bowel being divided above the fistula, the end near the fistula sutured, and the other end anastomosed to the bowel below the fistula. In other cases complete exclusion may be performed (see page 1118).

Ulcer of the Bowel.—In typhoid fever and in dysentery ulceration occurs. In erysipelas, septicemia, pemphigus, melena neonatorum, and uremia ulceration may occur. An ulcer may be due to tuberculosis or cancer. Most ulcers of the duodenum (see below) are due to the same causes as ulcer of the stomach. In rare cases ulcer of the duodenum results from a sur-

face burn (Curling's ulcer, page 162). An ulcer of the jejunum sometimes develops after the performance of gastrojejunostomy for gastric ulcer (see page 1090). An ulcer may heal and, by causing thickening and constriction, produce chronic intestinal obstruction. It may perforate, causing collapse and subsequent peritonitis.

Ulcer of the duodenum may be due to tuberculosis. It may exist in septicemia, erysipelas, melena neonatorum, and uremia. It may be caused by burns. The last named and very rare condition is called *Curling's ulcer*, he having described it in 1841. Moynihan shows in his book on "Duodenal Ulcer" that James Long, of Liverpool, was really the first one to describe duodenal ulceration following burns. He did so in the "London Medical Gazette," 1840. A duodenal ulcer following a burn or scald is "a toxic ulcer, and, therefore, analogous to the ulcer which occurs in septicemia, uremia, typhoid fever, erysipelas, and pemphigus" (Moynihan, Ibid.). It occurs only when the burnt or scalded area has become septic, and septic emboli may be responsible for ulceration. Some believe that the irritant cause is in the bile. Ulcer from a burn is extremely rare to-day, rarer than formerly, if older reports are correct. This is probably due to the modern cleanly treatment of burns and scalds. When we use without qualification the term "ulcer of the duodenum" we mean an ulcer like the ordinary stomach ulcer and which may be regarded as a peptic ulcer of the duodenum.

Septic ulcers are acute. The peptic ulcer is nearly always chronic.

Peptic Ulcer of the Duodenum.—The condition was first described by Travers in 1817 ("Duodenal Ulcer," by Sir Berkley G. A. Moynihan). It occurs usually in that portion of the duodenum which is above the opening of the bile-duct; in other words, in the region acted on by the acid fluid from the stomach. In Perry and Shaw's list of 149 cases the first portion was involved in 123, the second portion in 16, and the third and fourth portions in 2; in 8 the ulcers were scattered. Moynihan (Ibid.) says the first portion is involved in 95 per cent. of the cases. The most common seat of ulcer is on the anterior wall of the duodenum, $\frac{1}{2}$ inch below the pylorus. The pylorus is definitely marked for the surgeon by the pyloric vein which runs upward from the greater curvature (Moynihan, Ibid.). The ulcer is often puckered like a scar. Any old ulcer is much indurated. In rare cases there is no induration. Sometimes an extensive area of the duodenum is indurated, sometimes a duodenal pouch or diverticulum is formed. In rare cases an ulcer completely encircles the bowel. Duodenal ulceration is much more common in males than in females in the proportion of 3 or 4 to 1. It may occur at any period of life, from early youth to extreme old age, but is most common between the twenty-fifth and forty-fifth years. Duodenal ulcers are usually single, but may be multiple. It was long taught that gastric ulceration is vastly more common than duodenal ulceration. Some recent observers regard duodenal ulcer as likely to be met with one-seventh as often as gastric ulcer. In this connection Codman's statistics should cause us to revise our estimates. In 3000 autopsies held in the Massachusetts General Hospital an open duodenal ulcer was found in 1 per cent. of the cases. The duodenal ulcers were found twice as often as gastric ulcers (quoted by E. R. McGuire, "Buffalo Med. Jour.," June, 1912). A gastric ulcer may exist with a duodenal ulcer. Murphy sums up the supposed causes into hyperchlorhydria, local infection, embolism and thrombosis, and disturbances of the organs of elimination. An indurated chronic ulcer may exist, and this may heal and produce cicatricial stenosis. The scars of two ulcers may cause double constriction or hour-glass duodenum.

An ulcer may heal and break down many times. A duodenal carcinoma seldom arises from ulcer. What Moynihan calls the "tucked back" ulcer becomes adherent to the liver or posterior wall of the abdomen. An ulcer adhe-

rent to the pancreas may eat into that organ. An ulcer scar may clutch the common bile-duct in the duodenal wall or block the outlet of the ducts in the ampulla of Vater. Perforation is more common, but walling off is more frequent than in gastric ulceration (Wm. J. Mayo, "Med. News," April 16, 1904). In the vast majority of cases the patient gives a history of having suffered at intervals for many years from attacks of flatulent or acid and painful indigestion. A man suffers thus for days or weeks, and then gets apparently perfectly well, but after a variable time the attack returns. The attack comes on from two to six hours after a heavy meal. If he eats his heavy meal at 7 P. M. his attack may usually be expected about 10 o'clock or later. These seizures of "indigestion" may be brought on by worry, overwork, wet feet or chilling of the body, or by eating some indigestible article of diet. They may be caused to disappear by rest, ease of mind, or change of climate. They have been called "hunger-pains" because food for a time distinctly relieves them. A patient learns this and is apt as soon as the annoyance begins to eat some crackers or drink a glass of milk. It was long believed that hunger pain was due to an open pylorus allowing acid material to run into the duodenum, and that food or an alkali caused the pylorus to close. Moynihan, Hertz, and others now reject this explanation because x-ray studies show that food begins to leave the stomach at once and that pain begins when about half the food has left the stomach (Moynihan, "Duodenal Ulcer"). It must be that the last portion of food in the stomach is much more acid than the portions which pass out earlier. When the stomach is entirely empty there is no pain; when half empty there is pain.

Arbuthnot Lane would explain the relief of pain by food by invoking a reflex contraction of the duodenum caused by food and serving to empty that portion of the gut. The condition above described may go on for many years, periods of relief alternating with periods of pain, water brash, flatulence, etc. Usually, but by no means always, there is hyperacidity. In some cases acidity is normal; in some, actually subnormal. It is probable that during painful attacks there is hyperacidity. We have stated that the pain occurs from two to six hours after a meal. If it occurs very late the ulcer is posterior; if it occurs earlier than two hours stenosis has begun or the ulcer is adherent to the liver or belly wall (Moynihan, Ibid.).

Hemorrhage occurs in about 40 per cent. of the cases. The blood may be passed by bowel only or it may be passed by bowel and also vomited. In most cases it is passed by bowel and not vomited. When there is a severe hemorrhage the patient first has a peculiarly severe attack of indigestion, he then grows deathly pale, presents the symptoms of internal hemorrhage, and passes a quantity of blood which is first tarry black and later red, and perhaps he also vomits blood. Just as chronic gastric ulcer may be latent, no symptoms ever being observed, so may chronic duodenal ulcer be latent. The pain is located in the epigastric or right hypochondriac region and may last until the next meal. If the digestion of the evening meal is delayed the pain rouses the patient from sleep, but a glass of milk will quiet it. The pain is less severe than is usual in gastric ulcer and in many cases does not radiate to the back, although in others it does radiate to the right scapular region. There may be tenderness on deep pressure in the right hypochondriac region. Symptoms of indigestion are not nearly so marked as in ulcer of the stomach. Vomiting is far less common than in gastric ulcer and it does not relieve pain. The hemorrhage from the bowels may be so profuse as to kill or almost kill the patient. It may be so frequently repeated as to make him profoundly anemic. Unlike the bleeding from gastric ulcer, bleeding from duodenal ulcer is often fatal. In some cases the man bleeds insidiously, perhaps even without knowing it, losing some blood daily, and finally becoming extremely anemic. Probably in every case of duodenal ulcer occult

blood is at times present in the stools. In many cases there is no visible blood in the feces, but the guaiac or aloin tests show occult blood. Vomiting of quantities of blood is much rarer than in gastric ulcer. In very rare cases of duodenal ulcer the first symptom is perforation. I have operated on one such case. In other cases the first symptom is hemorrhage, or is due to stenosis or some other complication. Examination by x-rays after the taking of a meal containing bismuth shows, if there is ulcer, greatly increased activity of the stomach. In some cases stenosis is demonstrated, in some a pseudodiverticulum. Moynihan[1] mentions the following complications: severe hemorrhage; perforation; periduodenitis; cancer, and cicatricial contraction involving the bile-duct.

Acute perforation is more common than we once thought. Perforation is usually on the anterior wall. It is much less common on the posterior wall. It is extremely rare on the superior wall and practically never occurs on the inferior wall. Moynihan gathered 49 cases from literature and added 2 of his own. In the great majority of cases perforation of the duodenum cannot be differentiated from perforation of the stomach by a study of the symptoms. In some cases the symptoms resemble appendicitis. In most cases there is a sudden onset of violent abdominal pain, followed by vomiting, shock, rapid pulse, tenderness of the epigastric or right hypochondriac region, and board-like rigidity of the upper abdomen. Profound shock is rare. Often shock is trivial. Even if shock is severe the patient usually reacts after a few hours. Sheild's case got better in four hours and walked some distance to the hospital.[2] Lucy's case got better a short time after the onset, walked home, and attended to a horse, but then became rapidly worse. The improvement is apparent, not real, and is only temporary. The symptoms quickly become worse, and when they become worse, besides the pain, tenderness and rapid pulse, there will be occasional vomiting, rigidity of the abdomen, usually an elevated or normal temperature, and possibly diminution of the area of liver-dulness. Just as in stomach ulcer, there may be acute, subacute, or chronic perforation.

Treatment.—In duodenal ulcer the risks of serious hemorrhage and of perforation are much greater than in gastric ulcer, and operation should always be recommended if the diagnosis is made. We used to say operate only if the symptoms are not amended by rigid diet and medication; if severe hemorrhage occurs or if cicatricial contraction interferes with the passage of food through the bowel or bile into the duodenum. Moynihan refers to 4 cases of chronic ulcer operated upon, and all recovered. In some cases excision is practised; in others, excision with gastrojejunostomy; in still others, gastrojejunostomy alone.

If grave hemorrhage occurs and is repeated the surgeon should open the abdomen, ligate the bleeding vessels, bring the outer coats of the bowel together over the indurated area, and perform posterior gastrojejunostomy (Wm. J. Mayo, in "Surg., Gynec., and Obstet.," May, 1908). In such a bleeding ulcer the vessels entering it are usually varicose.

In perforation operation is performed, as in gastric ulcer, as soon as possible. In these cases, as in perforated gastric ulcer, I believe operation should be immediate and that we should not wait for a possible reaction from shock. Personally, I do not practise excision of the ulcer, as I believe that closure is just as permanently useful and is safer. The ulcer is inverted by two rows of silk sutures applied in a vertical line or as purse-string sutures. If the gap of the perforation is huge it may be impossible to close it by inversion. It may then be closed by the gall-bladder (as was done by Downes) or by an omental plug. Failing in this, a gauze tampon may be used or a duodenal fistula can be formed, a rubber catheter being inserted in the duodenum and

[1] "Lancet," Dec. 14, 1901. [2] Ibid., March 29, 1902.

wrapped about with a plug of omentum (Eliot, Corscaden, and Jamieson, in "Annals of Surgery," May, 1912). Then gastrojejunostomy should be done. Gastrojejunostomy is imperative if the suturing has narrowed the duodenum. It is valuable in any case because it removes irritants from the scar, allows of early administration of food, favors healing, and antagonizes recurrence. Some surgeons do not drain, but I feel it safer to drain. Sir Berkeley G. A. Moynihan[1] gathered 49 operations for perforated ulcer, with 8 recoveries. Mr. T. Crisp English reports 8 operations for perforation of duodenal ulcers, with 2 recoveries ("Lancet," Nov. 28, 1903). During 1912 in the Mayo clinic 6 cases of acute perforating ulcer were treated by suture and gastro-enterostomy. There was 1 death. In perforated duodenal ulcer the extravasated fluid is apt to flow into the right iliac region. If an erroneous diagnosis of appendicitis was made, an opening in the right iliac region, by giving vent to this fluid, might for a time confirm the surgeon in error, but the character of the fluid should make evident the condition of affairs.

In subacute perforation we may separate adhesions, find and close the perforation, and perform gastrojejunostomy, or follow Lund's advice ("Boston Med. and Surg. Jour.," 1905) and do gastrojejunostomy alone. Lund maintains that as the perforation is walled off it is not necessary to open it up in order that we may close it. The treatment for chronic perforation is that for an abscess about the duodenum. In every operation for duodenal ulcer Moynihan examines the appendix and often finds it diseased ("Lancet," Jan. 6, 1912).

Ulcer of the Jejunum After Gastro-enterostomy.—(See page 1090.)

Perforated Typhoid Ulcer.—Perforation occurs in 2 or possibly 3 cases out of 100. About 70 per cent. of perforations occur in the second, third, or fourth week. Perforation in a typhoid ulcer is usually effected rapidly, a large opening is formed, and a considerable quantity of fecal matter is passed into the peritoneal cavity. In a few perforations very little fluid escapes. Severe pain and a nervous chill indicate that perforation is occurring or has occurred. Some maintain that the two above-named symptoms associated with marked leukocytosis indicate that perforation is about to occur, and they call this stage the *preperforative* stage. That distinct symptoms may in some cases point to impending perforation is, I believe, true, and in 1 case I operated on the conviction and found two areas almost perforated. In most cases, however, I do not believe that there is a distinct preperforative stage, but the perforation exists when the symptoms are first noted. The conviction that perforation was occurring would be strengthened by a progressive increase in the leukocyte count. It is to be remembered, however, that the leukocyte count is increased by sweating, cold bathing, vomiting, hemorrhage, severe diarrhea, or some positive complication. When perforation occurs, violent pain develops. As a rule, there are tenderness, rapid pulse, costal respiration, abdominal rigidity, vomiting, and shock. Usually there is temporary reaction from shock, the subnormal temperature giving way to a normal or to an elevated temperature. The vomiting in some cases becomes stercoraceous. There is constipation and sometimes dulness on percussing the flanks. The face is Hippocratic. The patient may die of the preliminary shock or may react and die subsequently of toxemia. In a few hours after perforation distinct leukocytosis may be observed, but it may never take place at all. Even when leukocytosis arises, it may disappear as peritoneal infection spreads and systemic poisoning deepens. Le Conte points out that rupture of a mesenteric gland simulates intestinal perforation.

Treatment.—In 1884 Leyden suggested operation, and in the same year Mikulicz obtained the first operative success. Before Mikulicz's paper was

[1] "Lancet," Dec. 14, 1901.

published my colleague, Dr. James C. Wilson, published a paper in which he advocated operation. Death is practically certain without operation. Operation should save at least one-fourth of the cases. It should be done at once, proper means being adopted to combat shock. In many cases a general anesthetic should not be given, but a local anesthetic should be employed. The incision should be made in the right iliac region and the colon should be first located and then the end of the ileum. By locating the colon we obtain a fixed point from which to begin our search for perforations, and by opening the abdomen in the right iliac region we come down at once on to the perforated gut in the vast majority of cases. When a perforation is found, it should be inverted by two layers of Halsted sutures. It is not wise to excise the ulcer. If the bowel is very badly damaged, resection can be considered, but it is usually wiser to make a temporary artificial anus. In some cases the perforation can be used as the anus, a tube being inserted, or the bowel being stitched to the skin. After finding a perforation and closing it, examine to see if there are others. Close every perforation, and if a point is found where the thinning of the bowel wall indicates that perforation is liable to occur, protect this point by inverting the area of ulceration by sutures. Cleanse the peritoneum by flushing with hot salt solution. Leave the wound open, insert strands of iodoform gauze, and establish tubular suprapubic drainage. Elevate the patient a little in bed and employ continuous proctoclysis of salt solution. I have operated 10 times for typhoid perforation, with 3 recoveries; 3 cases died of shock. In 1 case the perforation was not found, but was discovered postmortem in the hepatic flexure of the colon, the gall-bladder being responsible for the ulcer of the bowel. One case improved greatly, lived for eight days, developed another perforation, and died of shock. The necropsy showed that the sutured perforation was soundly closed. One case, a young man, brought to me by Dr. Godfrey, was operated upon twenty-four hours after perforation. There was one perforation in the ileum and considerable fecal extravasation. The opening was large and the stitches would not hold. The 6 inches of bowel between the ulcer and the ileocecal valve presented several ulcers almost perforated. The patient was too weak for a resection. After cleansing the abdomen an artificial anus was made proximal to the perforation. The patient recovered and subsequently the anus was successfully abolished by resection. In another case, that of a young woman, on opening the abdomen violent appendicitis was found, the appendix being swathed in lymph and gangrenous. The appendix was removed. Search showed a perforation in a loop of gut 2 feet from the ileocecal valve. There was considerable extravasation. The perforation was closed. The peritoneum was cleansed, drainage was inserted, and the patient recovered. Cultures from the appendix and from the peritoneal cavity showed only the colon bacillus. In a third case, that of a young woman, impending perforation was diagnosticated by Dr. Kalteyer because of pain, tenderness, some rigidity, and definite and increasing leukocytosis. Two ulcers almost but not quite perforated were found. They were covered over by the use of inversion sutures, the wound was closed without drainage, and recovery followed. Culture from the peritoneal cavity was negative. These 3 successful cases were operated upon in the Jefferson College Hospital. Harte and Ashhurst collected the cases operated upon up to January, 1903. There were 362 cases, with a mortality of 74.03 per cent. Dr. F. D. Patterson ("Am. Jour. Med. Sciences," May, 1909) collected 369 cases occurring since the paper of Harte and Ashhurst. Of these cases 242 died, a mortality of 65.58 per cent. The perforations were located as follows: stomach, 1; jejunum, 1; Meckel's diverticulum, 2; ileum, 279; cecum, 5; appendix, 15; colon, 12; not stated, 54.

Primary Intestinal Tuberculosis.—Although intestinal tuberculosis is common in patients with chronic pulmonary tuberculosis, primary intestinal tuberculosis is a rare condition. The exact propriety of rigidly regarding such cases as *primary* is doubtful. Kocher's cases (reported before the Swiss Medical Congress in 1892) came from tuberculous stock, and suffered in infancy from enlarged glands, pleurisy, or bronchitis, and that surgeon says that, in all probability, there had for some time been somewhere in the body a latent tuberculous focus, and from this focus came the bacteria which attacked the intestine. Intestinal tuberculosis, in the victims of phthisis, begins with the formation of multiple ulcers, due to swallowing tuberculous sputum. Primary intestinal tuberculosis usually begins as one ulcer or several, or even many ulcers in the ileum or perhaps in the cecum. These ulcers when they heal tend to form strictures of the small bowel, seldom of the large. Primary tuberculosis is most common in the ileocecal region. It may exist as an ulcerative process with inflammation and abscess about the cecum or as enormous tumor-like thickening of the cecum. The first form is called by Hartmann *enteroperitoneal tuberculosis.* The second form is called *hyperplastic tuberculosis.* The cecum may be involved alone, but usually a portion of the ileum also suffers. The ulcers cause extensive sloughing. The appendix may be involved. All about the cecum a multitude of adhesions form containing masses of tuberculous matter, which may break into the intestine, through the skin of the abdomen, or in both directions. (See Hartmann, in "Revue de Chirurgie," Feb., 1907.) Tuberculous areas suppurate. In tuberculosis of the small intestine there are bloody diarrhea, colicky pain, emaciation, and weakness. There are very active peristalsis and gurgling. The abdomen may be tender. The bacilli may be found in the stools. As ulcers heal strictures develop and produce the usual symptoms. Peritonitis may arise or death may be due to pulmonary tuberculosis. In primary intestinal tuberculosis the urine is apt to show the diazo-reaction (Kocher).

In hyperplastic (conglomerate) tuberculosis the cecum and lower end of the ileum suffer as a rule. In some cases the colon participates in the process. Great fibromatosis with adiposis occurs simulating tumor and due to reaction of tissue *against infection.* Tuberculosis of the ileocecal region is most common between the ages of twenty and forty. There is seldom demonstrable phthisis.

The enteroperitoneal form of ileocecal tuberculosis simulates appendicitis. At first there may be diarrhea, the liquid stools containing blood. Pain in the right iliac fossa may be the first symptom. In any case pain becomes the permanent symptom. A lump can be palpated. After acute pain subsides the lump persists and increases. There may be attack after attack of pain. The symptoms of abscess arise. Spontaneous opening finally occurs, usually about Poupart's ligament. Several fistulæ may form. Each fistula discharges pus with fecal matter. An abscess may open into the intestine. When it does, pus appears in the stools. Bacilli may be found in the stools. In enteroperitoneal tuberculosis death occurs because of the development of pulmonary tuberculosis or, in a small number of cases, by peritonitis due to rupture of an abscess into the peritoneal cavity (Hartmann, Ibid.). The hyperplastic form develops slowly, the individual complaining of indigestion and annoying feelings in the right iliac fossa. During many months the patient feels at times better and at times worse. Then food begins to disagree radically. Several hours after a meal the patient suffers from colicky pain in the right iliac region and distention of the abdomen. Severe pain simulating appendicitis may occur intermittently. Constipation may be severe or may alternate with diarrhea. Gradually a tumor mass forms, evidences of obstruction become obvious, the patient becomes weak and emaciated. The lungs are involved very late, if at all. In some cases ulceration occurs. Con-

rath's study of 77 cases led him to believe that death occurs in from two and one-half to three years.

Treatment of Primary Intestinal Tuberculosis.—In the first stage the proper treatment is excision of ulcerated areas, possibly excision of the cecum. Later, if stricture is causing chronic obstruction, an operation may be performed to give relief. Laparotomy, careful separation of adhesions which are not fused with the gut, and the introduction of iodoform into the peritoneal cavity may prove of value. Hartmann ("Revue de Chirurgie," Feb., 1907) has collected 229 operations for ileocecal tuberculosis, viz., partial excisions of the cecum, resections (with end-to-end anastomosis, side-to-side anastomosis, or end-to-side implantation), resections in two séances, ileocolostomies, unilateral exclusions, bilateral exclusions, and other operations. There were 46 deaths in these 229 operations. He comments on the fact that there were 58 operations with 7 deaths since 1900, a mortality of 12 per cent.

Perforation in Intestinal Tuberculosis.—By this term we mean perforation into the peritoneal cavity, not into another segment of gut and not into a mass of adhesions. It is supposed to be a rare accident. Cruice estimates that it occurs in from 1 to 5 per cent. of phthisis cases ("Am. Jour. Med. Sciences," Nov., 1911). It may occur in either the primary or secondary tuberculosis of the gut. It is very rare in ileocecal tuberculosis, commoner in tuberculosis of the small bowel. It causes sudden and severe pain, shock, and usually nausea and vomiting. The abdomen becomes rigid. Distention soon occurs. Death may be due to shock or peritonitis. Now and then a perforation causes no characteristic symptoms at all (Cruice, Ibid.).

Tuberculosis of the Mesenteric Glands in Children.—This condition is very common. Corner ("Lancet," Feb. 17, 1912) makes a statement exactly in accord with my own experience when he says that "tuberculous mesenteric glands will be found in practically every child patient submitted to an abdominal operation." They are often recovered from unrecognized. They may produce the well-known symptoms of *tabes mesenterica*, viz., greatly enlarged abdomen, constipation or constipation alternating with diarrhea, loss of flesh, anorexia, anemia, and perhaps a palpable mass. There are abdominal pains about the umbilicus, coming on after taking food and particularly common at night.

In some cases vomiting occurs and pain is in the right iliac region and the case is mistaken for appendicitis. In such a case the pulse and temperature are normal or only slightly elevated and there is no leukocytosis. In mesenteric tuberculosis the appendix is apt to be dilated, constricted, or kinked. Mesenteric tuberculosis may undergo cure, the glands becoming fibrosed and calcified. It may lead to tuberculosis of the intestine, tuberculous peritonitis, or tuberculosis in some distant part.

I agree with Corner that the abdomen should be opened, the appendix removed, and the patient placed a long time on full antituberculous treatment.

Tumors of the Intestine.—**Innocent Tumors.**—Adenoma, lipoma, fibroma, myoma, fibromyoma, papilloma, angioma, and chylangioma may occur. Such tumors are rare. If attached by a pedicle or stem the growth is called a polypus. Adenoma is the commonest tumor. It may or may not be a polyp. It arises from an intestinal gland. There may be one, several, or many. Adenomata may produce no symptoms, may cause hemorrhage, may produce blocking, or may lead to intussusception.

Malignant Tumors.—*Sarcoma* is very rare, but does sometimes arise, particularly in young persons, and it enlarges very rapidly. It is most prone to attack the large intestine. Jopson and White[1] reported 1 case and collected 22 others. The mesenteric glands frequently enlarge. *Cancer* is not uncom-

[1] "Am. Jour. Med. Sciences," Dec., 1901.

mon, attacking especially the middle aged. According to Rolleston, the average age in duodenal cancer is fifty-two years; in jejunal and iliac cancer, forty-seven; in cancer of the cecum, nearly forty-eight, and in cancer of the rest of the large intestine, about forty-nine years. It is most common in the neighborhood of the ileocecal valve and in the sigmoid flexure. Ewald collected 1148 cases of cancer of the intestine. In 64 cases the cecum was involved; in 24 cases the ileum was involved. There is pain at the seat of growth. After a time constipation is noted, or constipation alternating with diarrhea. Finally, intestinal obstruction occurs. In some cases the symptoms appear suddenly, acute obstruction taking place or intussusception occurring. It is usually possible to palpate the tumor, which is hard and immovable. The patient wastes rapidly and is apt occasionally to pass blood at stool. The growth does not enlarge very rapidly and glands are not involved early. In some cases the supraclavicular glands enlarge. In more than one-half of the cases which die of intestinal cancer there is no lymphatic infection.[1]

Treatment.—Early in the case exploratory laparotomy should be performed, followed, if possible, by excision with end-to-end or side-to-side approximation. This is done for either cancer or sarcoma. It may be possible to remove enlarged glands. In cancer of the cecum extirpate the cecum and implant the end of the ileum into the side of the colon (Wm. J. Mayo). If excision is impossible, the growth should be side-tracked by performing lateral anastomosis. In advanced cancer of the large bowel, if resection is impossible, make an artificial anus above the tumor. (See Cancer of Rectum, page 1187.)

Appendicitis.—The vermiform appendix is found in man and anthropomorphous apes. Chimpanzees in captivity are apt to die of appendicitis. Some mammals "closely allied to the anthropomorphous apes possess very large ceca; and in some of these the terminal segment of the cecum resembles the vermiform appendix in that it possesses a very large proportion of the peculiar kind of tissue known as adenoid or lymphatic" ("Evolution and Disease," by Sir J. Bland-Sutton). The appendix is usually regarded as a vestigial structure. Prof. Berry, Dr. Arthur Keith, and some others regard the appendix as a specialized region of the cecum. The fact that the appendix of a newborn child is as long absolutely as the appendix of a full-grown man is regarded by Bland-Sutton as proof "that the part was of great importance to the ancestors of the human species" (Ibid.). Appendicitis, which is an inflammation of the vermiform appendix of the cecum, is almost invariably the primary lesion of all of those various conditions known as typhlitis, perityphlitis, paratyphlitis, etc.—terms which seldom imply pathological entities, and are in most instances well relegated to obscurity. I say in most instances, not in all, because I believe there is such a condition as primary inflammation of the cecum, although it is extremely rare. This rare condition may cause perforation, perityphlitic abscess, or peritonitis when the appendix is sound. It is not to be distinguished clinically from appendicitis (McWilliams, in "Annals of Surgery," June, 1907). Involvement of the cecum as a result of appendicitis is common. Such a condition should be expected because the mucous membrane is continuous. It was recognized by some observers many years ago that such a disease as inflammation of the appendix existed, but the majority of the profession did not grasp the fact. In 1759 Mestevier, of France, reported a case of perforation of the appendix by a pin.[2] In 1812 a perforated appendix was shown to the Medico-Chirurgical Society of London,[3] and in 1835 Southam reported an appendiceal abscess (Manley). In 1848 Hancock reported an appendiceal abscess ("Lancet," 1848, p. 380). It is interesting to

[1] Wm. J. Mayo, "Jour. Am. Med. Assoc.," Oct. 19, 1901.

[3] "Med. and Chir. Trans.," London, 1812, vol. iii.

note that this was a case of appendicitis in pregnancy. Ten days after a premature delivery an abscess was opened. About two weeks after operation two fecal concretions came out of the wound. In 1827 Dr. L. Mélier described appendicitis, and named among its symptoms fixed pain in the right iliac fossa and colic. This brilliant and original young Frenchman was years ahead of his contemporaries. He reported cases of undoubted appendicitis verified by autopsy, described gangrene, perforation, associated peritonitis, and appendiceal concretions. His original article, Manley[1] tells us, is in the "Journal of Medicine, Surgery, and Pharmacy" for 1827, second series, 110. Howard Kelly quotes it from "Jour. gén. de méd.," 1827, vol. c, p. 317. Mélier said: "If it were possible to establish with certainty the diagnosis of this affection, we could see the possibility of curing the patient by operation. We shall perhaps some day arrive at this result."[2] In spite of Mélier's writings, the profession adhered for half a century to the view of Dupuytren, put forth in 1833, that abscesses in the iliac region take origin from the cecum and not from the appendix. Dr. Reginald Fitz, of Boston, in 1886 persuaded the world that the appendix is the real seat of most inflammations in the right iliac fossa, and introduced the term "appendicitis" ("Am. Jour. Med. Sciences," 1886, vol. xcii). This structure is particularly liable to infection because of the large amount of lymphoid tissue in its make-up, because it is in a dependent position, is always full of bacteria, has a poor blood-supply, and is readily blocked by kinking or by swelling of its mucous membrane. Further, as a vestigial structure, it has a low resisting power. A functionless part, like a loafer in a city, is a dangerous element. Each is a menace. The loafer is apt to become a criminal; the appendix is apt to inflame and kill. The appendix is a long and narrow diverticulum (musculomembranous in structure), which comes from the posterior and internal part of the cecum, and which probably has no physiological function. The structure of the appendix is similar to the structure of the colon, except that the muscular structure is ill developed and trivial in amount. Lockwood[3] points out that there is an extensive lymph system in the appendix, and that the submucous and subperitoneal tissues communicate by numerous gaps in the muscles. This structure has a poor blood-supply, and in consequence gangrene occurs from rather trivial causes. It is supplied by a branch from the superior mesenteric artery. In women there is sometimes an additional supply by a vessel running in the appendiculo-ovarian ligament. The nerves are derived from the superior mesenteric plexus. The appendix averages about 4½ inches in length, but varies in size between the limits of ⅓ inch and a little over 9 inches. In 641 autopsies the longest appendix was 9⅓ inches and the shortest was ⅓ inch (Monks and Blake). Its diameter is, as a rule, about equal to that of a No. 9 English bougie; its canal is narrow and is partly closed by the valve of Gerlach (Talamon). The appendix enters the cecum at its posterior internal part, which is usually the seat of the most intense pain in inflammation, and corresponds to a point on the surface 2 inches from the anterior superior spine of the ilium, on a line drawn from the umbilicus to the iliac spine, which is known as *McBurney's point.* The free part of the appendix in one-third of all persons is in relation with the posterior surface of the cecum; in almost one-third of all persons it is fixed in the iliac fossa, so that if perforation occurs the contents will be voided into the retroperitoneal tissue (iliac abscess). In some cases it is external to the cecum; in some it passes downward, and in some inward. It is important to remember that the appendix may be met with in the most unexpected situations. When the ascending colon is displaced, the diverticulum may be upon the left side. It is not

[1] "Med. Record," July 19, 1902.
[2] See R. J. Lee Morrill's article in the "Amer. Med. Surg. Bull.," Dec. 19, 1896.
[3] "Brit. Med. Jour.," Jan. 27, 1900.

unusual to find its tip in the middle line, up toward or adherent to the gall-bladder, or in the pelvis. In about two-thirds of all cases the appendix is completely covered by peritoneum; in one-third of all cases it is in contact, in some part of its length, with cellular tissue (Talamon). Byron Robinson has called attention to the fact that the appendix in men is frequently in contact with the psoas muscle, and may be bruised by this muscle. In 10,000 autopsies the appendix is said to have been absent five times. In most cases in which surgeons have been unable to find the appendix it was not absent, but was covered by peritoneum. Occasionally the appendix is found in a hernial sac.

Etiology and Pathology.—Appendicitis is very rare in infants. I operated unsuccessfully on a male two years of age for gangrenous appendicitis. Savage operated unsuccessfully on a baby sixty-one days old, and Weiss operated unsuccessfully on a child twenty months old.[1] J. P. Crozer Griffith[2] has collected 15 cases in children under two years of age. One of these patients was three months old. Nine of the 15 were operated upon, with 7 recoveries. In 4 of the cases the appendix was in the scrotum. In 2 cases a diagnosis of intussusception was made. In children nine or ten years old the disease is by no means infrequent (see page 1013). Appendicitis is common at any period beyond childhood, being more frequent in young and middle-aged people than in the aged. It is about four times as common in males as in females. It is more common in summer than in other seasons, and in warm countries than in cold or temperate climes. Appendicitis is a bacterial disease. It is produced occasionally by pus cocci, but most commonly by the action of the Bacterium coli commune of Escherich. The colon bacilli, which normally inhabit the appendix, are harmless when the appendix is healthy, but become active for harm when the diverticulum is bruised, obstructed, irritated by the presence of uric acid, congested because of chilling of the cutaneous surface of the body, or distended by the ingress of colonic fluid (C. Van Zwulenburg, in "Annals of Surgery," March, 1905). It seems probable that flatulent distention of the colon may be responsible for forcing fecal matter in quantity into the appendix and may lead to plugging of the opening (Rubin, in "Jour. Am. Med. Assoc.," vol. xliii, No. 18). When inflammation occurs, swelling of the mucous membrane may occlude the opening into the colon. If this occurs, the lumen of the appendix is dilated, filled up, and becomes distended by a thick mucopurulent fluid. Ulcers sometimes form which may only involve the mucous membrane, may pass deeply into the coats, or may even perforate. Dieulafoy[3] maintains forcefully that appendicitis is due *always* to the conversion of the appendix into a *closed* cavity, but cases are met with which disprove this assertion. Various conditions may bring about this transformation. Partial obstruction may be caused by calculi, which are composed of stercoral material and hordes of bacteria mixed with salts of lime and magnesia. These calculi are not formed in the colon, but are formed in the appendix. The theory that concretions form in the colon and are forced into the appendix by peristalsis has been very largely abandoned. Dieulafoy speaks of the condition as *appendicular lithiasis*, and says it has a tendency to run in family lines, and has a kinship to gout and rheumatism. Obstruction may be caused by local infection of a catarrhal area, by the formation of a fibrous stricture, or by several causes acting in unison. The presence of a concretion is always dangerous. It is frequently associated with ulceration, either as cause or effect. It is a mass of virulent bacteria. It may lead to perforation or gangrene. Talamon taught that the appendix resents the presence of the concretion, reflex contraction of the muscular coat taking place, which is accompanied by violent pain (*appendicular colic*). The muscular structure is so rudimentary that it does not seem probable

[1] Manley, in "Med. Record," July 9, 1902. [2] "University of Penna. Med. Bull.," Oct., 1902.
[3] "Progrès médicale," No. 11, 1896.

that attempts at contraction, even should they arise, would produce violent pain and distant symptoms. Pozzi[1] believes that appendicular colic may be caused by torsion or bending of the appendix or malposition of the diverticulum, and holds that pain may arise when there is no lesion in the appendix and no inflammation of the peritoneum or pericecal structures. What is called appendicular colic is really inflammation of the appendix without involvement of the peritoneum. The term "appendicular colic" has led to much injudicious conservatism, and, as Lockwood shows, if an appendix is removed from an individual who suffers from attacks of appendicular colic, it will usually be found that the diverticulum is inflamed or the lumen contains a concretion. Foreign bodies, such as pins, fish-bones, nails, buttons, date-stones, cherry-stones, and grape-seeds, may enter the appendix, but they do so far less often than is generally supposed, most alleged grape-seeds from the appendix being fecal concretions. Fitz found concretions in 15 cases out of 300. Ranvier collected the records of 459 postmortems, and found reported 179 fecal concretions and 16 foreign bodies. In Burgess's 500 cases fecal concretions were found in 21 per cent. ("Brit. Med. Jour.," Feb. 24, 1912). Appendicitis due to a foreign body, such as a grape-seed or a pin, is known as *foreign-body appendicitis;* appendicitis in which a concretion is the assumed cause is known as *stercoral.* A foreign body may produce instant perforation. If impaction of a foreign body or concretion occurs, the orifice of the appendix is closed, the circulation is soon cut off, the secretions are retained, the coats become congested, the diverticulum enlarges enormously, microbes multiply with great rapidity, and the wall of the congested appendix inflames and may become gangrenous or ulcerated, and is finally perforated. Interference with the blood-supply of the appendix will predispose to appendicitis. This may be brought about by twists, bruises, adhesions, concretions, pressure, or bands; and the psoas muscle may play a part in the production of these conditions. In women appendicitis is occasionally secondary to tubo-ovarian disease. Appendicitis is rarer in women than in men, probably because in many females the appendix has a better blood-supply than in males, the additional supply coming through the folds of the appendiculo-ovarian ligament. In women disease of the uterus or adnexa frequently precedes or actually causes appendicitis. Catarrhal conditions of the intestine, habitual constipation, and indigestion with flatulence predispose to appendicitis. In fact, in a great many cases there has been a more or less prolonged history of diarrhea or constipation and flatulent indigestion before the development of acute appendicitis. An acute attack of appendicitis may arise after the eating of a large and indigestible meal, especially if such a meal was taken late at night. Bolting the food and eating large meals at irregular hours predispose to an attack. It seems probable that catarrhal appendicitis may result from extension of catarrh of the colon, and possible that, in rare cases, appendicitis may arise from external traumatism (*traumatic appendicitis*). In most cases, however, in which appendicitis seems to be produced by a blow, the injury at most simply "awakened a sleeping dog" and stirred into acute inflammation an appendix already diseased. It is well to be skeptical as to external force causing appendicitis. Sprengel ("Deut. med. Woch.," Dec. 14, 1911) says there is no case in literature, in which abdominal trauma is alleged as the cause, confirmed by scientific evidence. If before perforation the appendix adheres to the cellular tissue behind the cecum, cellulitis or abscess without peritonitis may result. When appendicitis goes on to perforation, there is always some peritonitis; but if the steps to perforation are gradual, and if the causative organism is the colon bacillus, the peritonitis may be local. Sometimes, by formation of adhesions, a barrier is made between the appendix and the peritoneal cavity before perforation occurs. When perforation takes place sud-

[1] "Progrès médicale," No. 19, 1896.

denly peritonitis is inevitable. When the causative organism is the streptococcus, general peritonitis is very apt to arise. Peritonitis may arise without perforation by contiguity of structure or by migration of bacteria through the congested walls of an obstructed appendix. In some cases perforation takes place into the peritoneal cavity, but pus is circumscribed by matting together of the intestines with plastic exudate. The appendix may become gangrenous very rapidly or after some time. A case of appendicitis in which gangrene and perforation come on very quickly is spoken of as *fulminating appendicitis.* In some cases, if the perforation is very small and the appendix is swathed in lymph, or if perforation does not occur, the inflammation may subside. Perforation rarely occurs from liquid pressure or from the pressure of a concretion; it is generally due to ulceration produced by the action of micro-organisms. Appendicitis which subsides may at any time recur, and the life of such a patient is under constant menace. An enormous number of people have had appendicitis. Toft recorded 500 autopsies, and in 36 per cent. of them there were positive signs of past attacks. The disease is occasionally unsuspected during life. These facts prove that the disease may subside without the aid of surgery.

Forms of Appendicitis.—In what is known as *appendicular colic* the appendix is temporarily obstructed because of transitory inflammatory swelling of the mucous membrane of the outlet, and the stercoral contents are retained in the diverticulum. The peritoneal covering is not involved in the inflammation. This condition is called by Fergusson *constipation of the appendix.* If not relieved, it will eventuate in appendicitis with involvement of the peritoneal coat. It is an unfortunate term, sometimes used as an excuse for avoiding operation. In such cases a concretion is frequently or usually present.

Simple parietal or *catarrhal appendicitis* does not remain limited to the mucous membrane; hence the term *catarrhal* is not strictly correct. The vessels of the appendix are distended with blood, the lumen at the intestinal end becomes partially or completely obstructed, the epithelium desquamates from numerous glands, the mucosa ulcerates, and the lumen of the appendix becomes filled with a mixture of mucus, bacteria, and portions of organic matter. Bacteria enter the lymph-spaces of the wall of the appendix, and pass rapidly from the submucous to the subperitoneal tissues. In from twelve to thirty-six hours after the mucous coat begins to inflame the peritoneal coat will probably be involved. The inflammation may undergo resolution and the patient get well, or a wait for cure may result disastrously. The appendix may thicken, ulceration may take place, and peritonitis may arise. Suppuration or gangrene may occur, perforation may take place, or pyemia, with abscess of the liver, may arise. The acute condition may pass into chronic appendicitis or ulcerations of the mucosa may remain; the mucous crypts may be filled with bacteria; a concretion may exist; cicatricial contractions may occur. In any of these conditions the patient is in danger of a fresh attack at any time. In a catarrhal inflammation secondary to catarrh of the colon the case may be chronic from the beginning. If the lumen of the appendix is gradually and completely obliterated the condition is denominated *obliterative appendicitis* (Senn). This progressive obliteration may result from repeated attacks of inflammation or may simply be a degenerative change. *Recurrent appendicitis*, it was once said, may be due to inordinate size of the mouth of the appendix, making of this diverticulum a drag-net for foreign bodies; but we now know that it is more probably due to smallness of the opening, so that it quickly closes from slight swelling and converts the appendix into a closed vase filled with septic material. *Suppurative appendicitis* is due to purulent infiltration of the walls. Pus in the lumen is not purulent appendicitis. Pus may form about the appendix, a condition known as *appendiceal* or *appendicular abscess. Gangrenous appendicitis* is a moist or septic

gangrene, due to interference with the circulation and to tissue destruction by the action of micro-organisms. Perforation occurs and multiple perforations are common. The entire appendix may slough off. Interference with circulation may be caused by an obstruction, by a bend or twist or bruise of the appendix, or by the action of virulent organisms on an appendix whose tissue resistance is lowered by injury or disease. In gangrenous cases the vessels of the meso-appendix are usually obstructed by thrombi of the veins or arteries. In rare instances appendicitis is due to tuberculous ulceration, in other cases to typhoid ulceration, and genuine appendicitis may arise during typhoid fever.

Fowler suggests the following classification of cases of appendicitis: Endo-appendicitis; parietal appendicitis; peri-appendicitis; para-appendicitis.

As a matter of fact, appendicitis is always one disease which varies in intensity and complication. It is useless to divide it into a great number of symptomatic groups.

Symptoms and Signs.—In what is known as *appendicular colic* the patient suffers from disorder of digestion and occasionally has a brief attack of abdominal pain associated with trivial and temporary tenderness in the right iliac fossa. The colicky pain is about the umbilicus and right iliac fossa; there is often nausea and usually constipation. This condition, if not soon relieved, is followed by the evidences of peritoneal inflammation. The symptoms of genuine acute appendicitis are as follows: In some cases the disease seems to begin suddenly, but in most of the cases there are noted for a few hours or even for a day or two distinct *premonitory symptoms*, among which are constipation or diarrhea, flatulence, nausea, anorexia, dyspepsia, coated tongue, weakness, general gastro-intestinal uneasiness, colicky pain about the umbilicus, and, perhaps soon, tenderness, a sense of weight, soreness, or uneasiness in the right iliac fossa. The acute symptoms suddenly appear after the premonitory symptoms have lasted a variable time, and the acute symptoms very frequently appear in the early hours of the morning. The first definite symptom is severe colicky pain. The tongue is coated and usually dry. Great thirst is often complained of. The face is expressive of pain or, later, in a severe case, becomes Hippocratic. The posture assumed for greater ease is one of recumbency, with the right thigh and knee or both thighs and knees partly flexed. Respirations in acute appendicitis are shallow and thoracic. The development of acute pain is usually the most prominent symptom. The pain is at first colicky and located about the umbilicus or through the abdomen in general, this distant, primary, or generalized pain, according to Treves, corresponding to the distribution of the superior mesenteric plexus. Mr. Burgess ("Brit. Med. Jour.," Feb. 24, 1912) states the present view when he says that the primary pain is referred to "the peripheral distribution of the spinal nerves arising from those segments of the spinal cord with which the appendix and small intestine are connected through their sympathetic nerve supply—eighth to eleventh dorsal." This primary pain may subside if the appendix succeeds in emptying its contents into the colon, but it may also subside if the appendix becomes gangrenous or ruptures (Murphy). Usually in from twelve to thirty-six hours the pain becomes localized in the right iliac fossa, and associated with tenderness and hyperesthesia of the skin—in other words, true inflammatory pain develops. It is due to peritoneal inflammation. "Thus, the closer the situation of the appendix to the parietal peritoneum, the earlier will the latter be irritated and the sooner will the pain be localized" (Burgess, Ibid.). The usual location of the pain in the right iliac fossa depends on the fact that the appendix is usually placed in that region. Occasionally, when the appendix crosses the belly, the pain is located on the left side, and occasionally, for like reasons, in the gall-bladder region, the right loin, or the pelvis. "If the appendix lies among coils of small intestine or in the pelvis there

Various forms of appendicitis (from drawings by Dr. M. H. Richardson): 1. Obstruction from stenosis of appendix. 2. Dilatation of distal end of appendix; perforation by a fecal concretion. 3. Gangrene of nearly the whole of the appendix; fecal concretion in lumen.

may at no time be local pain, the initial umbilical pain becoming steadily generalized" (Burgess, "Brit. Med. Jour.," Feb. 24, 1912). If the pain of appendicitis is violent the patient presents some evidences of shock. Nausea is the rule in appendicitis; vomiting usually occurs early—about three or four hours after the beginning of pain. In children vomiting is often early, violent, and persistent, but in adults, after the early hours of the attack, vomiting occurs, as a rule, occasionally or not at all, although nausea is complained of. Early vomiting is a reflex symptom due to distention of the appendix (Murphy). If vomiting persists, it points to peritonitis, to pus formation, or to intestinal obstruction unless it results from the administration of morphin. There is usually constipation in acute appendicitis, although diarrhea occasionally occurs. In appendicitis there is always some elevation of temperature, although it may be very slight and of brief duration. The fever is not ushered in by a chill, but the temperature mounts in the course of a few hours to 102° or 103° F. or even higher. The fever does not begin until several hours or a number of hours after the onset of pain. In a very mild case the temperature remains elevated for a day or two and then falls to normal. In severe cases it is apt to remain elevated for a longer period, but it is always to be borne in mind that in very grave appendicitis the surgeon may find very little elevation of temperature, no elevation, or actually a subnormal temperature. In gangrenous cases, and in cases in which a large perforation suddenly forms, and when general peritonitis develops, there is usually, for a time at least, a subnormal temperature. A *sudden* drop of temperature indicates, as a rule, a calamity, particularly gangrene of the mucosa of the appendix, which prevents absorption (Murphy), or perforation of the appendix. Leukocytosis is usually present (see Diagnosis). The pulse in appendicitis is in most cases rapid. A very rapid pulse (well over 100) is significant usually of a severe case, and the auguries are especially ominous if the pulse is rapid but the temperature is normal or subnormal. Occasionally, however, a slow pulse exists, even in the worst cases.

Examination of the abdomen may discover, early in the case, general abdominal rigidity; but usually in the course of twenty-four hours or more the general rigidity passes away, the abdomen distends more or less, and rigidity of the lower half of the right rectus muscle becomes evident and persists. If general peritonitis begins early, general abdominal rigidity does not abate or pass away. If general peritonitis begins later, general abdominal rigidity, which was present at first but which passed away, returns. Rigidity may not exist in the very beginning of appendicitis, in a case in which the appendix is retrocecal or pelvic, in some abscess cases, or in a case with relaxed belly walls.

A symptom almost invariably present in appendicitis is tenderness. In some cases the tenderness is diffuse; in most it is localized, or at least most acute, in the right iliac fossa. The point where tenderness is usually most acute is a spot about 2 inches internal to the anterior superior spine of the ilium, on a line drawn from that bony point to the umbilicus (*omphalospinous line*). This is known as *McBurney's point*, and overlies the usual point of origin of the appendix. In some cases, however, the greatest point of tenderness is nearer the gall-bladder; in others, in the loin; in others, toward the umbilicus, in the midline, or on the opposite side; in others, in the rectum. The seat of greatest tenderness depends on the situation of the appendix, and it is usually at McBurney's point, because this usually overlies the origin of the appendix. The lesson is that in appendicitis there is a point of tenderness or of greatest tenderness in a region which the appendix could occupy. If tenderness exists on the right side and then develops in the left side, severe spreading peritonitis usually exists (W. Meyer). When the appendix becomes gangrenous, local tenderness may for a time disappear, because the peritoneum of the involved region has become anesthetic; later, however, it returns, spreads,

and may become general. In view of the fact that tenderness in the right iliac fossa is often demonstrable in tubal and ovarian disease, the sign in males "is of greater significance than in females" (A. H. Tubby, on "Appendicitis," in "Medical Monograph Series"). Pressure upon the left side will, in some cases, cause pain in the right iliac region. When rigidity abates or disappears the case may go on to cure, but sometimes a mass becomes evident in the right iliac fossa. The mass, of variable shape, is at first hard, and if of any considerable size, is dull on percussion. In some cases when no mass is palpable through the abdominal wall, rectal examination detects one. This mass may be agglutinated bowel and omentum or a collection of coagulated inflammatory exudate. It may gradually disappear or an abscess may form. The evidences of general peritonitis are: great distention because of intestinal paresis, general abdominal tenderness, rectal tenderness, very rapid pulse, hiccup, persistent vomiting which may become regurgitation, and, as Meyer points out, percussion dulness over the right iliac region or entire lower abdomen.

In some cases the symptoms, at first trivial, become grave. In some all the symptoms are violent from the beginning, the attack tends to linger, and is followed by persistent soreness of the appendix and harassing digestive disturbances. Any case of appendicitis may become all of a sudden desperately grave because of perforation or gangrene, and in any case general peritonitis may develop. After sudden perforation or rapid gangrene the temperature falls, hiccup begins, abdominal distention, pain, and tenderness become marked and general, and the pulse becomes very rapid. In some cases these grave symptoms are present almost from the start (fulminating cases). A sudden perforation produces collapse and, if reaction takes place, general peritonitis arises. Peritonitis, be it remembered, may arise without either perforation or gangrene. If pus forms, it may be unlimited by adhesions. In such cases there is the rapid onset of fatal peritonitis and septicemia. Pus may be limited by adhesions and be practically extraperitoneal. In such a case a lump is felt in the right iliac region, but dusky discoloration and edema of skin very seldom exist. The surgeon does not wait for fluctuation before he makes a diagnosis. In an abscess case there are usually irregular fever and sweating, but rigors do not occur. Hawkins says we should always suspect pus if the symptoms continue after the sixth day, and particularly when the symptoms abate and suddenly increase between the seventh and tenth days. A limited collection of pus may be liberated into the peritoneal cavity by rupture of the abscess wall. Such a rupture may be caused by pressure or muscular effort; rupture is followed at once by shock and later by diffused peritonitis. An abscess may rupture externally or into the vagina, intestinal tract, or bladder. It is desirable, if possible, to locate the situation of the appendix, and this is usually determined by locating the seat of swelling and of greatest tenderness. The surgeon should not lose sight of the fact that the appendix may be found in the most unexpected situations. In every case a rectal or vaginal examination should be made in order to detect swelling and tenderness, and thus determine if the inflammation took origin in or has come to involve the pelvic region. Pain at the end of micturition points to involvement of the vesical peritoneum.[1] In cases in which there is no *localized* swelling and no local tenderness—for instance, in gangrenous or perforative appendicitis with general peritonitis—"diagnostic localization" is impossible (Van Hook).

Terminations and Prognosis.—Acute appendicitis may terminate in death, in complete recovery, or in a condition of lowered vitality during the existence of which acute attacks are almost certain to occur. Sometimes after and sometimes without an antecedent acute attack the patient develops

[1] Van Hook, in "Jour. Am. Med. Assoc.," Feb. 20, 1897.

persistent soreness and tenderness in the right iliac region. Between the attacks of recurrent appendicitis there may be soreness, tenderness, and gastro-intestinal disturbance, or there may be no evident trouble whatever; yet, even in the latter case, there may be an ulcer or ulcers of the mucous lining. If a patient has once had appendicitis he will always be liable to suffer from another attack if the appendix has not been removed. The liability becomes almost a certainty if the intestinal end of the appendix is narrowed or if the lumen is obstructed at any point, if a concretion exists, or if there is an area of ulceration or of desquamating epithelium. After an attack the appendix may remain enlarged and tender; exercise or indiscretion in diet may cause it to become tender, or the patient may have occasional attacks of colicky pain. If any of the above conditions exist, another attack may be confidently anticipated if operation is not performed. In such cases the appendix can usually be palpated. The method of palpation proposed by Robert T. Morris[1] is very useful. It is applied as follows:

The surgeon stands to the right of the patient and uses three fingers of the right hand to feel with and three fingers of the left hand to press with. Morris insists that no muscular effort should be used by the hand which feels. The feeling fingers are pressed by the other fingers beneath the margin of the right rectus muscle on a level with the umbilicus, and are drawn toward the patient's right side, and the colon will be felt to roll under the fingers. The process is repeated several times until the end of the cecum is reached. The appendix is sought for by rolling the cecum from side to side with the finger-tips, and working toward the proximal end of the appendix.

Adhesions may form as a result of appendicitis, general peritonitis may arise, the appendix may slough or become perforated, or abscess may ensue upon local peritonitis. Lymphangitis of the appendix may accompany, and septic lymphangitis or phlebitis and secondary hepatic and lymphatic infections may follow, appendicitis. They are thought to be most common after mild attacks of appendicitis. The secondary *lymphatic* and *hepatic infections* are of the greatest importance. There may be abscess of the liver, subphrenic abscess, or retroperitoneal lymphangitis.

A subphrenic abscess may result from infection carried from the appendix by the lymphatics, from pus ascending along the posterior cellular spaces, or by direct invasion from the peritoneal cavity (John C. Munro, in "Annals of Surgery," Nov., 1905); such an abscess is usually on the right side, but may be upon the left.

Lymphangitis is the rule in appendicitis, and when we open the abdomen there is usually evidence of it in the lymph-glands of the mesentery, and in children particularly these glands are apt to be enlarged. One lymph path from the appendix is through the ileocecal glands, another is posterior to the cecum and retroperitoneal, and the latter reaches the liver and diaphragm (Munro). In lymphatic infection an abscess may form anywhere in the course of the lymphatics. Abscess of the liver usually results from portal invasion, but may result from lymphatic infection.

Among other possible consequences of appendicitis may be mentioned pyemia, empyema, inflammation of the parotid gland, and thrombosis of the right iliac vein. A positive prognosis of any case of appendicitis is an absolute impossibility. The future of every case is clouded with uncertainty, and the most that can be attained in the field of prediction is a scientific guess of more or less probability. All surgeons have seen apparently hopeless cases recover, and have observed cases with the most trivial symptoms grow progressively worse or suddenly develop a fatal complication. Further, after one attack other attacks are very apt to arise. The medical man who

[1] "Medical Record," Sept. 17, 1898.

estimates that 80 or 90 per cent. of cases get well without operation has probably dealt with many catarrhal cases, and he certainly is optimistic as to freedom from future attacks, because, as stated before, recovery from an attack does not of necessity mean freedom from the disease. In appendicitis there may be delusive evidences of improvement; for instance, the abatement of pain and the lessening of fever, being regarded by the patient himself as indubitable signs of improvement, may, in reality, be indicative of gangrene. In spite of the previously mentioned difficulties and obscurities we can in the majority of cases decide with a reasonable probability of accuracy whether or not the patient is becoming worse. In a delusive improvement some signs and symptoms improve, but all do not; and in endeavoring to form a prognosis, *all* the signs and symptoms must be noted and weighed: pain, tenderness, rigidity, distention, nausea and vomiting, delirium, intestinal obstruction, shock, the temperature, the rapidity of the pulse, the blood examination, etc. If *all* these elements, not only some of them, point to improvement, we may be reasonably confident that improvement is really taking place. If only some of them point to improvement we will in many cases be altogether uncertain as to the significance of the change.

The **diagnosis** is not invariably so easy, as many light-hearted operators seem to believe. It is frequently far from easy and is sometimes altogether impossible without exploratory operation. Sonnenburg maintains that we can diagnosticate the pathological condition of the inflamed appendix. Personally, I am unable to do this with any certainty, although I always try, and am often right and just as often wrong.

In attempting to make a diagnosis, besides the ordinary examination of the abdomen a rectal or vaginal examination should be made, associated in many cases with bimanual palpation. If an appendix is enlarged and an individual has a thin abdomen which is not rigid, it may be possible to palpate the appendix. Sometimes it can be felt after the administration of ether when it could not be detected before. In an acute case forcible or prolonged palpation is always unjustifiable, as it may force an ulcer to perforate, or may rupture an abscess, and the information gained is not of sufficient importance to justify the risk. In a chronic case information of great value may be obtained and there is no real risk in the maneuver. I am persuaded John B. Murphy is correct in attaching the greatest possible importance to the order in which symptoms appear in acute appendicitis. Pain *precedes* nausea and vomiting, elevated temperature, and abdominal tenderness. If fever precedes pain the condition is not appendicitis. If vomiting precedes pain the condition is probably not appendicitis.

The disease may be confused with a number of different conditions. It sometimes is confused with typhoid fever; in fact, early typhoid fever associated with marked abdominal pain gives a picture very similar to that furnished by appendicitis.

In typhoid fever the temperature is usually distinctly higher than that commonly encountered in appendicitis. Maurice H. Richardson[1] tells us that in every case in which typhoid is suspected, operation is not justifiable on the hypothesis of existing appendicitis, unless there are local pain and localized tenderness in the appendix region, associated with definite muscular resistance or distinct rigidity; and that operation should be postponed in a case in which the constitutional signs are severe and the local signs are difficult to detect; but when there are pain, tenderness, and rigidity with or without distention, operation must be performed, even when one recognizes the possibility of the existence of typhoid fever. Richardson lays down the following rule: Soft abdomen plus high temperature suggests ty-

[1] "Boston Med. and Surg. Jour.," Jan. 9, 1902.

phoid, even if there are pain and tenderness. In appendicitis there is usually leukocytosis; in typhoid, leukocytosis is absent, except when perforation is imminent or has occurred, or when some other complication exists. I have seen the operation performed twice for supposed appendicitis when the condition in each case was found to be early typhoid fever.

Acute intestinal obstruction is sometimes confused with acute appendicitis, and the mistake is particularly likely to occur if the obstruction is due to intussusception. In acute obstruction, as in appendicitis, the pain is first appreciated about the umbilicus; but in acute obstruction it remains in that region, does not pass to and localize itself in the right iliac fossa, and is not associated with tenderness of the right iliac fossa. In obstruction the vomiting is persistent; in appendicitis, except in the beginning, it is usually trivial and often absent, although in children it may be violent and persistent. In acute obstruction shock is much more pronounced than in appendicitis, and early and great distention of the abdomen is noted. The temperature in obstruction is seldom elevated and is usually subnormal; while in appendicitis, at least in the majority of cases, the temperature is distinctly elevated. Further, in acute intestinal obstruction the constipation is absolute, not even gas passing. In children, intussusception is capable of particularly confusing the diagnosis, because, after the first day, it is by no means unusual to have distinct fever in this condition, and occasionally a tumor-like mass is found in the right iliac fossa; but in intussusception the tumor does not remain fixed, but alters its position; it is movable; and the patient usually suffers from tenesmus and the passage of bloody mucus. One should bear in mind that in acute appendicitis associated with septic peritonitis acute obstruction may exist; and that the diagnosis of obstruction may be made without recognizing the appendicitis.

In those rare cases of typhlitis occasionally encountered the symptoms are much milder than in appendicitis: the temperature is not much elevated, the pulse-rate is only slightly accelerated, the leukocytosis is not marked, there is seldom rigidity, there may be tenderness, but is seldom pain. Pain when present is colicky rather than continuous. There may be a doughy mass or a mass feeling "like an air-cushion" in the right iliac fossa (Raymond Russ, in "Surg., Gynec., and Obstet.," Oct., 1912). Chronic typhlitis causes muscular atony and intestinal stasis (Russ, Ibid.).

Lesions of the kidney are sometimes mistaken for appendicitis, but in renal colic the pain runs into the groin and testicle of that side, and occasionally passes down the front of the thigh or into the rectum; and if any tenderness exists, it is found in the loin or in the groin, rather than in the right iliac fossa. Besides, there are other symptoms of kidney trouble. The urine may contain blood or pus, and there may be a history of difficult or of frequent urination, though one should bear in mind that in appendicitis with inflammation of the vesical peritoneum there may also be a record of urinary difficulties. An *x*-ray picture may exhibit a calculus in the ureter or kidney, and a movable kidney is distinctly palpable. In ordinary renal colic there is vomiting in the beginning, just as in the beginning of appendicitis. In movable kidney and renal colic the vomiting is often more violent and prolonged than is common in appendicitis. Movable kidney and appendicitis may exist coincidentally. Very confusing cases are those in which *hematuria accompanies appendicitis*. I have seen it twice and in neither case was there any apparent connection between the appendix and the kidney, ureter, or bladder. The hematuria must have been due to acute nephritis which is known to occur in some cases of appendicitis, the nephritis resulting from the toxins of a bacterial disease. This form of nephritis Dieulafoy calls "nephrite toxique appendiculaire." As pointed out by M. G. Seelig ("Annals of Sur-

gery," Sept., 1908), hematuria may also be due to direct involvement of the kidney, ureter, or bladder.

Gall-bladder difficulties, too, may be confounded with appendicitis. I have operated upon 2 cases of cholecystitis under the supposition that they were cases of appendicitis; and upon several cases of appendicitis in the belief that the condition in each case was cholecystitis. In an inflammation of the gall-bladder, with a distended gall-bladder hanging low down, and with muscular rigidity, the distinction between appendicitis and cholecystitis is always difficult and sometimes impossible. So it is when the cecum has not descended and the appendix is in the gall-bladder region. So it is when the tip of the appendix is adherent to the gall-bladder. In ordinary gall-stone colic the condition is generally sudden in onset; it is characterized by pain in the epigastric region, passing toward the shoulder-blade and the shoulder, the pain being most acute and becoming more or less localized in the region of the gall-bladder; and there is always tenderness over the gall-bladder region. In gall-bladder colic the vomiting is usually violent and often almost continuous.

The perforation of a gastric or of a duodenal ulcer may be diagnosticated as appendicitis. In perforation of a gastric ulcer there is usually a history of previous difficulty with the stomach, though this is not always the case. The onset of acute perforation is sudden, with greater shock than is characteristic of the onset of appendicitis. The pain is violent, the rigidity intense, and the pain, rigidity, and tenderness are in the epigastric region.

Among other conditions that may be confused with appendicitis may be mentioned malignant disease of the cecum, tuberculosis of the cecum, acute tuberculous peritonitis, twisting of the pedicle of an ovarian tumor, tubal disease, extra-uterine pregnancy, membranous colitis, perinephric abscess, tuberculous abscess of the loin or of the groin, and abscess from hip-joint disease.

Pneumonia of the right base and pleurisy may cause abdominal pain and be mistaken for appendicitis. The pain may be due to inflammation of the diaphragmatic pleura or may be reflected along the lower six intercostal nerves which supply the lower part of the pleura and the abdominal wall. Irritation of the eleventh thoracic nerve causes pain in the iliac region. There may even be superficial tenderness in the abdomen, but deep pressure is well tolerated (Donald W. Hood, "Brit. Med. Jour.," Dec. 30, 1905). There may be abdominal rigidity. The abdominal pain seldom persists more than a few hours. It is intensified by deep respiration and is accompanied by high fever. As Hood says, whenever a patient suffers from vomiting, abdominal pain, and high fever, examine the chest. Sir Thomas Oliver has described what he calls "the abdominal type of pneumonia." It is characterized by the sudden onset of severe abdominal pain. Vomiting often occurs. There is then a chill, usually a rise of temperature, and in some cases collapse. The pain is accompanied by tenderness, and both these phenomena may be in the right iliac region. Early there are no physical signs of pneumonia. In a few hours the collapse passes away, the abdominal pain and tenderness subside, the temperature rises, and signs of pneumonia become evident. In young children pneumonia is particularly apt to cause abdominal pain and rigidity. Beyond a doubt, more than one abdomen has been opened for supposed appendicitis when the real condition was pneumonia.

In reaching a diagnosis in doubtful cases of appendicitis I believe that the blood-count is often of service. It is, of course, not to be maintained that the diagnosis of appendicitis may be made by counting the blood; but the blood-count may furnish evidence that, when added to the other signs and symptoms, may be of great importance. In nearly every case of acute appendicitis the hemoglobin is diminished by at least 30 per cent. In a catarrhal appendicitis or in an interstitial appendicitis the leukocytosis is trivial; but

in cases of abscess or of gangrene of the appendix the leukocytes, as a rule, rise from 15,000 to 20,000. It is to be remembered, however, that when the patient is profoundly septic the systemic condition is so depressed that leukocytosis is impossible; hence leukocytosis may be absent in trivial catarrhal cases or in grave cases with overwhelming general sepsis. This latter condition, however, is extremely rare. The blood-count will not help one in making the differentiation between appendicitis and an inflammatory disorder of the pelvis or abdomen, but will aid one in making a diagnosis from typhoid fever, intra-abdominal or pelvic neuralgia, and movable kidney (See J. C. DaCosta, Jr., study of 118 cases, "Am. Jour. Med. Sciences," Nov., 1901.)

Appendiceal Dyspepsia.—Indigestion may, for a longer or shorter time, precede an attack of acute appendicitis. A like condition may follow an attack.

In chronic recurrent appendicitis dyspepsia may so dominate the clinical picture as to lead the physician to regard the case as one of gastric disease. Such a patient has prolonged attacks of epigastric pain. There may or may not be tenderness in the appendix region. The condition may be due to hypersecretion of the gastric juice resulting reflexly from appendix inflammation. Fenwick regards chronic hypersecretion as a direct cause of this form of dyspepsia. The epigastric pain may be due to pyloric spasm or gastritis (Eusterman, "Jour. Missouri State Med. Assoc.," May, 1913). At times, however, during some of the attacks appendiceal tenderness is demonstrable and perhaps there is pain in the right iliac fossa. The epigastric or abdominal uneasiness may be constant. Food may immediately cause pain. Nausea and flatulence are common. "As a rule there is not the regularity of onset of pain after food—the periodicity of attack—which characterizes gastric ulcer" (Eusterman, Ibid.). Food does not relieve pain except in the less common cases in which there is hyperacidity.

Appendicitis in Children.—The disease is much more common than was once thought (see page 1003). Russel S. Fowler ("Am. Jour. Diseases of Children," August, 1912) collected 183 cases occurring in children under twelve years of age and brought to the German Hospital of Brooklyn. During the same period (1900–1912) the total number of cases was 1115, the proportion of children being 16.41 per cent. The youngest patient in this series was two years and nine months old. There is usually a history of antecedent attacks of gastro-intestinal disorder. The onset is apt to be sudden, but may be insidious, the symptoms as a general thing are violent, and the progress of the disease is rapid. Vomiting is usually more violent and prolonged than in adults. There is a great likelihood of pus formation, and general peritonitis is more common than in adults. Marked leukocytosis usually exists. Occasionally in young children pneumonia begins with so much pain and rigidity in the lower abdomen that the signs seem to point to appendicitis, and an attack of appendicitis may begin coincidently with or soon after a pulmonary inflammation. I have seen 4 cases in children in which pneumonia was ushered in by abdominal pain and rigidity. The surgeon should be awake as to the possibility of typhoid fever, indigestion, fecal impaction, intussusception, and tuberculous peritonitis. In children the appendix occupies a lower position than in adults, the point of abdominal tenderness is usually lower than in adults, the inflammation usually reaches the right side of the pelvis, a painful point can generally be discovered by a finger in the rectum, hence a digital rectal examination must always be made. This usual involvement of the pelvis is responsible for the frequent and painful micturition which is very common (Karewski). Sometimes when the bladder symptoms are very prominent they dominate the clinical picture and the bladder is thought to be the real seat of disease. An attack of peritonitis in a child is more apt to result in general peritonitis than is the same disease in an adult (Selter). I agree with Springer ("Prag. med. Woch.," 1909,

xxxiv, Nos. 7 and 8) that operation in children should invariably be prompt and that purgatives should not be given. In Fowler's series of cases ("Am. Jour. Dis. of Children," Aug., 1912) the operative mortality was 3 per cent.

Appendicitis in Pregnant Women.—Appendicitis is a very dangerous, but, fortunately, a very rare complication of pregnancy. In 731 women operated on for appendicitis in the Mount Sinai Hospital, of New York, from 1898 to 1907, only 7 were pregnant (Cooke, in "New York Med. Jour.," May 1, 1909). Lobenstine states that in 30,000 cases under the care of the New York Lying-in Hospital there were but 5 cases of acute appendicitis (Cooke, Ibid.). Most of the patients who develop appendicitis during pregnancy have had previous attacks.

The condition may arise at any stage of pregnancy. It is usually violent, rapid in progress, and accompanied by vomiting. Early in pregnancy the pain and tenderness are significant and are located regionally, as when pregnancy is absent. Cooke points out that later in pregnancy the pains may be so spasmodic as to cause them to be attributed to beginning labor, and they are often located in the region of the liver or even on the left side of the belly (Ibid.). Two hundred and fifty cases have been reported and over 100 have been operated on (Renvall).

Fig. 614.—Tuberculous appendix with perforation and abscess.

Appendicitis in the pregnant is far more dangerous than in the non-pregnant. In about 40 per cent. of cases abortion occurs, and usually the child dies from infection. In some cases of successful operation pregnancy continues to term. The diagnosis is often very difficult because of the enlarged uterus.

Appendicitis Following Childbirth.—Hilton collected reports of 29 cases and added 1 of his own ("Surg., Gynec., and Obstet.," Oct., 1907). Hilton demonstrates that childbirth and the puerperium may be causal of appendicitis. The signs and symptoms are apt to be masked or are thought to be due to the puerperal state. The prognosis is grave. In cases developing within ten days of labor 45.5 per cent. died (Hilton, Ibid.).

Tuberculous Appendicitis (Fig. 614).—Acute symptoms may develop resembling acute appendicitis. There is usually a history pointing to intestinal stenosis, the stenosis existing at the ileocecal valve.[1] There is always great thickening, and an abscess of large size is apt to form. The cecum usually, but not always, is involved in the tuberculous process. Chronic cases, with palpable enlargement, are sometimes mistaken for cancer of the cecum.

Malignant Disease of the Appendix (Fig. 615).—This is a very rare condition (less than $\frac{1}{2}$ of 1 per cent. of appendices removed for supposed inflammation). It is impossible of recognition clinically, but is sometimes discovered postmortem or during operation for supposed acute or chronic appendicitis or pelvic disease. Inflammation does not cause the malignant disease, but the malignant

[1] Andrews, "Annals of Surgery," Dec., 1901.

disease is apt to block the appendix and so cause inflammation. The condition may be carcinoma, sarcoma, or endothelioma, and usually there are distinct inflammatory changes. It is more common in women than in men. Rolleston and Jones collected 42 cases. McWilliams reported 3 cases and collected 45 not in Rolleston's table. This makes 90 reported cases ("Am. Jour. Med. Sciences," June, 1908). Since writing his article McWilliams has found 15 more cases reported. No case is counted in which the colon is diseased. The combined statistics show the average age of the patients to be only twenty-nine years. Two patients were only eight. In most cases the appendix alone is diseased; in some the colon or glands of the mesentery are involved. In three-fourths of the cases the growth is distal to the middle of the appendix. Glands are involved late. Out of 90 cases in McWilliams's table only 8 had enlarged glands, and in 4 of these it was proved that the glands were not cancerous. In about 5 per cent. of cases concretions were found. The chance for permanent cure after removal of an appendix the seat of malignant disease is very good if the disease is limited to the appendix, and is particularly good if the growth is spheroidal-celled carcinoma (Rolleston and Jones). Metastasis is rarely noted. The growth is seldom larger than an almond.

Treatment.—If the diagnosis were always certain from the beginning, and if the case were seen at the very start by a surgeon, immediate operation in every case would be eminently proper. If this plan could be followed, the mortality from appendicitis would be extremely small. At this early stage the peritoneum is free from infection, and the appendix can be rapidly and easily removed without risk of infecting the peritoneum. Whenever I see a case early, that is, during the first thirty-six hours of the attack, I practically always advise operation. Unfortunately, this plan cannot be habitually followed. As a rule, when the physician first sees the case the appendicular peritoneum is inflamed, and the surgeon usually sees the case at even a later period than the physician. At this time the barriers of leukocytes are being heaped up to limit the spread of infection, and delicate encompassing adhesions are usually being formed. Even in these later cases I often, in fact, usually, advise operation. Operation at this stage may be imperatively necessary because of the rapid spread and dangerous nature of the process; but when operation is not done, in some cases at least, a temporary limitation will be secured and the case will go on to an interval. Operation in the acute period is always dangerous; operation in an interval is safe. In some instances, when the case is not seen early, it is wiser to avoid operating at the time, and it is proper to wait for an interval. The period in which the surgeon usually sees the case for the first time was said by Maurice Richardson to be "too late for an early operation and too early for a late operation." Those

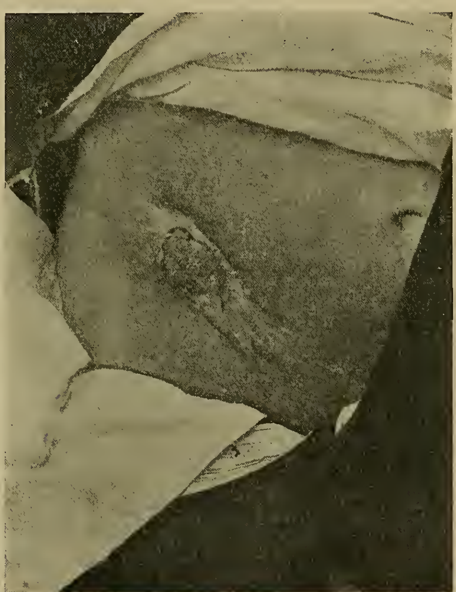

Fig. 615.—Carcinoma of bowel and belly wall after appendix operation. Appendix removed by English Army Surgeon in Burmah. Portion of bowel removed at Heidelberg.

who say "operate as soon as the diagnosis is made," operate, as a rule, in this dangerous period, and in this period I do not believe that every case should be promptly cut. Many cases, it is true, must be operated on as soon as seen, irrespective of the duration of the disease. We must operate promptly if the pulse is small, tense, and well above 100; if there is persistent vomiting; if there is delirium; if intestinal obstruction exists; if a chill has occurred; if the pain and rigidity are very marked; if a mass can be felt in the right iliac fossa or by rectal examination; if there is marked abdominal distention; if there are evidences of pus formation; if the patient is growing worse; if there is or has been shock; or if the pain suddenly passes away without the use of opiates.

In an ordinary mild case, not seen early, in which none of the above-named conditions or symptoms exist, it is best to defer operation. Those who advocate operating upon every case consider such delay reprehensible and dangerous, point out that even in apparently mild cases gangrene or perforation may quickly occur, and cite striking cases to emphasize their belief. There is much force in this view, and it must not be hastily rejected. The choice, however, is not between a dangerous delay and a safe operation, but rather between a dangerous delay and a dangerous operation. It is a question of two dangers, and each side chooses the danger which seems to it the least. Richardson's elaborate study of 750 cases, showing a mortality of 18 per cent. in operations for acute appendicitis, determined us in the practice of the more conservative plan.

In an ordinary mild case of appendicitis in which operation is refused, it is a common custom to purge by means of Epsom or Rochelle salt. This practice was begun because of the belief that inflammation of the appendix is associated with fecal impaction in the head of the colon. This belief has been exploded, but the treatment is still used by some who regard it as beneficial. If the condition of the stomach prevents the administration of salines, high enemata are often given. My own belief is that if operation is refused, or if the surgeon determines to wait for an interval, he should not give a purgative, but follow the plan of treatment suggested by Ochsner to control peristalsis and favor limitation of infection. The patient is kept perfectly quiet, is placed in the Fowler position, no cathartics are given, no food or drink is administered by the mouth, and thirst is allayed by enemata of salt solution. Nutritive enemata may be given. It is also my custom to place a hot-water bag instead of an ice-bag over the appendix region.

To permit peristalsis favors diffusion of the infection; to prevent peristalsis is to favor the formation of encompassing and defensive adhesions. A purgative is very dangerous. It may cause rupture of the appendix. By causing peristalsis it diffuses the infection.

Many surgeons use the ice-bag, but I do not believe in it in these cases. We have already shown (see page 97) that cold as a remedy for inflammation is useful only in the brief stage of hyperemia, and when a surgeon sees a case of appendicitis there is certainly more or less stasis. Cold adds to stasis and does harm, and I am persuaded that the routine use of the ice-bag is responsible for some cases of gangrene. Again, cold actually antagonizes the migration of leukocytes and the formation of adhesions. For a number of years I have believed and taught that the ice-bag weakened resistance in appendicitis. These views seem to find confirmation in the article of Dr. A. M. Fauntleroy, U. S. N. ("The Ice-bag and Appendicitis," "Med. Record," August 3, 1912). The study of a number of cases led him to the conclusion that the ice-bag is often responsible for "a noticeable lack of effort on the part of Nature to wall off from the rest of the abdominal cavity the appendix." Further: "It was also noted in the ice-bag cases that there was a surprisingly low white count when one took into consideration the condition." These reports are most significant.

They are in strict accord with my own results. It is my belief that the use of the ice-bag antagonizes the limitation of the infection and favors dissemination of toxins and bacteria. I believe that its employment is a grave mistake.

Heat is a remedy which favors limitation of the process. It relieves stasis, draws leukocytes to the part and stimulates their activity, favors the formation of an encompassing barrier of phagocytic cells, and aids the cellular proliferation which leads to the formation of adhesions. Hence I prefer the hot-water bag.

The ice-bag, when applied before the diagnosis has been made, that is, in the earliest hours of the attack, when it might be thought to be most serviceable, allays pain and lessens rigidity in some cases almost like a full dose of opium, and hence masks the symptoms as does that drug.

Opium should never be given until the diagnosis is made. In the first place, it is not needed, for if the pain is so violent as absolutely to demand opium, operation should be performed. In the second place, opium masks the symptoms, makes the patient feel comfortable, and gives the physician an unfortunate and ill-founded sense of security. The pain about the umbilicus, if severe, can be distinctly and safely relieved by the administration of 30 min. of spirits of choroform every half-hour until three doses have been taken. Opium should not be given if the surgeon, having decided not to operate at once, is awaiting an interval, because it may prevent or delay the recognition of some disastrous change. If a patient refuses operation, it can be given.

When we are inclined to wait for an interval, the case should be seen again within six hours. We are accustomed to follow McBurney's rule, which is as follows: If on seeing the patient again, six hours after the first visit, the patient is worse, operate at once. If he is no worse there is no pressing danger.

If in twelve hours after the beginning of the attack the symptoms are not intensified, they will soon begin to abate; if the symptoms have become worse during this time, operate. If in twenty-four hours after the beginning of the attack the severity of the symptoms lessens, it is usually possible to wait for an interval; but if during the second twenty-four hours the abatement in the severity of symptoms has not gone on and there is doubt as to the condition, operate at once.[1] When the attack has subsided, and about three weeks or more have passed, the appendix can be removed with remarkable safety. After a patient has had two or more attacks of appendicitis all surgeons agree that the appendix should be removed.

If pus is present some surgeons delay operation in the hope that firm adhesions will form around the pus, and that the necessary operation will simply be the opening of an abscess. I do not believe it is safe to delay operation in a pus case. The pus may become limited, but it may instead pass up toward the liver or down into the pelvis. Delay is fraught with peril.

If only one attack has occurred, there may never be another, and the question arises, Should the appendix be removed after one attack? We do not know that a man has really recovered after purely medical treatment. Many cases reported as cured by medical means have subsequently required operation. As Lockwood[2] puts it, "To say that a man with appendicitis has been cured by medical means is in many cases equivalent to saying that a man with a stone in his bladder has recovered from calculus after the cure of a cystitis by rest in bed."

Even after a first attack, if the appendix remains tender or becomes tender after exercise, or if attacks of colicky pain occur, operate.

In some cases a single attack of appendicitis is followed by persistent dyspepsia and ill health, and in such cases operation should be performed. In the majority of cases, even after one well-marked attack, operation is

[1] For McBurney's views, see "New York Polyclinic," Jan. 15, 1897.
[2] "Brit. Med. Jour.," Jan. 27, 1900.

necessary. It is always necessary after two attacks. (See Operation for Appendicitis.)

Appendicitis cases which are far advanced in general peritonitis when seen by the surgeon some operators decline to touch. If we make a custom of operating on such cases we will lose very many, but will save some few, and these few would have died if we had not operated. To operate spoils statistics, but occasionally saves lives. The operation should consist of a simple incision to relieve tension and afford exit to infected fluids—rapid removal of the appendix if it is easily accessible, otherwise leaving it alone—and drainage of the pelvis. After such an operation the patient is placed in Fowler's position and a continuous stream of salt solution at low pressure is caused to trickle into the rectum. (See Murphy's Treatment for Peritonitis, page 1024.)

Appendicitis in a child is treated exactly as in an adult. Appendicitis in the pregnant woman is treated as in the non-pregnant. Early operation is particularly indicated, and it is not proper to induce premature labor in a patient far advanced in pregnancy unless there is general peritonitis. Then it is proper to empty the uterus—primarily, to obtain drainage and to give the patient a chance for life, and secondarily, to obtain a living child.

When operating upon a woman for appendicitis, bear in mind that ovarian, tubal, or uterine disease may have preceded, actually caused, or resulted from the appendicitis; examine the adnexa and remove them if necessary.

An operation for tuberculous appendicitis is rather apt to be followed by a fecal fistula. An ordinary laparotomy is sometimes followed by cure, but the rule of an operator should be, when possible, to remove the appendix and resect the diseased bowel. Andrews[1] mentions as expedients suited to special cases of tuberculous disease: total exclusion; partial exclusion; lateral anastomosis, and the formation of an artificial anus.

Intestinal Diverticula.—Congenital diverticula sometimes exist in the duodenum. Pressure diverticula may arise in the small intestine; they are, as a rule, small and multiple. The descending colon and the pelvic colon are the most common seats of diverticula. They occur at any portion of the circumference of the tube, are usually multiple, and vary much in size. Occasionally a diverticulum becomes enormous. A diverticulum contains fecal matter and, perhaps, fecal concretions. When free from acute inflammation and when unobstructed a diverticulum may cause no symptoms whatever. A diverticulum may inflame, suppurate, cause pericolonic suppuration, perforate, or become the focus of a great fibrous area (fibromatosis), which is usually mistaken for cancer.

Acute diverticulitis occurs in "adults, mostly in males in midlife and given to obesity" (Joseph Ransohoff, in "Annals of Surgery," August, 1913). There may be catarrhal inflammation. An abscess may form about the diverticulum. Perforation may occur, followed by abscess or general peritonitis. As most diverticula are in the lower colon the symptoms are usually left sided and strongly resemble appendicitis. Suppuration about the sigmoid does not of necessity arise from acute diverticulitis. Acquired diverticula do not exist in children, and yet Ransohoff (Ibid.) reported cases of acute perforating sigmoiditis in children.

Meckel's Diverticulum.—(See page 988.)

Treatment of Acute Diverticulitis and of Perforating Sigmoiditis.—As for appendicitis.

Fibromatosis of the Colon.—This condition produces symptoms strongly resembling those caused by carcinoma, and many cases have been operated upon under this conviction, the truth having been discovered by microscopical

[1] "Annals of Surgery," Dec., 1901.

examination of the specimen. It is an inflammatory condition most often met with in the pelvic colon. A large, hard mass forms and constriction occurs. The mucous membrane is thrown into deep folds and ulceration occurs in the hollows.

The fibromatosis is a reaction to infection. The infecting agent gains entrance through a desquamating area, a wound of the mucous membrane, an ulcer, or an inflamed diverticulum. Even when cancer exists there may be extensive fibromatosis about it, the area of real malignancy being much less than the induration suggests.

Fibromatosis may arise at any age, but is most common during and beyond middle age. There is continuous abdominal uneasiness now and then rising to pain. The general health deteriorates. The victim suffers from habitual constipation, but occasional attacks of diarrhea occur. Blood and mucus are at times found in the stools. If the constricting mass is within reach of the finger, it will be found that the induration is beneath thick and soft mucous membrane. If it can be seen by the sigmoidoscope, the folds of mucous membrane will be obvious. Abdominal palpation often detects the mass, which is sausage shaped. (See Miles, in "A System of Surgery," edited by C. C. Choyce.)

Treatment.—Resection and anastomosis if possible. If real obstruction exists, or if the mass seems irremovable, do colostomy. After colostomy the mass usually shrinks greatly and may actually disappear.

Congenital Idiopathic Dilatation of the Colon (Hirschsprung's Disease; True Megacolon).—This condition is of prenatal origin. The large intestine is chiefly involved. The rectum and small bowel seldom suffer, "and in more than one-third of all the cases the sigmoid flexure is alone involved" (Finney, in "Surg., Gynec., and Obstet.," June, 1908). There is no definite mechanical obstruction demonstrable at autopsy or operation. It is in this that Hirschsprung's disease (true megacolon) differs from pseudomegacolon (Finney, Ibid.). The diameter may reach 6 or 8 inches, and the colon may seem elongated and be in loops. Dilatation and hypertrophy produce marked changes in the wall of the gut. The condition may be obvious in early life or it may not become so until adult years, being aggravated and developed, but not caused by habitual atony of the bowel. The supposed cause is an anatomical anomaly (perhaps elongation) leading to looping of the colon, a muscular aplasia leading to dilatation and valve formation. Various causes have been suggested.

The victim of this condition is obstinately constipated and has a distended abdomen, usually from early infancy, although, as previously stated, the condition may not manifest itself until childhood, youth, or even adult life. It is most difficult to get the bowels to move at all. Gay reported a case in which there was no bowel movement for three months. Periods of several weeks without a movement are by no means uncommon. Now and then an attack of diarrhea may cause the emptying out of great quantities of feces. The abdomen is enormously distended and the patient is emaciated.

The abdominal veins are distended and the rectus muscles may be separated. In Finney's cases (as in some other reported cases) the cords of distended gut could be seen or felt to be more prominent on one side than on the other. There is no abdominal tenderness and pain is absent unless there is diarrhea. Borborygmus is often very loud. Vomiting is rare. The urine shows a marked increase of indican.

The disease does not directly cause death, but the ill-nourished condition lessens the chance for recovery from any attack of illness.

Treatment.—Medical treatment consists of the ordinary plans for combating constipation. Some surgeons have removed almost the entire large intestine; others have performed entero-anastomosis; others, colopexy; others

have established a permanent artificial anus; others have made an artificial anus preliminary to entero-anastomosis. Finney believes that the operation of choice is resection of the affected gut followed by entero-anastomosis.

Splanchnoptosis (Visceroptosis).—Coffey ("Surg., Gynec., and Obstet.," Oct., 1912) points out that in man special provisions are made to keep the viscera from riding down because of the upright posture. He names four forms of support: (1) Peritoneal fusions before birth to the parietal peritoneum; (2) a shelf above each psoas muscle; (3) tone of the abdominal wall; (4) packing of subperitoneal fat which regulates intra-abdominal pressure. Visceroptosis is generally said to be due to relaxation of the abdominal walls and decrease of intra-abdominal tension, which leads to gradual stretching of suspensory ligaments and finally to movement of the viscera downward. The prolapse may involve all the abdominal viscera, one viscus, or several viscera. According to Coffey (Ibid.), when the intestine descends kinks occur at the junctions of fixed and movable parts, and general ptosis is an attempt on the part of Nature to prevent intestinal kinks. Prolapse of the stomach is known as gastroptosis (see page 976); prolapse of the liver, as hepatoptosis (see page 1039); prolapse of the spleen, as splenoptosis (see page 1065); prolapse of the kidney, as nephroptosis (see page 1275); and prolapse of the intestines, as enteroptosis or *Glenard's disease* (see below).

The causative relaxation of the abdominal walls is most common in women, but is by no means confined to that sex. It may be produced by ascites, pregnancy, muscular effort, febrile maladies, or wasting diseases. In some cases no cause can be assigned. Such a relaxed abdomen may or may not be thin. The fascial strands and muscular fibers are stretched, and usually attenuated and separated, the belly bulges downward and forward, and a viscus or the viscera follow because of lack of support.

Enteroptosis, or Glénard's Disease.—This disease is a prolapse of the intestine. It may be but a part of ptosis or prolapse of all the abdominal viscera; it may exist alone; it may be associated with movable kidney, prolapse of the stomach, of the liver, or of the spleen.

In Glénard's disease the intestines occupy the lower portion of the abdomen, and the belly below the costal margins is flat, is dull on percussion, and the pulsations of the aorta are very evident. The right portion of the transverse colon begins to descend first, and other portions of the intestine follow. The splenic and hepatic flexures are elongated, and sometimes there is venous engorgement of dependent parts of the mesentery (Lambotte, in "Presse Med. Belge," Nov. 24, 1901). The victims of this disease are dyspeptic, anemic, and neurasthenic. Normally the tenth rib is firmly attached by fibrous tissue to the ninth costal cartilage. In enteroptosis the tip of the tenth rib is freely movable and obviously separated from the ninth costal cartilage (*Stiller's sign*). The *x*-rays used after a bismuth meal are of the greatest help in diagnosis. The ptosis may arise without apparent cause, but may follow the wearing of ill-fitting corsets, falls, blows, lifting heavy weights, or prolonged vomiting. The dyspepsia is due to dragging on the duodenum, the tube becoming flattened out (A. K. Stone). The flattening of the duodenum may be followed by kinking of the pylorus, and in such a case the stomach dilates, otherwise it does not dilate. Where a movable portion of the gut has a junction with a fixed portion a kink forms and intestinal stasis ensues.

Treatment of Visceroptosis.—In many cases medical treatment is of benefit. The following is the usual plan: Employ lavage, abdominal massage, and electricity; order a proper abdominal corset; insist on regular exercise, and treat the anemia and dyspepsia. Surgery is resorted to if intestinal stasis exists and cannot be relieved by medical and dietary treatment. The surgical methods

applicable to special organs are discussed under those headings. When the intestines are ptosed and there is stasis there are two commonly employed surgical plans, and each has its advocates: (1) The suture of the prolapsed intestine to some adjacent structure or the shortening by sutures of its supporting ligaments. (2) Plastic operation to lessen the area of the abdominal wall and thus increase intra-abdominal tension. Depage makes the abdominal wall less in both directions. Webster, in cases with separation of the recti, resects and sutures the fascia of the muscles. I believe that Depage's method of shortening the diameters of the abdominal wall cannot permanently succeed, because the viscera, hanging to relaxed ligaments, will eventually stretch the wall; it will be stretched easily because of damage done to its nerve-supply by operation, and hernia will be apt to occur, and if it should, the patient will be worse off than before operation. Of course, whatever operation is done, diastased rectus muscles should be approximated and sutured. For ptosis of the small intestine the mesentery may be shortened, as suggested and performed by Davis, of Omaha, in 1897.

In prolapse of the transverse colon good results are said to have been obtained by attaching the splenic and hepatic flexures to the abdominal wall (*Lambotte's operation*). The surgical treatment of ptosis of the stomach is considered on page 977; of the liver, on page 1040; of the spleen, on page 1065; of the kidney, on page 1278.

The Peritoneum

Acute Peritonitis.—Peritonitis, or inflammation of the peritoneum, is a common and usually a very dangerous disease.

Aseptic irritation by a traumatism or a chemical irritant produces *aseptic peritonitis*, a condition which is strictly limited; which may produce local pain and tenderness; which may cause aseptic fever from the absorption of fibrin-ferment and the products of tissue change; which leads to the formation of temporary or permanent adhesions, and which is, in reality, a process of repair.

"Peritonitis," as the term is used by the surgeon, is always due to bacteria. Bacteria may reach the peritoneal cavity by means of an abdominal wound or the entrance of foreign bodies; by extravasations from the stomach, bowel, vermiform appendix, gall-bladder, urinary bladder, kidney, Fallopian tube or uterus, or by the passage of micro-organisms through the damaged walls of any of these viscera or structures; by way of an open Fallopian tube; from the breaking of an abscess into the peritoneal cavity; from areas of necrosis due to volvulus, strangulation, or intussusception of the intestine; twisting of the pedicle of an ovarian tumor, a floating kidney, or a floating spleen; blocking of a mesenteric vessel by a thrombus or an embolism; gangrene of the pancreas or spleen, and fat-necrosis.[1] In some cases the peritoneum may contain a point of least resistance, and bacteria contained in the blood reach this point and produce infection. It was once taught that cold could produce peritonitis, but it seems probable that it can only act by producing an area of least resistance. The capacity of the rheumatic poison to produce peritonitis is doubtful.

The peritoneum, as Byron Robinson pointed out and Fowler confirmed, is, in reality, a great lymph-sac, and peritonitis is lymphangitis. "When the peritoneum is infected the lymphatics furnish an exudate which clots in the lymph-channels, blocks them, and limits or prevents absorption. This blocking of the lymph-channels serves to preserve the life of the subject, on the one hand, while a failure in this respect, either because of the enormous and overwhelmingly rapid increase of septic material and the large

[1] See Park's "Surgery by American Authors."

size and number of channels necessary to destroy and obstruct, on the other hand, permits the destruction of the organism."[1] Absorption takes place most actively from the region of the diaphragm, hence peritonitis in this region is peculiarly fatal. Absorption takes place very rapidly from the intestinal region, although not quite so quickly as from the diaphragmatic area. Absorption takes place slowly from the pelvic region, hence peritonitis of this region is much less dangerous than is the disease in the intestinal region, and vastly less dangerous than is the disease in the diaphragmatic region (Fowler).

When severe bacterial infection of the peritoneum occurs, exudation of blood-liquor takes place, luekocytes migrate from the blood-vessels beneath the endothelial layer, particularly into the peritoneal cavity, and the causative bacteria rapidly spread about the cavity. The fibrinous exudate, in many infections, coagulates in masses on the free surface of the peritoneum, and thus serves a useful purpose by blocking the lymph-channels and hindering the absorption of toxins and bacteria. The fibrinous exudate may break down in a widespread suppuration or may be organized into an adhesion. In very virulent streptococcic infections a patient may die and there may be scarcely any coagulated exudation or may be none at all. Exudation and migration take place also in the subserous tissues and into the muscular coat of the bowel, and the segment of bowel which is attacked becomes paralyzed and distended with gas, the gas within causes it to rise up, and, as peristalsis is absent, obstruction occurs (James P. Warbasse, in "Am. Jour. Med. Sciences," July, 1905). Absorption of poison in peritonitis takes place in part from the peritoneal cavity and in part from the subserous tissues. Warbasse believes that the inflamed peritoneum is scarcely an absorbing surface, but in cases in which coagulated exudate has not formed or has been destroyed, it seems probable that it is an active absorbing surface, and absorption may occur from some regions, but not from others.

Various bacteria may be responsible for peritonitis, especially staphylococci, streptococci, pneumococci, and colon bacilli. The infections which spread most rapidly and widely are due to streptococci. In streptococcus infection the protective exudate does not coagulate, barriers of leukocytes are not heaped up, encompassing adhesions do not form, there is rapid absorption of toxins, and overwhelming systemic poisoning. Colon bacilli cause a very grave form of peritonitis, but less rapid and diffuse than that caused by streptococci—in fact, the process is often encompassed for a time by coagulated lymph, leukocytes, and adhesions. The omentum particularly is thickened, and is apt to apply itself about the area of infection. Staphylococci and pneumococci produce peritonitis which is more apt to be limited than that produced by colon bacilli. In most cases of peritonitis a mixed infection exists; for instance, colon bacilli and staphylococci or colon bacilli and streptococci. In some apparently severe cases of acute peritonitis cultures have remained sterile.

Forms of Peritonitis.—An accurate bacteriological classification is not as yet possible.

Peritonitis can be named, according to regions, *pelvic*, *subdiaphragmatic*, etc.; it can be divided pathologically into *diffuse septic*, *putrid*, *hemorrhagic*, *suppurative*, *serous*, and *fibrinoplastic* (Senn); it can be classified, etiologically, into *traumatic*, *puerperal*, *perforative*, *metastatic*, *scarlatinal*, etc.; and it can be divided, clinically, into *circumscribed suppurative*, *diffuse suppurative*, and *diffuse septic*.

Circumscribed Suppurative Peritonitis.—In this condition, which is frequently met with in appendicitis, the area of infection is circumscribed

[1] George R. Fowler, "Diffuse Septic Peritonitis," in "Medical Record," April, 14, 1900.

by coagulated exudate, leukocytes, and adhesions, and an abscess forms. After a time distinct localization becomes evident.

The *symptoms* of circumscribed peritonitis are pain, at first general and then local, tenderness in a particular region, muscular rigidity, distention, vomiting, rapid and often wiry pulse, constipation, fever, great weakness, and dorsal decubitus with the thighs flexed. After a time a distinct mass can usually be detected by palpation, and there may be dulness on percussion, local rigidity, irregular temperature, sweats, and possibly edema of the belly wall. An abscess, though limited for a time, is always liable to break through its walls and produce general peritonitis. Such an accident may be produced by muscular effort on the part of the patient or by injudicious palpation on the part of the surgeon; its occurrence is announced by shock, and the symptoms of general peritonitis quickly arise.

Diffuse or **general septic peritonitis** is apt to destroy life even before the peritoneum presents any marked change. Death ensues from the absorption of toxic alkaloids. Septic peritonitis may arise during puerperality, through lymphatic infection; it may be due to infection from without by an operation or an accident; to perforation of an ulcer; to gangrene of a portion of the intestine; to rupture of an abscess into the peritoneal cavity; or to migration of micro-organisms through a damaged wall of the bowel. Peritonitis due to perforation is called *perforative peritonitis*. Perforation is made manifest by pain, a chill, shock, or perhaps collapse. Gas may pass into the peritoneal cavity, and if it does so, the area of liver dulness may be lessened or abolished. Symptoms and signs of hemorrhage may arise. Diffuse septic peritonitis is announced by a very rapid pulse, which is at first wiry and later gaseous; a temperature which may at times be febrile, but which is apt to be subnormal or which soon becomes so; general abdominal pain and tenderness, dry tongue, delirium, persistent vomiting, constipation, and collapse. Rigidity exists, and also intestinal obstruction due to paralysis of the gut. Usually, but not invariably, there is distention. In puerperal peritonitis or septic peritonitis from operation there is often no severe pain. In perforative peritonitis there is acute pain. Victims of general septic peritonitis if unoperated upon usually die within five or six days.

Diffuse or **general suppurative peritonitis** differs clinically from diffuse septic peritonitis in the fact that it is less apt to be fatal and widespread. In fact, adhesions may form about an area representing a considerable portion of the peritoneal cavity. The causes of both are identical. In septic peritonitis death occurs from absorption of toxins before obvious pathological changes occur in the peritoneum; in suppurative peritonitis the microbes are fewer, are less virulent, or vital resistance is more decided, and suppuration follows marked changes in the peritoneum. In suppurative peritonitis the pyogenic bacteria are always present, and there exists in the peritoneum a wound or damaged area to constitute a point of least resistance.

Symptoms.—Chilliness or a rigor is common, followed by fever, the temperature rising to 102° or 104° F.; pain is intense, and is accentuated by motion and pressure; the attitude of the patient is assumed to relieve pain (he lies upon his back, with the shoulders raised and the thighs drawn up); there are vomiting, obstinate constipation, and rigidity of the abdominal walls, followed by distention when the intestine becomes paretic from septic poisoning. The pulse is rapid; is at first wiry, but may become gaseous. The constipation may be due either to tympanitic distention or to the shock and toxemia inhibiting intestinal peristalsis. Obstruction arises. Vomiting is frequent. In perforation gas often passes into the peritoneal cavity, and it may obscure the liver dulness; in tympanites without perforation the liver is apt to be pushed up and its dulness remains, but on a higher level. Pus unconfined by adhesions will

gravitate to the most dependent part of the peritoneal cavity. In some cases of suppurative peritonitis there is no tympanitic distention or rigidity; in some cases there is no elevation of temperature, in fact, the temperature may be actually subnormal.

Treatment of Peritonitis.—After an abdominal operation the patient may have pain, slight rigidity, constipation, nausea, flatulence, etc., and the surgeon is in doubt if peritonitis is beginning or about to begin. Our custom is in such cases to give a saline cathartic, which will empty the peritoneal cavity of fluid, will favor the elimination of microbes, and will combat inflammation. The old-time remedy was opium, but Tait denounced it as inefficient, and showed that it masked the symptoms and often created a false sense of security in the very midst of imminent dangers. The usual method of administering salines is to give 1 dram of Rochelle salt and 1 dram of Epsom salt every hour until a free movement occurs. Administer an enema of turpentine at the time the first dose of the saline is given. Atropin, eserin, and pituitrin may be useful (see page 992). This treatment will often abolish pain and distention and will perhaps prevent peritonitis after an abdominal operation. If, however, genuine peritonitis is known to actually exist no purgative should be

Fig. 616.—Murphy treatment for suppurative peritonitis.

given. It is a deadly dangerous thing to give one, as it diffuses infection. Operation is required. Prompt operation is the only hope in genuine postoperative peritonitis and any delay means certain death. When diffuse septic or suppurative peritonitis exists from any cause and the surgeon sees the case early (within thirty-six hours) the abdomen should be opened. In a perforative case operate even if the case is first seen later than thirty-six hours. If a nonperforative case is seen later it may be wise to use Ochsner's treatment and wait for localization (Stanton, in "New York Med. Jour.," Aug. 27, 1910). If a perforation exists, it should be closed. A perforated or inflamed appendix should be removed. Until recently it was surgical custom to break up adhesions, eviscerate, wash the belly with gallons of very warm salt solution, wipe out the space between the liver and diaphragm, wipe out the pelvis, wipe off the intestines, and remove masses of adherent coagulated exudate. We thus produced dreadful shock, tried to cleanse the peritoneal cavity when it is impossible thoroughly to cleanse it, carefully removed the exudate which was doing good by plugging the lymph-spaces, and yet we did not reach the infection inside of the lymphatics, which is, after all, the greatest source of danger. Then we drained through two or more incisions and put the patient recumbent in bed, and thus permitted infected material to flow up to the diaphragm, where

it is quickly absorbed. The mortality from this procedure was dreadful. John B. Murphy has taught us wisdom and has combined some of the conservative views of Ochsner with the use of the semi-erect position of Fowler, and with the continuous rectal irrigations that several advocated. Murphy's plan is founded upon the following principles:

First, that the initial lesion of the peritonitis should be got rid of as quickly as possible and with the slightest possible amount of handling. For instance, we should remove a gangrenous appendix; we should close a perforation in the bowel, etc. Flushing of the peritoneal cavity with gallons of salt solution is inadvisable. It cannot thoroughly cleanse the peritoneum; it may diffuse the infection to regions that it had not previously reached, and it may tear up adhesions. Inflammatory exudate should not be removed from the intraperitoneal structures. It is Nature's method of sealing the lymph-spaces, and if we remove it we open thousands of channels, previously sealed, for the dissemination of the infection. A drainage-tube should be introduced through the operation wound, and suprapubic incision should also be made and a drainage-tube be carried through this into the pelvis. When the operation is completed the patient should be placed in the semi-erect position, which is commonly called *Fowler's position.* This is done in order that the intraperitoneal fluids may gravitate away from the diaphragm, where absorption is extremely rapid, and into the pelvis, where absorption is much slower.

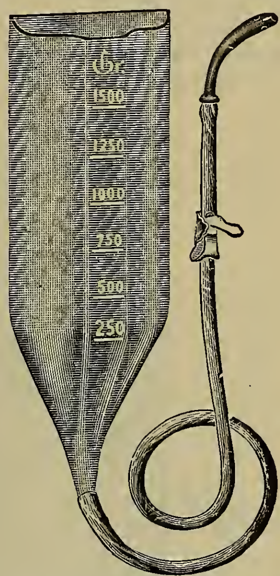

Fig. 617.—Proctoclysis apparatus consisting of fountain syringe, large rubber tube, and vaginal hard-rubber or glass tip (Murphy).

When the patient is placed in the bed quantities of warm salt solution are passed slowly into the rectum. The mucous membrane of the large intestine absorbs fluid with great rapidity when that portion of the gut is in its normal condition of moderate distention. Overdistention leads to spasm, which expels the fluid. Hence the fluid must be given at low pressure and administration should be continuous. The simplest sort of apparatus is shown in Fig. 617. It consists of a fountain syringe, a large rubber tube, and a rectal tip of hard rubber. The nozzle that is used is angled, has one opening on the end and several on the side, and this nozzle is passed so that the angle fits to the sphincter (see Fig. 619). The tube is strapped to the thighs by adhesive plaster. The hose that comes from the nozzle is attached to a reservoir, the base of which is hung from 4 to 6 inches above the level of the patient's buttocks; and the fluid, therefore, enters the rectum only about as fast as the rectum will absorb it. The reservoir is kept warm by bags of hot water hung about it. The fluid is allowed to enter continuously, unless it should run out from the side of the tube; if this happens, the flow may be cut off for a short time and then allowed to begin again. Gas from the bowel passes into the openings of the tube, and every now and then bubbles up through the reservoir. By this continuous, low-pressure instillation (*proctoclysis*) an enormous quantity of fluid is absorbed by the rectum. In some cases a number of quarts are taken up in twenty-four hours. The absorption of this fluid greatly increases the amount of urine eliminated, removes toxins, and stimulates the heart. The reservoir must not be high. Increase of pressure will cause expulsion of fluid and defeat the possibility of continuous administration. The plan so often followed of keeping the reservoir

high and limiting the flow by a clip on the tube is a mistake. Murphy says: "It should never have a headway of more than 15 inches hydrostatic pressure, and it gives the best and most uniform results at 4 to 7 inches" ("Jour. Am. Med. Assoc.," April 17, 1909). A straight tube is sometimes responsible for expulsion of the fluid, because it touches the posterior rectal wall of a patient in Fowler's position. Fig. 618 shows a more elaborate apparatus than that just described.

After the water has been entering the rectum for some time a profuse discharge of sour-smelling material comes from the drainage-tube. This discharge may be profuse for one day, two days, or longer, when its sour smell disappears and it greatly lessens in quantity. The outflow of this fluid from the wound means that saline fluid from the rectum has entered the lymph-spaces and flowed into the peritoneal cavity. Murphy thinks the lymph-current has been reversed. Whether this is true or not the peritoneum certainly seems to become a secreting instead of an absorbing surface, and the lymphatics are washed out. During the time that this treatment is pursued the patient

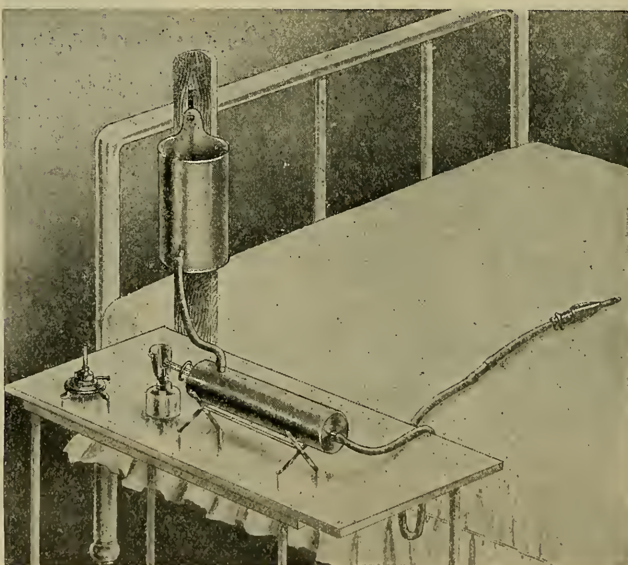

Fig. 618.—Alcohol or gas heater in operation, showing it properly connected. A short glass tube connects catheter to rubber tubing (Murphy).

has no food or water given him by the mouth. Stomach feeding is rigidly forbidden in order to prevent peristaltic movements. Small amounts of opium may be given to prevent peristalsis. If the patient is in a weak condition, stimulants or food can be given by the rectum, the solution in the reservoir being allowed to reach a low level, and then the material that it is desired to give being poured into the receptacle. Besides the above method of treatment antistreptococcic serum is usually given.

I am convinced that this method of treatment is of the greatest value, and that the principles upon which it rests are entirely sound, and I have had a number of striking successes from its employment.

If a case of diffuse peritonitis has lasted for three or four days and any sign points to localization, do not operate at once. Wash out the stomach, place the patient in Fowler's position, give salt solution by the rectum, and withhold purgatives and food. The inflammation may subside or may localize into

a circumscribed suppuration. When in a patient with peritonitis the skin is blue, cold, and moist, the pulse very rapid and weak, the abdomen immensely distended, and the temperature subnormal death is almost certain, and the only chance is the conservative plan set forth above. We wait in hope that the infection may localize in an abscess. (See Buchanan, in "Med. Record," Jan. 28, 1911, and Stanton, in "New York Med. Jour.," Aug. 27, 1910.)

A *circumscribed suppuration* is treated as follows: Open the abscess. It will be possible, if the abscess is adherent to the abdominal wall, to open the abscess directly without opening the peritoneal cavity. If this is not possible, after opening the abdominal cavity pack gauze pads in such a manner about the abscess as to prevent the diffusion of pus when the abscess is evacuated. After opening the abscess the primary lesion is sought for and, if possible, removed. The surgeon should not, in most cases, tear away the abscess walls in an attempt to find the primary lesion, but should rather let it go undiscovered. Pack iodoform gauze against the intestines to reinforce the barrier of lymph and insert a tube. It is frequently advisable to leave the wound wide open and drain by means of gauze.

Every patient with peritonitis requires stimulants.

Tuberculous Peritonitis.—Tuberculosis of the peritoneum is not very common. In 1170 autopsies in the Boston City Hospital tubercle existed in some region in 197, and in 14 of these the peritoneum was involved.[1] Primary local peritoneal tuberculosis is occasionally, though rarely, seen by the surgeon. In a great majority of cases of peritoneal tuberculosis other distant structures are involved. In about half of the cases the lungs are involved. In 28 cases reported by Bottomly[2] not one was primary. In every one of these cases the diagnosis was confirmed by the microscope, by the tuberculin test, or by autopsy. In most supposed cases of primary peritoneal tuberculosis another focus of disease exists, but is not demonstrable by clinical methods or has been overlooked. The disease sometimes exists as a part of general tuberculosis. Tuberculous peritonitis may be only a part of acute miliary tuberculosis. Bacteria may be swallowed with tuberculous food or a tuberculous patient may swallow tuberculous sputum and intestinal tuberculosis may result, the peritoneum being involved later. Peritoneal infection may follow a tuberculous lesion of the intestine, the bacteria may enter by way of the Fallopian tube, the initial lesion may be tuberculous appendicitis or tuberculosis of the mesenteric glands. The germ may lodge from the blood or lymph. The lymphatic form most commonly attacks the cecum. Tuberculous peritonitis is four times as common among women as among men, and most frequently attacks those between twenty and forty years of age, but I have seen it in a child of five and in a colored man of sixty. There are two groups of cases—the common chronic form and the rarer acute condition. The acute form begins suddenly, and such cases, as pointed out by Lejars, resemble acute appendicitis. In either the acute or chronic condition it is frequently

Fig. 619.—Tube with orifices filled with chalk in order to show openings better.

[1] Bottomly, in "Amer. Med.," Feb. 15, 1902. [2] Ibid.

the case that pulmonary phthisis exists. Cirrhosis of the liver is sometimes found with tuberculous peritonitis. There are three forms of chronic tuberculous peritonitis: the *ascitic*, the *fibrinoplastic*, and the *caseous*,[1] although, as a matter of fact, these so-called forms are only stages of the same disease. Tuberculous infection may exist for some time without causing symptoms, acute symptoms may suddenly arise, or intestinal obstruction may take place. Symptoms sometimes develop quickly after pregnancy. In other cases the symptoms appear gradually and progressively grow more positive.

Symptoms of the Chronic Form.—Usually the disease begins insidiously. The digestion is found to be disturbed, there is nausea, the bowels are out of order, the abdomen is distended and tender, there is occasional colicky pain, and the patient is weak, loses flesh rapidly, and becomes very anemic. Frequently pain is the symptom which leads the patient to seek advice. The pain may be present from the very beginning, it may arise after malaise and gastro-intestinal disorder have existed for some time, but sooner or later it will develop.

In many cases there is ascites, but the amount of fluid is rarely very great. In some cases the fluid is serous, in some seropurulent, in some purulent, and in some bloody. Chylous fluid occasionally exists because of fatty degeneration of tuberculous masses. Ascites may be either unconfined or sacculated by adhesions. In some cases, and especially in early youth, there is little or no ascites, and the condition is characterized by the production of a quantity of adhesions which bind coils of intestine to each other, to the omentum, to the stomach, liver, and other viscera. In this condition, which develops very slowly, small cavities are formed between adhesions and the spaces contain fluid and bacteria. This is the most chronic form of the disease. In any case of tuberculous peritonitis the mesenteric glands may enlarge. There is usually moderate fever, but there may be episodes of high fever and protracted periods of subnormal temperature, or the temperature may be slightly elevated in the evening and subnormal in the morning. When the temperature becomes markedly elevated, pain, tenderness, and distention notably increase. In some cases there is a continued fever resembling typhoid. Tumor-like formations may be detected. These formations may consist of indurated omentum, encysted exudate, or enlarged mesenteric glands. If diarrhea exists for a long period there is probably tuberculous ulceration of the gut.

In every suspected case a bimanual examination should be made under ether, in order to discover if there are any matted masses of intestine (Thomson).

In many cases a careful examination will detect tuberculous disease of other regions of the body, particularly of the lungs. If tuberculous disease of the lungs or pleura is detected, if tuberculous glands exist or have been present, if a nodule not due to gonorrheal inflammation is palpable in an epididymis, or if there are indurations in the prostate, the probability of the presence of tuberculous peritonitis is much enhanced. In many cases there is dilatation of the superficial abdominal veins. In some cases tuberculous peritonitis undergoes spontaneous cure. In the majority of instances death ensues from the tuberculous peritonitis directly or from associated or secondary disease in other organs.

If an intraperitoneal tuberculous area caseates, a large cold abscess may form, and such an abscess may break into the intestine or may be opened externally, and may be responsible for the formation of a fecal fistula.

In a case of tuberculous peritonitis intestinal obstruction may occur, the gut getting caught by bands or adhesions, or becoming a rigid tube because of the formation of tubercles.

[1] Parker Syms, in "Medical Record," April 2, 1898.

Symptoms of the Acute Form.—This is sometimes mistaken for appendicitis. It comes on rather suddenly, but a carefully elicited history will usually show the previous existence of malaise, gastro-intestinal disturbance, loss of flesh, and anemia. The symptoms are not so strictly localized to the right iliac fossa as in appendicitis. There are abdominal distention, a certain amount of rigidity, nausea and vomiting, colicky pain which may be very severe, general abdominal tenderness, fever, and exhaustion. It may be possible to palpate masses like tumors, or to feel nodules in the prostate or epididymis, or to detect tuberculosis in some other part.

Treatment.—In some cases there is a tendency to spontaneous cure, and in them medical treatment is of great service. The patient should be placed under antituberculous conditions, nutritious food and tonics should be administered (see page 230), the abdomen should be counterirritated and massaged, and purgatives should be given frequently. Guaiacol applied daily to the abdomen is thought by some to be of service, but I doubt it. A mixture is made of 1 part of guaiacol and 5 parts of olive oil; 1 dram of this mixture is rubbed into the abdomen, and the part is covered with a piece of flannel held in place by means of a binder. If medical treatment is not soon productive of benefit, the advisability of operating must be considered. It is a curious fact, but one confirmed by ample evidence, that after simple abdominal section, without the introduction of germicides and without drainage, at least 30 per cent. of the cases recover from the disease in from six months to one year. Some surgeons doubt the curative effect of operation. For instance, the late Professor Fenger was strongly of the opinion that many patients recover after operation, but not as a result of operation. In his opinion they recover because they are strong, free from fever, and well nourished, and because the disease tends to spontaneous cure. He further believed that some die from operation because the traumatism lessens the already lowered tissue resistance. The majority of surgeons, however, believe that operation in many cases tends to cure. Ochsner, in a paper before the American Surgical Association in 1902, apparently proved that simple incision and evacuation of fluid tends to cure. It is uncertain how an operation tends to cure. It has been thought that the ascitic fluid is a culture-medium for bacilli, and when it is withdrawn the bacilli die, but opposed to this view is the fact that aspiration is rarely curative. It has been suggested that the operation brings numerous phagocytes to the peritoneum; that it stimulates vital resistance; that it leads to the exudation of antitoxic serum. The entrance of air seems to play a definite and important part in effecting a cure.

The ascitic cases are most frequently benefited by operation. In encysted fluid operation often cures.

In cases in which there are numerous adhesions operation is not so likely to produce a cure. Great care should be exercised in separating adhesions, because the bowel is apt to be torn and a fecal fistula may result. It may be necessary to separate adhesions or short-circuit a portion of gut to relieve obstruction. Drainage should not be used unless a cold abscess exists. Not only is drainage of no service, but it is dangerous; death is more apt to ensue in a drained case and a fecal fistula will arise in nearly one-fourth of the drained cases. If operation is performed for cold abscess, tube-drainage must be used for some days. In a woman with tuberculous peritonitis the abdomen should be opened in the midline, and if the Fallopian tubes are tuberculous they should be removed. In a man the incision should be made over the appendix, and if this is tuberculous it should be removed. In either sex it may be necessary to resect tuberculous intestine or perform anatomosis because of stricture. (In confirmation of these views see W. J. Mayo, in "Jour. Am. Med. Assoc.," April 15, 1905.) The Mayos have performed 26 radical tubal operations

on cases of tuberculous peritonitis and 25 recovered. Of these, 7 had previously been operated on from one to four times by simple laparotomy ("Jour. Am. Med. Assoc.," April 15, 1905). In a very advanced case, in a case with notably high temperature, or in a case with marked and advancing tuberculosis in another region, an operation should not be performed except to relieve obstruction or drain an abscess. If a patient does not die within a few months after an operation, he will probably recover, and in most cases operation secures at least temporary improvement (Bottomly, "Amer. Med.," Feb. 15, 1902). The mortality from operation is 1 or 2 per cent. (Fenger).

Pneumococcus Peritonitis.—This condition is an unusual one. It is most apt to arise during the progress or after the termination of pneumonia or some other pneumococcic lesion, but is sometimes primary—is far commoner in females than in males and in children than in adults. Out of 74 reported cases, 57 were children under five years of age (Dr. Max von Brunn, in "Beiträge zur klinischen Chirurgie," Bd. xxxix, Heft i). In primary cases the bacteria may enter by way of the blood-stream or, perhaps, in some cases through the bowel wall or Fallopian tube. In secondary cases infection may arise from an adjacent pneumococcic area (pleura) or be carried by the blood from a distant point (*pneumococcic septicemia*). The condition may appear in a sufferer from otitis media. The symptoms in children are sudden in onset. The first symptoms are general abdominal pain, usually a continuous pain with colicky exacerbations, tenderness, rigidity, vomiting, elevated temperature, distention, and diarrhea. In a few days the symptoms abate and some of them disappear, although pain, tenderness, and rigidity are apt to localize at some point, particularly about the umbilicus, and may remain for a number of weeks. In such a chronic case physical signs of a fluid collection are usually demonstrable. In the chronic stage, as Brunn points out, there is seldom severe tenderness and there may be no fever at all, and a septic temperature is very rarely observed. Pus may form, and if it does, it contains pneumococci. Adhesions practically always form. These adhesions glue the intestines together and often encompass pus. Rapid emaciation and progressive weakness are always noted. In adults the symptoms are irregular and less characteristic than in children (Brunn). The prognosis is excellent.

Treatment.—Incision and drainage.

A **subphrenic abscess** is a collection of pus beneath the diaphragm. It is a rare condition. The pus may occupy a part of the lesser peritoneal cavity; it may be extraperitoneal (when it is of **renal origin**); in some cases it is contained in the area between the diaphragm, cardiac end of the stomach, and liver or spleen. It is impossible to classify accurately these abscesses by anatomical position. George A. Ross ("Jour. Am. Med. Assoc.," August 12, 1911) classifies them as right, left, anterior, and posterior. Most are on the right side, but even an abscess due to appendicitis may be on the left side. It is an unusual thing for such an abscess to break into the general cavity of the peritoneum, but it may break into the pleural sac (Maydl).

Causes.—Perforation of a gastric ulcer, perforation of the gall-bladder or gall-ducts, ulceration of the duodenum, disease of the liver, spleen, pancreas, intestine, appendix, or kidney, hydatid disease, internal injury, metastasis, external injury, caries of rib, disease of the pleura, general peritonitis, or portal infection may be responsible for a subphrenic abscess. We have abandoned the notion that the infecting source must be in the upper abdomen. Appendicitis is the most common cause. Charles A. Elsberg[1] has collected 73 cases of subphrenic abscess after appendicitis. He points out that the condition may arise from direct extension or by way of the lymph-channels, and may be either intraperitoneal or extraperitoneal, although in the majority of cases it is

[1] "Annals of Surgery," Dec., 1901.

intraperitoneal. In rare cases extension is by way of the portal vein. Ross claims that in most cases due to appendicitis the infection extends by cellular tissue directly upward from the lower peritoneal fossæ. In some cases infection ascends between the colon and the parietal peritoneum (the *parietocolic sinus* of our French colleagues). In all but 7 of Elsberg's cases there was suppuration about the appendix. The pus was thick and foul in all the cases. In 15 per cent. of them gas was also present, and in 25 per cent. of these cases the diaphragm was perforated. In 3391 consecutive cases of appendicitis operated on in the German Hospital of Philadelphia there were 30 cases of subphrenic abscess (Ross, "Jour. Am. Med. Assoc.," Aug. 12, 1911). Subphrenic abscess may develop soon after an appendicitis, it may develop extraordinarily late. Ashhurst's case arose four years after appendicitis ("Trans. Phila. Acad. of Surg.," 1910), 1 of Ross's cases, one year after (Loc. cit.). If ascending retroperitoneal infection exists during appendicitis, removal of the appendix does not arrest it (Lance, in "Gaz. d. Hôp.," 1909, lxxxvii). In 2 cases on which I operated the abscess developed after cholecystitis; in 2 others, after suppurative appendicitis.

The **symptoms** usually come on suddenly, but may do so gradually. There may or may not be abdominal symptoms. A patient with subphrenic abscess usually complains of pain in the lower part of the chest on the right side. Usually there is high temperature and often delirium, but, as Jopson ("Annals of Surgery," July, 1910) says, the temperature may be only moderately elevated and the pulse may be nearly normal. The area of liver dulness is, in many cases, distinctly enlarged, and there is tenderness in the lower part of the right chest when pressure is made through one or through several intercostal spaces. Frequently friction sounds may be heard about the region of the dome of the liver. Breath sounds and vocal fremitus are lessened. The signs are usually best heard posterior, but may be lateral or anterior. There is cough and bulging of the chest wall. Jaundice is absent in uncomplicated cases. Sometimes the symptoms are obscure or indefinite, and not accompanied by particular pain. If the abscess happens to contain not only fluid but also a considerable amount of gas—and about one-half of such abscesses do contain gas—not only will there be no increase in the area of liver dulness, but the normal area of dulness may be diminished or obliterated. The presence of gas may be due to some connection with an organ which contains gas or to gas-forming bacteria. It is very common for a pleural effusion to be associated with a subphrenic abscess. A pleural effusion will be preceded by or accompanied by symptoms pointing to the lung or pleura; and it is to be remembered that the area of percussion-dulness found in the pleural effusion shifts its position whenever the position of the patient is changed, which is not true of the area of dulness found in subphrenic abscess. When the abscess breaks through the diaphragm the patient collapses, cough and other thoracic symptoms develop; and if the abscess breaks into a bronchus the patient will expectorate pus. In subphrenic abscess the diaphragm of the diseased side is paralyzed—a condition rarely met with in liver abscess. There are general symptoms of suppuration and a swelling in the subdiaphragmatic region following some recognized causative condition. The history of chills with recurrent fever and sweats is rather indicative of abscess of the liver; but in abscess of the liver there is usually pain in the shoulder-blade of the right side, and this is rarely encountered in subphrenic abscess. The x-rays show that the diaphragm is elevated on the side of the lesion. The proof of the diagnosis is not, however, obtained until an exploratory incision has been made and the purulent matter has been found. Empyema and subphrenic abscess resemble each other. In empyema the upper limit of the fluid is concave; in subphrenic abscess it is convex. In empyema the flow of pus through an aspirating-needle will be most marked

during expiration; in abscess, during inspiration. The same is true of the rush of gas. In empyema the needle does not oscillate; in abscess it does.[1] If an abscess contains gas, percussion elicits a tympanitic note over a part of the cavity, and there is an alteration in the area of tympany with an alteration in the position of the patient. An abscess of the liver almost never contains gas and decidedly changes the outlines of the organ.[2] Empyema may follow subphrenic abscess.

Treatment.—Incision and drainage. The incision is made in the lumbar region if the abscess points there. In some cases it is made through the abdominal wall (epigastric region, iliac region, hypochondrium). In other cases the chest wall is incised, the ninth or tenth rib is resected, and the abscess is opened below the pleura or the pleura is opened, the parietal and diaphragmatic layers are sutured together, if possible, and the diaphragm is incised. If appendicitis was the cause, be sure the appendicitis is well; and if it was not, open the appendix region and drain freely (Elsberg). If it is necessary to open the pleural sac, first try to stitch the parietal to the diaphragmatic layer of the pleura, or, if this is impossible, protect the cavity with iodoform gauze to prevent infection.

The Liver, Gall-bladder, and Bile-ducts

Rupture and Wounds of the Liver.—Rupture of the liver is due to very great force, and is usually accompanied by injury of other viscera. It may be produced by a blow, by a fall, or by the end of a broken rib. The superior surface or margin most often suffers. It is a very fatal accident. Out of 543 reported cases over one-half died of hemorrhage within twenty-four hours of the accident.[3] At least 80 per cent. will die if not operated upon. Wilms[4] collected 19 cases, and only 3 recovered after operation. Eisendrath[5] has collected 37 cases of suture of the liver for rupture and 22 of them recovered (59.5 per cent.). The first operation was performed by Willette in 1888. Out of Kraussine's 13 stab-wounds of the liver 7 died (Murphy, in "Practical Medicine Series," 1910, vol. ii). An attempt should certainly be made to save the patient by opening the abdomen and arresting hemorrhage, and in a suspected case an exploratory operation should be performed. A wound of the liver causes violent hemorrhage, which is usually rapidly fatal. Such a wound is apt to divide bile-ducts and allow bile to escape into the peritoneal cavity, and perhaps externally. Bile, if sterile, will do little harm to the peritoneum, but if it contains bacteria it will produce diffuse peritonitis. Even sterile bile is corrosive and may cause fibroplastic peritonitis. The symptoms of a rupture or wound of the liver are those of severe intra-abdominal hemorrhage, with collapse, accompanied by hepatic tenderness and respiratory embarrassment. Soon after the injury the abdomen is soft and flat, but it quickly becomes rigid and ultimately distended. The diagnosis becomes more probable when it is known that violence was applied to the hepatic region. Usually there is abdominal pain and often pain in the back. Sugar may appear in the urine. In a few cases after several days jaundice and skin itching have been noted. The area of liver dulness is usually increased. Patients do not always die from a serious traumatism of the liver. Some recover because operation has saved them. Some few recover without operation. This last fact is proved by reports of autopsies in which scars were found in the liver parenchyma (Nussbaum). The fatality which usually ensues on a liver injury may be due to hemorrhage or peritonitis. If a surgeon is called

[4] "Deut. med. Woch.," Nos. 34 and 35, 1901. [5] "Jour. Am. Med. Assoc.," Nov. 1, 1902.

to a patient suffering from wound of the liver, he must open the abdomen to arrest hemorrhage. If a penetrating wound is suspected, it may be desirable to enlarge the wound in the abdominal wall layer by layer, in order to determine that the liver is wounded. If the left lobe of the liver is wounded, or if it is uncertain which lobe is wounded, the incision should be median. If the right lobe is wounded, a curved incision is made along the line of the costal cartilages. In some cases these two incisions are joined.[1] The convex surface of the liver can be reached by Lannelongue's plan. Lannelongue resects the eighth, ninth, tenth, and eleventh costal cartilages and draws the ends of the ribs well out. It can also be reached by Langenbuch's plan, that is, by cutting the coronary ligament and the right lateral ligament. This allows the liver to be pulled well up into the wound in the belly wall. The site of the wound can be discovered if the hepatic vessels are grasped between the thumb and a finger (the finger in the foramen of Winslow and the thumb in front on the gastrohepatic omentum). This completely arrests hemorrhage, and the blood that has gathered may be sponged out and the wound sought for in a clear field. (See Pringle, of Glascow, in "Annals of Surgery," Oct., 1908.) When the wound in the liver is discovered and well exposed, deep sutures of catgut should be inserted in the liver and the capsule should be stitched with fine silk (Schlatter). If sutures fail to arrest hemorrhage, the organ should be sutured to the belly wall and the wound in the liver packed with iodoform gauze. It is useless to try packing without first attaching the liver to the abdominal wall, because pressure will simply push the liver away and will not arrest the bleeding. The cautery is a very useful means of arresting bleeding. It should be avoided if possible in a large wound, because, even if it arrests primary hemorrhage, secondary hemorrhage may occur. After arresting hemorrhage, wash out the abdomen with hot saline fluid, insert drainage, and close the abdominal wound. In a case of the author's in the Philadelphia Hospital the liver was wounded by the sharp ends of fractured ribs. The abdomen was opened, a wound was found, and bleeding was arrested by suturing the liver to the belly wall and packing the wound. The patient died, and necropsy showed another wound on the posterior portion of the organ. The possibility of such an occurrence should not be lost sight of.

Tumors and Cysts of the Liver.—The liver may be the seat of primary carcinoma, sarcoma, endothelioma, angioma, lymphangioma, adenoma, fibroma, myxoma, or lipoma. Many tumors called adenomata are really adenocarcinomata. Secondary malignant growths are far more common than primary neoplasms—in fact, 96 per cent. of liver tumors are secondary. Primary cancer of the liver is found once in every 2000 autopsies (Eggel). The commonest variety is nodular, but the diffuse form, known as *cancerous cirrhosis*, may occur. The nodular form is most often encountered in the right lobe, and it has been found in persons under the age of twenty. Metastases occur early. "There is always more or less coexisting cirrhosis of the liver" (Leonard Freeman, in "Trans. Am. Surg. Assoc.," 1904). It takes origin from the hepatic cells. The frequency of cancer of the liver secondary to cancer of the stomach has already been alluded to. The commonest primary tumor of the liver is cavernous hemangioma. It is especially apt to take origin in the atrophying liver of an elderly individual. Primary sarcoma may arise at any age and may even be congenital. The growth is rapid and emaciation is soon noted. The liver enlarges, often greatly. Jaundice and ascites are rather rare. The patient soon becomes very weak. There is always pain. As Knott ("Surg., Gynec., and Obstet.," Sept., 1908) points out, the condition may simulate abscess, and if it arises in a middle-aged or elderly person can scarcely be differentiated from carcinoma.

[1] See Schlatter, "Beiträge zur klinischen Chirurgie," Bd. xv, Heft ii, 1896.

Knott ("Surg., Gynec., and Obstet.," Sept., 1908) has collected 59 cases of primary sarcoma from literature, and adds 14 reported by personal communications and 1 of his own, 74 in all.

He shows that 28 cases have been operated upon. In 9 the operation was exploratory and no attempt was made to remove the growth. In 19 the growth was extirpated, with 10 recoveries and 9 deaths. One of these patients was well after nineteen months, 1 after two years, 1 after seven months. Operation is indicated for a circumscribed growth.

Among the cysts occurring in the liver are blood cysts, congenital cysts, bile cysts, and hydatid cysts. Terrier and Auvray in 1901 collected 52 operations for hepatic tumors.

Angiomata have been removed successfully by hepatectomy, a cautery-knife at a red heat being used to cut through the normal liver tissue around the base of the tumor, the large vessels being tied with catgut. Enucleation is not feasible because of excessive hemorrhage. If a tumor is pedunculated, the base may be encircled by an elastic ligature held in place by a steel needle, and five or six days later the tumor may be cut across by the cautery.[1] I assisted Prof. W. W. Keen in such an operation.

Carcinoma of the liver has been extirpated, but it is seldom that a growth is recognized early enough and is found to be sufficiently limited to justify such a procedure. Operation is proper only when there is a limited nodule of primary cancer. In 1901 Terrier and Auvray collected 9 operations for primary cancer. In most cases there has been rapid recurrence or secondary growth, but Schrader's case was well at the end of seven years and Leonard Freeman's at the end of sixteen months. (For operative methods, see Leonard Freeman, in "Trans. Am. Surg. Assoc.," 1904.) Hunbald has collected 96 cases of resection of the liver, with a mortality rate of 26 per cent. Probably the best method of arresting hemorrhage is the use of suture ligatures of doubled catgut passed by round, blunt needles, as advised by Mikulicz.

Hydatid cysts of the liver may be of small size and productive of no signs or symptoms; or may be of large size and productive of the signs of tumor. In the epigastrium the mass may be prominent and fluctuate. In cyst of the right lobe the dulness is found in the axillary line and the growth encroaches on the pleura. In a large cyst fluctuation and hydatid fremitus may exist. Hydatid fremitus is a vibration imparted to the palpating fingers of one hand when the fingers of the other hand knock upon the cyst. There may be no discomfort produced by even a large cyst, but, as a rule, the patient suffers from a dragging sensation in the epigastrium and pressure symptoms. Suppuration in the cyst produces the symptoms of abscess of the liver and septicemia. Rupture of the cyst produces shock and even death. Rupture may take place into the pleural sac, the lung, or the peritoneal cavity. If the shock is recovered from, inflammation arises, the area of which depends upon the structures damaged. The escape of even a small quantity of hydatid fluid into the peritoneal cavity produces urticaria (*hydatid toxemia*). Aspiration for diagnostic purposes is not advisable.

Treatment.—Exploratory incision may be necessary to confirm the diagnosis, and the operation is completed at this time. After exposing the cyst it is packed around with gauze and a trocar is introduced. If there is a considerable thickness of liver tissue over the cyst, incise the liver by the cautery knife. When the fluid is evacuated the sac is incised and is drawn partly through the wound in the abdominal wall, and is attached to the wound margins (*marsupialization*). The endocyst can then be removed by the hand or by irrigation. A large drainage-tube is introduced.

Syphilis of the liver is a very able actor and often impersonates with

[1] Russell S. Fowler, on "Tumors of the Liver," "Brooklyn Med. Jour.," Dec., 1900.

surprising accuracy various other diseases. It may be congenital or acquired. The congenital condition may cause cirrhosis, miliary gummata, spots of fibrosis, and occasionally large gummata. Sometimes the liver manifestations of congenital or hereditary syphilis may be postponed for years (ten, fifteen, or more) and then appear as ordinary tertiary lesions. Acquired syphilis may cause hepatic disease in the secondary and in the tertiary stage.

In secondary syphilis there may be temporary jaundice due, Rolleston thinks, to catarrh of the smaller bile-ducts within the liver. It is possible, according to Rolleston, for temporary pericellular cirrhosis to exist in the secondary stage.

The tertiary lesions are the most common and important. Among these lesions are gummata and scars. They are most common ten years or more after the primary sore. Tertiary syphilis may appear as irregular patches of inflammation in Glisson's capsule (a condition apt to eventuate in hepatic sclerosis)—as a large solitary gumma (only one-eighth of cases of gumma present a solitary lesion)—or as multiple and usually small gummata. Gummata are most usual upon the anterior surface of the right lobe. A gumma adjacent to the common duct or the hepatic duct causes jaundice. A large gumma is often mistaken for cancer of the liver, and it is a curious fact that in many cases of hepatic gummata we are unable to obtain any history of syphilis. Syphilis may be mistaken for ordinary cirrhosis, but in the latter disease the general nutrition is more impaired than in the former, and vomiting of blood, dilated cutaneous veins, ascites, and indigestion are far more apt to be present (Archibald MacLaren, in "Annals of Surgery," August, 1908). The victims of gumma are apt sooner or later to develop jaundice, colicky pain, moderate fever, and palpable enlargement of the liver. The spleen may enlarge. The fever may be continuous or may occur episodically. In some cases it continues for weeks. It may be intermittent, preceded by a chill and followed by a sweat. Such a fever may be due to Spirochæta cholangitis. It may be due to absorption of toxic material from a breaking-down gumma. The Wassermann reaction is a valuable aid to diagnosis. A gumma sometimes undergoes secondary infection and an abscess forms. A gumma may rupture into the pleural or peritoneal cavity or some viscus.

Treatment.—Mercury and iodid will cure most cases. If these drugs fail, it is proper to remove the tumor, if solitary, by resecting the involved area of the liver. MacLaren (Ibid.) collected 9 cases of resection for solitary gumma and added 1 of his own. There were 2 deaths in this series. MacLaren's 10 cases added to Keen's 12 ("Annals of Surgery," Sept., 1899) and Cumston's 15 (quoted by Rolleston in his work on "Diseases of the Liver") make 37 cases.

If an area is opened for exploration and a solitary gumma is discovered, the abdomen should be closed and specific treatment be tried before resorting to resection, that is, if specific treatment has not been tried before.

Abscess of the Liver.—An abscess of the liver may be produced by bacteria, especially staphylococci and streptococci. These organisms reach the liver by the general circulation or, what is more frequent, are taken up from the intestinal tract and reach the liver by the portal circulation, or pass to the liver by the lymphatics. Appendicitis with lymphatic infection may result in hepatic abscess. A subphrenic abscess may break into the liver and thus induce a liver abscess. Liver abscess may directly result from peritoneal infection. The fact that abscess of the liver is in hot countries frequently preceded by amebic dysentery led to the presumption that the Amœba coli produces the abscess, and in a large majority of cases of tropical abscess amebæ exist in the pus or at least on the abscess walls. Habitual intemperance and constant overeating predispose to abscess of the liver. The disease may follow traumatism, dysentery, diarrhea, cholangitis, suppuration of a hydatid cyst,

gall-stones, typhoid fever, appendicitis, and a chill to the surface of the body.[1] Abscess of the liver may be metastatic, and such abscesses are multiple. It may be caused by foreign bodies and parasites. A tropical abscess is an abscess of the liver in an inhabitant of a hot country.

There are three forms of abscess of the liver: traumatic, pyemic, and tropical.

Traumatic abscess may result from a wound of the liver or may follow a contusion without a break of the skin. In the latter case bacteria from the blood are arrested in the injured liver tissue. Such an abscess is usually solitary. Streptococci, staphylococci, or colon bacilli may be found. Traumatic abscesses are more common in children than in adults, are situated superficially, and the symptoms are usually acute. Recovery is usually rapid and permanent after incision unless the causal injury brings danger or fatality.

Pyemic Abscess.—Multiple abscesses exist, but they may fuse into one. It is frequently due to suppurative inflammation of radicles of the portal vein, infected emboli forming and reaching the liver; it may follow ulceration of the intestine, hemorrhoids, or appendicitis.

Occasionally abscess may arise from the extension of an infective process, such as pylephlebitis. It may arise from cholecystitis or cholelithiasis with obstruction. In these latter cases both the Bacillus typhosis and the pneumobacillus of Friedländer have been found as the direct bacterial agent. Colon bacilli are a common cause. Abscess of the liver following appendicitis may be due to portal infection (*portal pyemia*) or to lymphatic infection. It is usually multiple, but in a case of mine in the Jefferson Hospital it was solitary, several cavities having probably joined to form one. Echinococcus cyst of the liver may suppurate and form abscess. I operated unsuccessfully on 1 such case which was brought to me by Dr. Hultsizer. The round-worm, the liver fluke, and the Balantidium coli sometimes cause abscess, and, finally, it has been observed in measles, epidemic influenza, and perforating ulcer of the stomach.[2]

Tropical abscess of the liver is rare in temperate climates, but is extremely common in the tropics. Its usual antecedent in either climate is dysentery. The reason for the great frequency of the disease in tropical regions is that the chief causative agent, the Amœba coli, is found widely distributed in hot countries; and that passive congestion of the liver is a common condition among the white inhabitants of tropical regions. It has been pointed out that tropical abscess is particularly common among white persons who abuse alcohol, the condition of passive congestion of the liver making that organ a nutritious soil for a fruitful infection. Predisposing factors are protracted malaria and chilling of the surface of the body.

Major Charles F. Kieffer, U. S. A.,[3] in a lecture on tropical abscess of the liver, stated that in his own experience he found, in a series of 33 abscess cases in soldiers, that dysentery was present in every case; and that in a second series of 25 cases in natives and civilians he elicited a history of dysentery in 22 cases. Some observers—notably McLeod—state that dysentery is the antecedent factor in 97.5 per cent. of cases. Kieffer points out that in all the figures allowance must be made for a number of latent dysenteries, as well as for cases in which no effort was made to elicit a history of dysentery one or two years previously. It is also to be remembered that a case of amebic infection of the colon may have been so mild in the beginning as to have caused but a transient diarrhea, which the patient may have forgotten. Amebæ occasionally exist in the colon without producing any dysenteric evidences. From 20 to

[1] G. B. Johnston, "Annals of Surgery," October, 1897.
[2] Major Charles F. Kieffer, U. S. A., in "Phila. Med. Jour.," Feb. 21, 1903.
[3] Ibid.

25 per cent. of severe amebic dysenteries lead to the formation of abscess of the liver, and that at least 85 per cent. of all tropical abscesses are due to infection with the Amœba coli. Occasionally, an abscess begins very soon after the dysentery; but, as a rule, it does not form for some time afterward —weeks, months, a year, or even two years.

When an abscess of this sort forms in the liver that organ becomes enlarged and congested, and an area or areas of necrosis exist in it. But one abscess may be present; there may be an abscess with satellite abscesses about it; several abscesses may coalesce, making a very large cavity; or genuine multiple abscesses may exist. In about 70 per cent. of cases, however, the tropical abscess is solitary.

The right lobe of the liver is the region most frequently involved. The abscess is found in the right lobe in at least 90 per cent. of cases, and it is more often toward the convexity of the liver than toward the base.

An abscess of the liver contains characteristic and peculiar material; it is different from the pus found in other abscesses, and, in fact, is not pus, but is necrotic liver substance. Liver abscesses due to pyogenic organisms contain true pus; a tropical abscess, free from pyogenic infection, does not. Ordinary pus contains hordes of leukocytes, but the fluid of a tropical abscess contains very few. Riesman is of the opinion that the reason there are so few leukocytes is that the abscess contains a substance that, by chemotaxis, repels leukocytes. The matter is of a reddish-brown color, is thick, and frequently contains some blood. Occasionally it is offensive in odor. Microscopic examination shows it to contain portions of necrotic liver tissue, some liver-cells that are not destroyed, elastic tissue, blood, pus-cells, and amebæ. On bacterial examination it may be found that the fluid is infected, containing staphylococci, streptococci, or pyogenic bacteria. In about 20 per cent. of the cases the matter contains neither bacteria nor the Amœba coli. In over 60 per cent. of the cases the matter of a recently opened abscess is free from bacteria. In cases in which the fluid is sterile it is possible that bacteria were originally present, but have died. The reason for the death of micro-organisms in this matter is in great doubt, because, as Riesman points out, bile cannot kill them and organisms may be grown in the fluid. In the large majority of cases amebæ are readily demonstrable in the matter; but that in some few cases it is necessary to rub a piece of gauze on an abscess wall in order to obtain amebæ, and that in others they can be demonstrated only after the abscess has been discharging for some days. The causative rôle of the amebæ has been doubted by some observers, but most surgeons who have had experience in the tropics believe it to be a fact.

The *symptoms* may be very definite and positive; they are frequently misleading and obscure; and in some cases nothing whatever directs the surgeon's attention to the liver until the patient passes a huge quantity of puriform fluid at stool or coughs up an enormous amount of the characteristic material. If rupture takes place, death usually ensues. As a rule, the symptoms of a tropical abscess are positive and marked.

Kieffer sums up the chief symptoms under four heads: *fever*, *sepsis*, *enlargement of the liver*, and *pain*. In about three-fourths of the patients fever and sweats are definitely present; in about one-fourth they are absent or are very trivial. The type of fever met with is what has been previously spoken of as hectic. Usually there is an evening rise, preceded by a chilly sensation or by a chill; and as the temperature begins to fall, toward morning, there is a profuse sweat. It is seldom that there is any violent chill, though there are frequently slight ones. The sweats are extremely exhausting. They may occur either during the night or in the daytime, according to the time in which the patient sleeps. Kieffer says that they should not be called

night-sweats, but rather *sleeping sweats*. In very chronic cases there may be no pyrexia. As a rule, the temperature resembles that of malaria, but it is not controlled by quinin and the blood is free from malarial parasites. Sometimes the temperature suggests typhoid, with the exception that from time to time there are episodes of subnormal temperature. The patient loses flesh and strength, the appetite fails completely, and the skin becomes pasty or dirty yellow.

The entire liver is usually enlarged, and the enlargement may be detected by percussion, and in some cases a hard, smooth area can be palpated. Sometimes the liver reaches as high as the third rib anteriorly, or to the spine of the scapula behind, and it may extend downward to the anterior superior spine of the ilium. It is rarely, however, that the enlargement takes place in a downward direction; it is usually upward. In many cases the right side of the chest appears to be rather full, and sometimes there is actual obliteration of several intercostal spaces. If an abscess becomes adherent to the surface, there may be skin edema and dusky discoloration. In rare instances, if a very large abscess comes near the surface, fluctuation may be obtained. By auscultation it is frequently possible to obtain friction sounds in the region of the diaphragm and the superior surface of the liver.

The liver becomes tender. This tenderness may be developed particularly by pressure upon the lower edge of the organ, and sometimes by pressure through the intercostal spaces. There is not always pain, but, as a rule, there is. The pain may be dull and heavy, but as the abscess nears the surface of the organ the pain becomes sharp and lancinating. The pain is persistent and is not strictly localized, but radiates to the back, the right shoulder-blade, and the point of the shoulder. Pain is increased by pressure, coughing, sudden or violent movement, and is sometimes felt in the esophagus when food is swallowed. When the upper surface of the liver is involved the patient breathes as if he had pleurisy; and pleurisy frequently does develop, with marked effusion.

Paralysis of the diaphragm rarely occurs in abscess of the liver, and the respiration is not much affected unless the diaphragm of that side and the pleura become involved, though the patient frequently has a dry cough. A severe cough suggests that the abscess is on the convex surface of the organ. Such a cough is aggravated by recumbency. Kieffer points out that the patient lies on his right side, and almost on the right front aspect, the shoulder being drawn down and the right knee drawn up to relieve the tension of the abdominal muscles. In about one-fourth of the cases of tropical abscess of the liver jaundice occurs. It is most apt to occur when the abscess is on the inferior surface. Jaundice does not occur unless the common or hepatic ducts are compressed or cholangitis exists. The leukocyte count is of no particular help in the diagnosis, as there may or may not be leukocytosis. The urine is usually scanty. Diarrhea is a common accompaniment, but constipation may exist, and nausea and vomiting are by no means unusual.

Diagnosis.—With an antecedent history of dysentery the diagnosis is easy. Without such a history, it is always difficult and may be impossible. In the tropics exploratory aspiration is freely used, but exploratory incision, if necessary, with subsequent exploratory aspiration of the liver after the organ is exposed, would seem to be safer and more certain.

Symptoms of Traumatic Abscess.—Similar to those of tropical abscess.

Symptoms of Pyemic Abscess.—The liver is enlarged and tender, there is slight jaundice, and the general symptoms of pyemia are present.

Treatment of Tropical Abscess.—If in doubt as to the diagnosis, make an exploratory incision, exposing enough liver surface to permit of exploration by finger and needle. If pus is not found, pack the wound with gauze to keep it

open, and when adhesions form explore again. The operation for abscess is incision and drainage. The *abdominal route* is used when the liver bulges front or when it extends well below the costal margin (McGill, in "Surg., Gynec., and Obstet., Nov., 1911). If the abscess is adherent to the parietal peritoneum and is not covered by liver substance open it at once. If it is not adherent, or is covered by a considerable layer of liver substance, make a ring of gauze about the periphery of the abscess cavity. The abscess may be opened at once within the ring, the gauze being a coffer-dam to protect the peritoneal cavity. It is safer to catch the gauze to the parietal peritoneum with two or three fine catgut sutures and wait for forty-eight hours before opening. This is an easier plan and just as safe as attempting to stitch the liver to the visceral peritoneum or to the parietal peritoneum. The operation consists in evacuating the pus by a trocar and cannula, incising the abscess, stitching its edges to the edges of the abdominal wound, irrigating, and inserting a drainage-tube. If the abscess is covered by a layer of liver tissue, after locating it by an aspirating cannula open into it by a cautery knife and arrest hemorrhage by packing. When the parietal and visceral layers of peritoneum are adherent, packing will arrest bleeding; if they are not adherent, packing will only push away the movable liver (John O'Connor). The *transpleural route* gives the best access to the right lobe, which is far and away the commonest region for liver abscess. The operation devised by McGill (Ibid.) may be at first exploratory; it avoids pneumothorax and empyema. It is performed as follows:

The ninth and tenth ribs are exposed by a curvilinear incision; the flap (which does not include the fascia of the muscles) is raised; 4 inches of the tenth rib are resected; the gutter left by the removal of the bone is closed by catgut suture. This gutter can be pushed against the diaphragm by two fingers of an assistant, and while the pressure is being made an incision is carried along near to the upper border of the eleventh rib. The incision goes directly into the peritoneal cavity through the layers of chest wall and through the diaphragm, but, as the parietal pleura is being pressed directly against the diaphragmatic pleura, pneumothorax does not occur. The edges of the chest wall and diaphragm are clamped together and sutured, the pleural cavity being thus closed. The liver is exposed and may be needled for exploration, or an abscess can be drained at once or after causing adhesions by gauze, as previously described.

Rogers and Wilson ("Brit. Med. Jour.," June 16, 1906) advocate aspiration and examination of the pus. If amebæ only are present, they inject a solution of quinin, a material quickly fatal to amebæ. The dose is 30 gr. of bihydrochlorate of quinin in a sterile solution. If the abscess holds less than 10 oz. of matter the quinin is given in 2 oz. of fluid; if it holds more, in 4 oz. of fluid. The authors report 2 cases cured by this method.

Treatment of Traumatic Abscess.—Same as for tropical abscess.

Treatment of Pyemic Abscess.—Surgery is usually futile, because multiple abscesses exist, but an operation should be performed in the hope that it may do good. In a case in the Jefferson Hospital in which abscess of the liver followed appendicitis the patient recovered after operation.

Hepatoptosis (Floating or Movable Liver).—Hepatoptosis may be congenital, but is usually acquired. In a congenital case certain ligamentous supports of the liver are absent. In the following discussion the acquired form is the variety referred to. This condition is rare. Ninety-eight cases have been reported.[1] It is a form of splanchnoptosis and is due to relaxation of the abdominal wall and stretching of the supports of the liver. It may occur alone, but it is more often a part of a general abdominal relaxation or of Glénard's disease, and often a kidney is movable, or uterine displacement or hernia may exist. The liver may descend into the lower abdomen, may

[1] J. H. Carstens, "Jour. Am. Med. Assoc.," May 17, 1902.

be upside down (Demarquay), may rotate on its transverse axis (Griffiths), the anterior surface may become posterior, or the organ may lie with the superior surface in the right flank and the inferior surface looking to the left,[1] may be movable, or may be anchored by adhesions. It is most common in women. The liver is supported by ligaments and also by the inferior vena cava (which vessel is firmly adherent to the central tendon of the diaphragm—Faure), by the abdominal wall, and by the intestines (Glénard). The cause of the condition is in dispute. It can result from relaxation of the belly wall, relaxation of the ligaments, enteroptosis, great enlargement of the gall-bladder, increase in weight of the liver, atrophy of the connective tissue between the liver and diaphragm, pregnancy, the growth of a liver tumor, and tight lacing. Either a strain, cough, or the dragging of an adherent tumor may be the exciting cause.

Signs and Symptoms.—An abdominal mass may appear suddenly after a blow or a strain, and if it does appear suddenly there is always pain in the hepatic region, nausea, and weakness. When the condition comes on gradually there may be no symptoms for a long time, but, as a rule, there is some pain in the loin which becomes worse after exercise or effort. In rare cases jaundice appears, and occasionally there is ascites. The abdominal walls are relaxed and the signs of splanchnoptosis are manifest. When the patient stands, a transverse furrow of skin covers the lower part of the umbilicus (*Glénard's sign*). In most cases the shape, the movability, and the absence of the liver from its proper position are diagnostic. Even when the organ is dislocated and attached in its new situation, it is missed from its proper abode, and palpation outlines the characteristic shape. When the patient lies down the liver usually returns to place, and in most cases it can be restored by manipulation. In some cases, however, it will not return to place and cannot be restored by manipulation. A floating liver causes a recognizable enlargement in the right loin, and the mass usually moves on respiration.

Treatment.—In many cases the patient can be kept comfortable by wearing an abdominal support, and can be distinctly improved by the use of massage and electricity to the abdominal wall, the administration of tonics, and a course of forced feeding. If these means fail and the patient suffers, an operation should be performed. The operation of ***hepatopexy*** was devised by Marchant. He opens the abdomen and tries to restore the liver to its proper position. This can usually be accomplished. In some cases it can be done after adhesions have been separated. In other cases it can be only partially accomplished. After the liver has been restored, he sutures it by means of catgut or silk to the abdominal wall or costal cartilages, the stitches passing through the hepatic parenchyma and being carried through the liver by means of a round and blunt needle. The sutures attaching the liver to the belly wall are tied beneath the skin. Marchant scarified the dome of the liver in order to favor adhesions. Ramsay rubs the upper surface of the liver with gauze to promote adhesion and transfixes the round ligament with a suture which is carried around the cartilage of the seventh rib. In a severe case Depage advises us to associate hepatopexy with an excision of a portion of the abdominal wall to amend relaxation (*laparectomy*). If, in operating on a floating liver, it is found impossible to get the liver back into its normal position, fix it with sutures as near its proper abode as is possible. Terrier and Auvray report 11 cases of hepatopexy. One case died and 8 completely recovered.

Floating Hepatic Lobe (Partial Hepatoptosis).—This condition is not uncommon in cases of chronic disease of the gall-bladder and is most

[1] Terrier and Auvray, "Rev. de Chir.," Aug. and Sept., 1897.

often met in cholelithiasis. It is believed that it can be caused by tight lacing. A tongue-like projection forms upon the right lobe of the liver (*linguiform lobe, lacing lobe*). It can be palpated below the costal margin and the dulness of the mass on percussion is continuous with liver dulness. A linguiform lobe can usually be moved laterally and forward and backward; it is always tender and is sometimes the seat of pain.

Treatment.—When this condition is associated with gall-bladder trouble, it may disappear, or at least cease to cause pain, when the gall-bladder is drained by cholecystostomy. Langenbuch has successfully removed a linguiform lobe.

Cholecystitis (Inflammation of the Gall-bladder).—Inflammation of the gall-bladder is produced by infection. Healthy bile is sterile; and when bacteria are found in the bile, the condition is one of disease. Micro-organisms may find entrance into the gall-bladder by way of the blood, the bile becoming infected secondarily to the infection of the gall-bladder; or they may enter by way of the ducts, from the intestine. The conditions that follow infection depend upon the characteristic tendency and the virulence of the infecting germs. A trivial infection produces mucous catarrh; a more active infection causes suppuration, and possibly ulceration; a very violent infection leads to gangrene.

In most cases of cholecystitis an inflammatory swelling blocks the cystic duct, and obstructs it so that the bile stagnates in the gall-bladder. In many cases this condition lasts but a short time; and when the obstruction is relieved, bile flows down the duct. Occasionally, as a secondary consequence, cholangitis, or infection of the hepatic duct, follows.[1] Occasionally, also, the obstruction of the duct is not relieved, and a quantity of clear, thin mucus gathers in the gall-bladder and overdistends it—the condition known as *hydrops*. The gall-bladder may likewise become distended with pus, constituting an *empyema* of the gall-bladder; and any overdistended gall-bladder may rupture. A gall-bladder may distend to a most enormous size. Terrier reported a case of distended gall-bladder in which the viscus contained 42 pints of fluid. F. W. Collinson ("Brit. Med. Jour.," May 29, 1909) reports the case of a woman thirty-one years of age who was tapped twice before operation and at each tapping 25 pints of fluid were withdrawn. At the operation 22 pints were obtained. Collinson's case arose from blocking of the common duct as a result of traumatism, followed by kinking of the cystic duct and subequent opening of the common duct. In cases of very chronic inflammation of the gall-bladder this structure becomes fibrous and contracts, until it may become no larger than the thumb, in which condition it may contain a very small amount of thickened bile. In some inflammatory conditions due to infection the bile mixes with thickened mucus, and micro-organisms form the nucleus upon which bile salts are deposited to form gallstones. As the same author points out, cholelithiasis may result from cholecystitis, and may cause chronic cholecystitis, because the stones existing in a gall-bladder are sources of irritation.

Bacteriology of Cholecystitis.—It has been proved by abundant observation that the fact that bile contains micro-organisms is no evidence that the gall-bladder is inflamed; but that when the gall-bladder is inflamed micro-organisms are demonstrable in the bile. We know that the bile is infected during the course of typhoid fever, and that it is frequently so in pneumonia. The colon bacillus is not unusually demonstrable in cholecystitis; and pus cocci, either in pure culture or mixed with other germs, constitute the most common cause of the inflammation. It is probable that bacteria entering the gall-bladder and not being particularly virulent produce

[1] Joseph McFarland, "Proceedings of the Phila. County Med. Soc.," Sept., 1902.

no immediate harm when the flow of bile is unobstructed, though even then they may become the nuclei of gall-stones; but if the bacteria are very virulent they may actually lead to obstruction. Stagnation of the bile favors infection, and infection may be the cause of stagnation. Each influence reacts upon the other and aggravates the other, and it seems more than possible that infection of the gall-bladder is to be regarded as serious only when there is obstruction to the outflow of bile. The same variety of germ may, under some circumstances, cause catarrhal, and under others suppurative, inflammation; that is, when bacteria are virulent and tissue resistance is slight, suppurative cholecystitis results; but when the bacteria are not virulent and the tissue resistance is powerful, the gall-bladder is not infected at all, or only catarrhal inflammation is produced. I operated upon a case of acute suppurative inflammation of the gall-bladder three weeks after the termination of an attack of typhoid fever. The culture taken from the gall-bladder showed an unidentified bacillus, which was not the colon bacillus or the paracolon bacillus, and which was not identical with the typhoid bacillus or the paratyphoid bacillus. It strongly resembled the typhoid bacillus, but possessed no agglutinative power (the author, in "New York Med. Jour.," April 8, 1905).

A patient in the medical ward of the Jefferson Hospital was supposed to be developing a typhoid relapse, but no fresh spots appeared, and there were pain, tenderness, and rigidity in the region of the gall-bladder. I operated and found the gall-bladder full, dark colored, and surrounded by numerous recent adhesions. It could be emptied slowly by pressure. There was no pus. It was drained and the symptoms promptly passed away and the man recovered. The culture was reported sterile. I cannot understand this finding, as inflammation undoubtedly existed. It may have been peritonitis rather than cholecystitis, but from what cause is unknown. No culture was taken from the peritoneal cavity. The finding of sterile bile at the end of an attack of undoubted typhoid is of interest.

Catarrhal Inflammation of the Gall-bladder and Bile-ducts.—This condition is known as catarrhal jaundice, acute or chronic, and is usually treated by the physician; but, as A. W. Mayo Robson points out, chronic catarrhal jaundice sometimes resembles the jaundice of organic disease, and is occasionally associated with gall-stones, malignant disease, or hydatid cyst. The same authority asserts his belief that chronic catarrhal jaundice usually results from interstitial pancreatitis and duct obstruction. This condition usually comes on without pain. If there is pain it means some complication. Robson ("Surg., Gynec., and Obstet.," Jan., 1908) names among such complications catarrhal cholecystitis, cholangitis, gall-stone, and duodenal ulcer. The jaundice is striking. There is loss of flesh and anemia, and the liver is enlarged and smooth. Robson tells us that if the gall-bladder is not shrunken from stone, and if there is great duct obstruction, the bladder will be distended. Chills and fever mean infective cholangitis. In a case of chronic catarrhal jaundice in which medical treatment fails, surgical treatment must be considered (cholecystostomy or cholecystenterostomy).

Catarrhal Cholecystitis.—This is a catarrhal inflammation of the gall-bladder usually without jaundice. The gall-bladder becomes thick and its mucous membrane is frequently plicated. Very thick mucus is secreted, which gathers in masses, and the descent of these plugs causes pain that is sometimes indistinguishable from that produced by the passage of a gall-stone. Such a plug may temporarily block the cystic duct. In catarrhal cholecystitis the gall-bladder is frequently distended, but rarely admits of palpation; and there are no adhesions to surrounding structures, unless gall-stones have been present (Robson). Catarrhal cholecystitis may lead to the

formation of gall-stones; may result from the presence of gall-stones; or may be found in cases in which gall-stones have been present, but have passed. In 1 case upon which I operated the gall-bladder was enlarged, thick, and without adhesions; the mucous membrane was convoluted; and the viscus was filled with thick, tenacious mucus, and the mucous membrane of the gall-bladder contained many minute concretions. In this case stone formation was probably beginning to follow upon catarrhal cholecystitis. In another case a woman had presented violent symptoms of gall-stone colic, and stones had been recovered from the feces; but on opening the gall-bladder no stones were found—only a condition of catarrhal cholecystitis. Jaundice is rare in catarrhal cholecystitis unless gall-stones are present; it is, however, occasionally noted. Even if jaundice does occur, it is slight and lasts but a short time. The painful attacks that occur during catarrhal cholecystitis are similar to gall-stone attacks; but the pain is less violent and of briefer duration, and jaundice is not apt to follow the passage of a plug of mucus and is apt to follow the passage of a gall-stone. Further, as Robson has shown, in catarrhal cholecystitis with gall-stones there may be tenderness, but there is rarely tenderness in uncomplicated catarrhal cholecystitis.

Treatment.—The majority of the cases recover under medical treatment. If a case fails to recover under medical treatment, one cannot be sure whether there are gall-stones or not; but an operation is indicated in either case. Cholecystostomy should be performed and the gall-bladder should be drained for a week or two. This treatment will almost always produce cure.

Croupous Inflammation of the Gall-bladder and the Bile-ducts.—This is an extremely rare condition, due to the formation of a thick membrane in the bile-passages, which causes obstruction to the flow of bile and spasmodic contraction of the gall-bladder. The symptoms are identical with those of gall-stones. Robson points out that a study of the evacuations may discover membranous intestinal casts; and that, as membranous enteritis is usually associated with croupous inflammation of the gall-bladder and bile-ducts, a diagnosis may thus be reached. The same author says that one may, in some cases, even find a cast of the gall-bladder in the evacuations.

Treatment.—If medical treatment fails, cholecystostomy should be performed and drainage should be employed for a considerable time.

Suppurative Inflammation of the Gall-bladder and Bile-ducts.—Adopting the classification of Mr. Robson, we divide these suppurative inflammations into simple suppurative cholecystitis, suppurative and infective cholangitis, phlegmonous cholecystitis and gangrene of the gall-bladder, ulceration of the gall-bladder and bile-ducts, pericystic abscess with adhesions, and certain consequences of these conditions, such as stricture of the gall-bladder and bile-ducts, perforation of the gall-bladder and bile-ducts, and fistula of the gall-bladder and bile-ducts. Suppurative inflammations of the gall-bladder and the bile-passages are due to infection by virulent organisms or to infection when the tissue resistance is at a low ebb.

One fact must strike the physician in regard to these cases; that is, that there is a strong similarity between the possible changes of acute cholecystitis and the possible changes of acute appendicitis. In the gall-bladder, as in the appendix, there may be a catarrhal inflammation, which may not advance beyond this stage, or which may advance into a more dangerous form; in each structure blocking and stagnation favor infection and aggravate existing infection; in each there may be suppuration, ulceration, gangrene, and perforation; in each there may be grave complications and disastrous and fatal consequences; and in each prompt surgical operation is usually life-saving.[1]

[1] The author, "Proceedings of Phila. County Med. Soc.," Sept., 1902.

Simple Suppurative Cholecystitis.—This condition is also spoken of as *suppurative catarrh* of the gall-bladder or *simple empyema* of the gall-bladder. It is a rare condition unless gall-stones exist or unless some infectious disease—especially typhoid fever—has antedated the condition. I operated for this condition upon a boy eleven years of age three weeks after the termination of an attack of typhoid fever. It is not only typhoid fever that may be causative, but also other continued fevers. No matter, however, what organism is primarily responsible—be it colon bacillus, typhoid bacillus, or what not—a mixed infection with pyogenic cocci usually takes place. Pyogenic cocci may alone be causative. In simple suppurative catarrh of the gall-bladder, when the duct becomes blocked, the condition known as simple empyema exists; and when hydrops of the gall-bladder undergoes suppuration simple empyema is produced.

In an ordinary case of suppurative catarrh following gall-stones one usually obtains the history of a number of attacks of biliary colic, the pain finally having become persistent instead of intermittent, and a definite swelling being palpable in the gall-bladder region. This swelling is tender on pressure. There are usually constitutional symptoms, sometimes trivial,

Fig. 620.—Gall-bladder filled with calculi. Removed by cholecystectomy.

often severe. The trivial symptoms are a somewhat rapid pulse, sweating at night, and some elevation of temperature. The more severe symptoms are chills, a remittent fever, and profuse sweats. The development of severe symptoms indicates that a dangerous change is taking place—usually ulceration of the gall-bladder, occasionally phlegmonous cholecystitis. Distinct jaundice is rare in simple empyema, though the patient usually shows loss of flesh, has a very poor appetite, and suffers considerably from thirst.

To distinguish an enlarged gall-bladder from any other intra-abdominal mass is sometimes difficult. Very large gall-bladders, such as have been placed on record by Collinson, Terrier, Lawson Tait, Gersuny, and others, may be mistaken for ovarian cysts. Alban Doran discusses such cases in the "Brit. Med. Jour.," June 17, 1905. An enlarged gall-bladder moves on respiration unless the mass becomes adherent to the abdominal wall, when it will cease to do so. An enlarged gall-bladder is sometimes mistaken for a movable kidney, and the diagnosis between these conditions is discussed in the section on Movable Kidney (see page 1277).

Treatment.—The gall-bladder should be opened and drained by the operation of cholecystostomy. After it has been exposed, it is packed about

with gauze pads, a considerable portion of the contents is removed through an aspirator, the gall-bladder is opened and irrigated with salt solution, and a search is made for any cause of obstruction in the cystic duct. This cause should be removed, and any gall-stones that are present should, of course, be taken away. The walls of the gall-bladder will frequently be found diseased and softened, so that it is impossible to apply stitches. In some cases, if the gall-bladder is badly diseased, it should be removed, but in others incision with drainage is sufficient.

Recurrent Simple Empyema of the Gall-bladder.—In this condition a person develops, at intervals, pain, fever, tenderness, and enlargement of the gall-bladder. Then the symptoms clear up and he is well for a time, but they again become manifest; and at last they may become persistent or violent because of the development of some complication. In these cases it is impossible, after a number of attacks, to palpate any enlargement of the gall-bladder; and when an operation is performed the gall-bladder is found shrunken, thickened, and deeply placed, containing some purulent matter, and strongly fixed to the surrounding structures by adhesions.

Treatment.—Cholecystectomy is usually the proper operation.

Acute Phlegmonous Cholecystitis.—Some call this condition *acute empyema.* It is extremely dangerous, and is apt to cause gangrene of the gall-bladder. It is due to infection by extremely virulent organisms. It may, even without perforation, produce rapid peritonitis and death. As a rule, in advanced cases perforation takes place. It is generally associated with the presence of calculi, but sometimes none are found; and the condition sometimes develops during typhoid fever or septicemia.

This disease begins with sudden and violent pain in the gall-bladder region. This pain usually radiates toward the right shoulder-blade, and soon becomes general throughout the abdomen. There are tenderness in and great rigidity over the gall-bladder region, thoracic respiration, exhausting vomiting, septic fever, and in some cases jaundice. If an operation is not performed promptly general peritonitis quickly takes the patient's life. In one case upon which I operated there were intense jaundice, tenderness, violent pain, abdominal rigidity and distention, chills, and septic fever; and when the abdomen was opened it was found that a portion of the gall-bladder was gangrenous and that a calculus projected through the gangrenous opening.

It is this form of cholecystitis that is especially likely to be mistaken for appendicitis. In making a diagnosis the situation of the primary pain is of importance, and likewise the situation of the tenderness; but a displaced gall-bladder or an abnormally situated appendix may lead to error. Acute phlegmonous cholecystitis is usually accompanied by absolute constipation, and the sudden onset and the abdominal distention may lead to the disease being mistaken for intestinal obstruction. It may also be confused with perforating ulcer of the stomach or of the duodenum.

Treatment.—In any case of doubt an exploratory incision should be made. If phlegmonous cholecystitis is found to exist, the gall-bladder should, whenever possible, be extirpated; but if the desperate condition of the patient forbids this operation, the bladder should be incised, surrounded with iodoform gauze, and a drainage-tube should be carried well up toward the cystic duct.

Pericystic abscess may follow infection of the gall-bladder. It is especially common in the condition known as recurrent simple empyema. When a pericystic abscess exists there are great localized abdominal tenderness and rigidity and the temperature is usually indicative of suppuration. The causative micro-organisms may have passed through a diseased gall-bladder wall, rupture not existing; or the abscess may follow ulceration or perforation of the gall-bladder wall.

Treatment.—Operation should invariably be performed, though it is frequently difficult. After a pericystic abscess has been drained it will be found necessary in some cases to extirpate the gall-bladder, whereas in others incision of the gall-bladder and drainage will prove sufficient.

Infective Cholangitis.—Cholangitis is usually inaugurated by infected bile, but when it arises during a general infection the bacteria may be brought by the blood. It may arise in a case of hepatic cirrhosis. Naunyn ("Deutsche medizinische Wochenschrift," Berlin, Nov. 2, 1911) says that most germs can cause cholangitis; that mixed infection may occur, and that during an acute general infection cholangitis is seldom recognized. The usual cause of infective cholangitis is gall-stones lodged in the common duct. Some maintain that duct-stones are causal, particularly in those cases in which a gall-stone acts as a ball-valve. A. W. Mayo Robson, though he believes that infective cholangitis does occur when the gall-stones are freely movable in the common duct, sets it forth as his experience that it is much more common in such cases to find gall-stones impacted in the common duct.

In such cases the patient gives a history of attacks of gall-stone colic without jaundice for several years, and then of attacks followed by temporary jaundice (see page 1051). Finally comes an attack that is followed by a chill and fever; and jaundice, varying in intensity, ensues upon this, and now, though it may fade, it seldom completely disappears between the attacks of pain. Robson points out that the interval between the attacks may be short or long, and that the rigors may be repeated daily or at uncertain intervals; that the gall-bladder is usually, but not always, contracted; and that after the condition has persisted for some time the liver becomes distinctly enlarged. There are tenderness over the gall-bladder or in the epigastric region, loss of flesh, and persistent jaundice which may vary in hue.

Infective cholangitis, even after it has lasted for a considerable length of time, may be recovered from; but it may pass on into an acute condition in which poisoning takes place from the biliary elements, suppurative cholangitis may arise, an empyema of the gall-bladder may develop, and there may be an abscess of the liver or some other dangerous or fatal complication. The ague-like attacks of infective cholangitis have been called by Charcot *intermittent hepatic fever* (see page 1051).

Treatment.—After an incision has been made the common duct is opened, the cause removed, and the duct drained; but, as Mr. Robson points out, the complication should be anticipated. When one finds that carefully applied medical treatment has failed to free the patient from gall-stones, they should be removed surgically.

Suppurative cholangitis is usually a development of the ordinary infective cholangitis, which has just been discussed. Among the other causes that Robson sums up are acute infectious diseases, particularly typhoid fever and influenza, cancer of the bile-ducts, and hydatid disease.

In this condition the liver enlarges notably and becomes tender. In some cases there is an empyema of the gall-bladder, but this is rare; in fact, the gall-bladder is usually very much shrunken. When, in a chronic case, there are enlargement of the liver, blocking of the common duct, and enlargement of the gall-bladder the inference is in favor of cancerous obstruction of the common duct. If the obstruction is due to cancer there will usually be little pain; but when it is due to gall-stones there will be violent attacks of pain, accompanied by rigors and fever, with deepening of the jaundice. In this disease there is always jaundice, usually unfading; but in cases of ball-valve gall-stone in the duct it will be mitigated from time to time (see page 1051). The patient suffers form septic fever and there is very rapid loss of flesh.

The condition is generally fatal unless operation is performed early. There is a strong tendency for abscess of the liver to form, and in 1 case upon which I operated a subphrenic abscess had developed.

Treatment.—Cholecystostomy with free and prolonged drainage. If an abscess of the liver exists it should also be drained. If gall-stones are gathered in the common duct they should be removed.

Typhoid Cholecystitis.—Typhoid bacilli were first found in the bile by Futterer in 1888, and typhoid cholecystitis was first described by Giroche in 1890. As previously stated, typhoid bacilli are usually present in the bile during, and perhaps are present months or years after, an attack of typhoid fever. They are not always present, however, for in a case of cholecystitis following typhoid on which I operated an unidentified bacillus was found ("New York Med. Jour.," April 8, 1905); in a case on which I had made an artificial anus for typhoid perforation and subsequently performed intestinal resection I drained a greatly distended gall-bladder at the second operation and cultures of the bile remained sterile; and in a case of typhoid with distended and apparently inflamed gall-bladder on which I operated the bile was reported to be sterile. Because typhoid bacilli are usually present in the bile during typhoid does not mean that most cases of typhoid have cholecystitis; cholecystitis is not very common, and arises when bacilli are very numerous or very virulent, when vital resistance is lowered, when there is antecedent inflammation of the gall-bladder, when there are gall-stones, and particularly if there is a block of the duct causing stagnation of bile. Bacilli in bile may do no harm at all, but they may cause catarrh, purulent catarrh, suppuration of the gall-bladder walls, suppuration outside of the gall-bladder, or perforation. When bile or inflammatory exudate contains typhoid bacilli, agglutinins are present and may precipitate masses which become nuclei for gall-stones.

The usual period for cholecystitis to arise is during the third week of the fever, but it is not uncommonly met with during convalescence and is perhaps mistaken for a relapse.

The condition may arise months or a year after the attack of typhoid, and yet a pure culture of typhoid bacilli may be obtained from the gall-bladder. Strange to say, cases of cholecystitis have been operated on in persons giving no history of having had typhoid, and typhoid bacilli have been obtained from the gall-bladder. Such a person may have had a very mild attack of typhoid, or he may be immune to typhoid fever and yet the bacillus may be capable of causing inflammation. Many cases of typhoid cholecystitis are probably unrecognized because of the trivial symptoms, or because a high position of the liver renders the real seat of pain obscure, because the general symptoms are uncertain, because toxemia blurs perception of pain, or because the condition is confused with appendicitis. It is rare in children, more common in adults. Most infections result from the bacilli ascending the common duct, some are by way of the lymphatics (Charles H. Mayo), some by an adhesion of the gall-bladder to the bowel, some by way of the portal circulation and the bile-ducts. Mixed infection may occur, and a secondary staphylococcus infection may be followed by disappearance of the typhoid bacilli. The symptoms of typhoid cholecystitis are pain and tenderness in the gall-bladder region, rigidity of the upper half of the right rectus muscle, perhaps a palpable mass, an elevated and remittent temperature, sweats, perhaps jaundice, and sometimes leukocytosis. In some cases perforation occurs. Erdmann reported 1 case and collected from literature 34 cases of perforation ("Annals of Surgery," June, 1903).

Treatment.—In an ordinary case without perforation incise and drain the gall-bladder. If perforation exists, do cholecystectomy if possible; if not, drain. No attempt should be made to suture the perforation. If perforation

exists and operation is not done, death is practically certain. Of 27 cases not operated upon, all died; of 7 cases operated upon, 4 recovered (Erdmann).

Gall-stones are formed during life in the gall-bladder or bile-ducts by the agglutination of materials which have precipitated from bile. The nucleus of a gall-stone may be a mass of bacteria, a blood-clot, epithelium, crystals of cholesterin or carbonate of lime, or a cast of a small duct.[1] A condition of the body thought to lead to the formation of gall-stones is designated by the term *cholelithiasis* (Brockbank). But one stone may be present or great numbers may exist. Solitary stones may be nearly round or cylindrical. When several stones or many stones exist the mutual pressure often leads to the formation of facets (Naunyn). In color, calculi may be pale yellow, green, black, or brown. Some are heavier than bile and some are lighter. Brockbank gives the following varieties of gall-stones: pure cholesterin stones, stratified cholesterin stones, common or gall-bladder calculi, mixed bilirubin-calcium calculi, pure bilirubin-calcium calculi, and certain rare forms.[2] Gall-stones usually take origin in the gall-bladder, but may arise in the common duct, the cystic duct, the hepatic duct, or the smaller ducts of the liver. As a rule, however, calculi in the common or cystic duct were not formed there, but were transported from the gall-bladder or hepatic ducts.

Causes.—Gall-stones are very commonly found postmortem. In Germany it is estimated that they are found in 12 per cent. of all cases. In 1655 autopsies in the Johns Hopkins Hospital gall-stones were present in 6.94 per cent. of all cases.[3] The usual estimate is 5 per cent. of autopsies. The cause is a catarrhal condition of the bile-ducts, due particularly to the entrance of bacteria from the intestine (colon bacilli, typhoid bacilli, pus organisms, pneumococci). This catarrhal condition causes stagnation of bile. Healthy bile is sterile, but not germicidal, and bacteria will grow in it. Bacteria have been found in bile years after the termination of an attack of typhoid fever. Experimental infection of the gall-bladder producing mild cholecystitis is almost always followed by gall-stone formation.[4] Welch pointed out that recent gall-stones have bacteria in their center. Cushing tells us that 30 per cent. of gall-stone cases operated upon in the Johns Hopkins Hospital had previously suffered from typhoid fever, but the experience of the Mayos is not in accord with this opinion. In view of the fact that bile containing typhoid bacilli may contain agglutinins we can understand how masses could be precipitated to form nuclei—30 per cent. of Ochsner's cases had had appendicitis.

The chief predisposing causes are advancing years, insufficient exercise, the daily consumption of unnecessarily large quantities of food, gouty tendencies, and conditions which interfere with the emptying of the gall-bladder. Cardiac disease and cancer of the liver predispose. Gall-stones rarely form before the age of thirty-five. The youngest patient from whom I have removed stones was a girl of twenty. The disease is more common in the insane than in the mentally sound, in the white race than in the black, and in women than in men. In 25 per cent. of all females beyond sixty years of age gall-stones are present (Naunyn). The special liability of women may be brought about by tight lacing, pregnancy, inactivity, or movable right kidney. Stout and lazy women are particularly liable to gall-stone formation, and women who have borne children are far more liable than those who have not. Total abstainers seem to possess a greater predisposition than users of alcohol, probably because they are more apt to be large eaters (Herbert F. Waterhouse, in "Lancet," May 8, 1909). There

are two forms of the condition to be considered: the acute type, due to efforts made by the gall-bladder or duct to expel the concretion; and the chronic condition, in which a calculus is lodged for a long time, or in which, as soon as one calculus is passed into the intestine, "another begins its journey" (Brockbank's treatise on "Gall-stones"). The fact that bacteria cause the condition must not lead us to infer that pus is of necessity formed. If the bacteria are present in small numbers, or if their virulence is greatly mitigated, they produce only catarrhal inflammation, the bile stagnates, and a stone forms. There may be one stone, two, several, or many stones. I have removed 200 from a patient. Multiple stones are usually facetted. Solitary stones are not facetted.

Many observers believe that inflammation of the mucous membrane causes the secretion of quantities of cholesterin, which material forms a large part of most gall-stones. Others maintain that cholesterin is a normal constituent of bile and is not obtained from the mucous membrane.

Bachmeister ("Münch. Med. Woch.," Feb. 18, 1908) demonstrates that if pure sterile bile is permitted to stand for a considerable time cholesterin will be precipitated, and that if epithelial cells are added to this the cholesterin is precipitated much more rapidly. The catarrhal inflammation furnishes quantities of epithelial cells and the cells precipitate cholesterin, and in this way inflammation causes gall-stones. It is probable that when gall-stones exist they are all due to a common cause and all began to form at the same time. It is not likely that one begins and then another, and so on. After a stone once begins it may progressively increase in size. In many cases the stone or stones never cause trouble. A gall-stone may begin to descend because of violent muscular exertion, external pressure, or at the onset of a fresh inflammation which leads to loosening of the stone. A very small stone usually passes freely. A larger stone in passing causes colic. A still larger stone remains in the gall-bladder, or becomes fixed in the cystic duct or in the common duct. In most cases gall-stones form in the gall-bladder. In some they form in the common duct if stones have previously existed in the gall-bladder. When the common duct retains a stone and is suffering from some degree of obstruction and from infection, stones not very unusually form in the hepatic ducts (Wm. J. and Chas. H. Mayo, in "Am. Jour. Med. Sciences," March, 1905). Stones are occasionally found at necropsy in the radicles of the hepatic duct.

Symptoms.—The formation of a stone requires several months, and during the antecedent period of gastro-intestinal catarrh, *the prodromal state* of Kraus, certain symptoms may exist, viz.: constipation, flatulence, loss of appetitie, migraine, uneasy sensations in the epigastrium or right hypochondrium, sallowness of the skin, slight yellowness of the conjunctivæ, scantiness of urine, which excretion is saturated with uric acid, and may after a time contain a little bile. If this condition is not arrested by treatment, it grows worse. The abdomen becomes decidedly distended; pressure over the stomach or liver may cause distinct uneasiness or even pain; acid indigestion is very troublesome; violent attacks of migraine occur; constipation becomes more decided, the feces become clay colored, gastralgia may occur, the skin is apt to be slightly jaundiced, itching is complained of, the patient is irritable and sleeps poorly. The liver is found to be enlarged and the urine contains distinct amounts of bile. When the patient reaches this stage, gall-stones have formed or are very liable to form. These symptoms may pass away even if a concretion forms. It is quite true that in some cases a stone exists for years without causing trouble. This is particularly true in elderly people. A stone seldom fails to cause symptoms, but often the symptoms are unrecognized. In many cases the symptoms which stones cause are thought to be due to disease of the stomach (indigestion, flatulence, pain after eating, pyloric spasm,

etc.). Most of the cases I have seen long thought they had stomach trouble, and the real condition was recognized only when there was a seizure of colic or an attack of inflammation.

As Waterhouse ("Lancet," May 8, 1909) says, the symptoms do not bear any relation to the size or the number of the stones. In fact, gall-stones give rise to active symptoms only when infection occurs or when the ducts become occluded and cease to drain, or when a stone starts to pass. If infection occurs, it may pass away spontaneously, but seldom does so. When a stone forms, pain is apt to become a marked feature of the case. John B. Murphy ("Med. News," Nov. 2, 1903) points out that in a person with stones in the gall-bladder there may be:

1. The pain of acute inflammation, the result of a severe infection. In this condition there are abdominal rigidity and contracted gall-bladder.

2. The pain of tension. In this there is not persistent abdominal rigidity, but pressure always causes sudden and transient tension of the belly muscles. Murphy's method of demonstrating tenderness of the gall-gladder is most valuable, and I always use it. It is as follows: Hook the fingers well up under the liver and tell the patient to take a deep inspiration. On inspiration pain becomes acute and respiration suddenly ceases.

3. Referred pain, which may exist with either of the above conditions. *Colic* is spasmodic pain, and means that a stone has left or is trying to leave the gall-bladder, and is in or is trying to enter a duct. Many persons with a stone or with stones in the gall-bladder never have colic. A sense of pressure or of soreness in the hepatic region, the result of cholecystitis, has added to it sudden and transient paroxysms of pain, due to the passage of thick bile from the gall-bladder and small ducts, or of gravel from the small ducts, urged on by bile pressure. When any stone but the very smallest begins to pass from the gall-bladder, violent colic is experienced. Such a colic usually comes on very suddenly, and often about three hours after a meal. It may, however, come on gradually, the patient complaining greatly of flatulence. In some cases it is so sudden and violent as to simulate perforation of the stomach or duodenum. The reason colic is particularly apt to come several hours after a heavy meal is that at that time bile is passing down into the intestine. A bladder containing calculi often tolerates the presence of the foreign bodies for an indefinite length of time, and then suddenly resents their presence and ejects them forcibly or tries to eject them. The pains are violent, spasmodic, and paroxysmal, and over the hepatic and epigastric regons, "radiating upward over the right half of the thorax" (Kraus), and passing particularly from the epigastrium to the right shoulder-blade. The patient is profoundly nauseated and usually vomits. In many cases the vomiting is violent. The abdomen is distended and a condition almost of collapse is soon reached. The temperature is usually normal or subnormal, but is occasionally somewhat elevated. The patient may shiver and sweating may follow, but rigors are rare. The respirations are shallow, the patient groans, cries out, flings himself about in the bed, and often, in seeking relief, assumes some strange or contorted position. He frequently holds one hand over the liver region. His expression is indicative of intense suffering and apprehension and sometimes of abject terror. The pain is one of the most awful a human being can feel, and women who have felt it assert that the pains of parturition are trivial in comparison. The attack lasts a variable time, and terminates when the stone passes into the intestine or drops back into the bladder. The usual duration of an attack is from four to twenty hours. I have seen attacks that lasted three days, four days, or even five days, almost without intermission. It terminates suddenly if the stone passes or falls back in the gall-bladder. It abates very gradually if the stone becomes wedged in a duct.

In many cases at the termination of the attack an enormous amount of clear pale urine is passed. During and for a time after the attack the gall-bladder may be very tender. After the cessation of colic, if the feces are examined carefully during several days, the stone may be discovered. The fact that no stone is discovered does not prove that one was not passed, because a cholesterin stone may be destroyed in the intestinal canal. If the stone is passed, jaundice almost invariably follows the colic in from twenty to thirty-six hours and lasts several days. The jaundice results from the stone being in or having passed through the common duct. If stones do not pass from the cystic duct so as to enter or protrude into the common duct, jaundice does not occur. In 80 per cent. of my cases of gall-stones (excluding common duct cases) there was no history of jaundice. Even when a stone is lodged in the common duct jaundice may be slight or absent. When jaundice arises after a colic, it comes on gradually, bile appears in the urine, and often, but not always, the stools become clay colored from absence of bile. Jaundice may be first noticeable in the urine or in the conjunctiva. The skin is apt to itch annoyingly, even atrociously. The patient is constipated and very thirsty. The liver is enlarged and tender and the spleen is enlarged. Some writers state that the pulse is slow in jaundice. My experience is in agreement with the much larger experience of Moynihan, who says: "I have not found any reduction in the pulse-rate in jaundice unless a degree of chronic pancreatitis is present" ("Gall-stones and Their Surgical Treatment"). If the stone becomes impacted, after a time the pains become gradually less violent, and may entirely cease. If it ceases and the stone does not move, pains do not recur; if the stone moves pains recur, and, usually, again and again the patient suffers from severe pain. An individual may get about when a stone is impacted, but again and again fierce attacks of colic occur, and if the stone is wedged immovably in the common duct, producing absolute obstruction, the patient becomes and remains deeply jaundiced. Continued deep jaundice is seldom seen when stones are lodged in the common duct, because they are not often absolutely fixed and hence rarely produce complete obstruction. Usually the stone moves from time to time or is at least lifted, so that bile gets by it at intervals. This condition constitutes the *ball-valve stone*, and in it jaundice, though present more or less, is at times much more intense than at other times. It is a jaundice in which the hue is yellow, not deep brown, and it is a jaundice that wanes and deepens. It deepens after each colic and later wanes, but seldom entirely disappears while the stone remains in the duct.

In persistent jaundice due to gall-stones the gall-bladder is seldom enlarged. Courvoisier showed that when persistent jaundice is associated with enlargement of the gall-bladder the cause is usually pressure on the duct from without (malignant disease of the pancreas).

Slight jaundice is not always easy of recognition. Recognition is particularly difficult in sallow individuals and by artificial light. Moynihan praises Hamel's test for slight jaundice. It is made by drawing a little blood from a puncture of the lobe of the ear into a capillary tube and permitting the tube to stand for a few hours. If any jaundice is present the serum, which collects in the upper part of the tube, will be yellow (Moynihan).

In certain cases when a stone is in the common duct an attack of colic is followed by or accompanied by a chill or chills, which may be very violent, moderate, or slight, and by a febrile seizure resembling malaria and called *hepatic fever* or *Charcot's fever*. The temperature rises rapidly, and in an hour becomes 104° F. or more, remains high for several hours, and then drops suddenly to normal. It may remain normal for a few hours, a day, two days, several days, or weeks. In this condition there are jaundice and tenderness of

the liver. Charcot's fever is brief in duration. It usually means stone in th common duct. If stones are in the bladder, we are more apt to get a persis ent slightly elevated temperature. These intermissions distinguish Charcot fever from the remittent fever of sepsis, and the absence of the plasmodiu in the blood and the history of colic distinguish it from malaria. The feve is due to intoxication with toxins from infected bile retained in the duct by obstruction. The condition is ominous because it is due to infectio and means inflammation of the large ducts (*cholangitis*).

The chart of Charcot's fever shows sudden elevations, precipitate descent and complete intermissions. Moynihan calls it the "steeple chart" ("Gal stones and Their Surgical Treatment"). When infection spreads widely in th smaller intrahepatic ducts the temperature is high and does not remit. Con tinuous fever of this type has usually been preceded by Charcot's fever.

If a stone lodges in the cystic duct, it does not cause jaundice unless a end of the stone projects into the common duct. It grows in size from incrus tation, prevents the entrance of bile into the gall-bladder, and the bladde may shrivel and thicken or become distended and filled with mucus, th bile being absorbed (*hydrops* of the gall-bladder). If a bladder so blocke becomes infected, pus forms, and the condition known as *empyema* of th gall-bladder arises. An empyema of the gall-bladder may rupture into th bowel, the peritoneal cavity, or even through the skin.

The common duct is involved in 1 out of 5 or 6 cases of gall-stone disease. Brewer points out that in 67 per cent. of common duct cases the stone is in th duodenal extremity, in 15 per cent. in the hepatic extremity, and in 18 per cent in the middle. If a stone *blocks* the common duct, jaundice always exists an persists. Blocking may be complete and the stone may ulcerate into the bowe or the peritoneal cavity. Blocking may be incomplete, the stone acting as a ball-valve and producing *intermittent* colic and jaundice, which wanes an deepens (see page 1051). Fenger pointed out that if a stone remains fixed in th common duct the liver becomes tender and enlarged, but if a stone float about in the common duct the gall-bladder undergoes atrophy. In complet obstruction the stools become clay colored and bilirubin is found in the urine Fluctuating jaundice, with attacks of pain and fever, and a shrunken gall bladder are strongly suggestive of a "ball-valve" stone in the common duct Persistent deepening, painless jaundice, the color of the skin becoming brow or even of a mahogany hue, associated with a distended gall-bladder, is strongl suggestive of malignant disease compressing the common duct. The abov statements constitute *Courvoisier's law.* It is found true in 90 per cent. o cases. We may add that a persistent jaundice of yellow hue, varying some what, and associated with pain or with actual colic, suggests blocking of th duct by an immovable stone.

Gall-stones may lead to suppurative inflammation of the gall-bladde or bile-passages, ulceration, occlusion of the neck of the gall-bladder, dilata tion of the stomach from the formation of adhesions which kink the pylorus, pericystic abscess, peritonitis, empyema of the gall-bladder, and cancer of the gall-bladder. In cancer of the ducts gall-stones are seldom found, at least are seldom found in the ducts. Eddes collected 22 cases of cancer of the papilla. In 3 of these cases there were stones in the gall-bladder, in 1 there was a stone in the common duct ("Boston Med. and Surg. Jour.," March 7, 1901). If the patient develops distinct infection of the gall-bladder or bile-ducts, he will suffer from chills, fever, and sweats.

Gall-stones may lead to cirrhosis of the liver. A stone may ulcerate into the bowel and cause intestinal obstruction. It may be difficult to make a diagnosis between gall-stones with icterus and cirrhosis of the liver with

[1] Robson, in "Lancet," April 12, 1902.

icterus. In the former case the urine contains bilirubin and in the latter case urobilin.

Treatment.—In the prodromal stage and after recovery from an attack insist on the patient taking considerable outdoor exercise. Direct him to take a cold sponge-bath every morning, to move the bowels freely every day, and to employ a simple diet. He should avoid all highly seasoned foods, pastry, rich soups, fatty food, cheese, alcohol, and sweets. Alkalis internally are of value.

During colic give a purgative enema, apply hot turpentine stupes over the hepatic region, and administer hypodermatic injections of morphin and atropin. If vomiting does not occur, let the patient drink a large amount of warm water to favor it. After the attack administer a saline purgative.

When the attack has terminated, examine carefully for any evidence of inflammatory trouble in the hepatic region.

In certain cases operation becomes necessary. Mr. A. W. Mayo Robson[1] advises operation in the following cases: in frequently recurring biliary colic without jaundice, whether the gall-bladder is enlarged or not; in cases of enlargement of the gall-bladder without jaundice, even if there is no pain; in persistent jaundice which was ushered in by pain, painful seizures occurring, whether or not febrile attacks occur; in empyema of the gall-bladder; in peritonitis beginning in the gall-bladder region; in intrahepatic abscess and in abscess about the liver, gall-bladder, or bile-ducts; in some patients in whom the stones have been passed, but adhesions remain and produce pain; in fistula cases; in some cases of persistent jaundice due to obstruction of the common duct, although there may be a possibility of cancer existing; in phlegmonous cholecystitis and gangrene of the gall-bladder. Besides these conditions, which may be produced by gall-stones, Robson operates for wounds of the gall-bladder, infective and suppurative cholangitis, and for some conditions of chronic catarrh of the bile-ducts and gall-bladder.[2] The tendency to operate early for gall-stones is growing. It is true that stones *may* cause no trouble, but sooner or later they are apt to cause it, there is no tendency whatever to spontaneous cure, and medicine cannot dissolve them in the bladder. Early operations are easy and comparatively safe; late operations are difficult and dangerous, and by early operation dangerous complications (infection, adhesions, obstructive jaundice) are avoided. As Maurice H. Richardson[3] says: An early operation is less dangerous than the passage of a stone; complications are avoided or lessened; even if the diagnosis is wrong, the real condition may be found and removed. If obstructive jaundice exists operation is dangerous because of the possibility of fatal oozing of blood.

The common operation is *cholecystostomy*, which consists in opening the gall-bladder, removing the stones, and making a temporary fistula in the gall-bladder. The drainage cures the diseased mucous membrane. The fistula is permitted to heal after a time, hence many call the operation cholecystotomy rather than cholecystostomy. Operation should be done promptly and should not be delayed. Delay permits the gall-bladder to thicken and shrink, and allows the stone to enter the duct. After drainage gall-stones rarely re-form. Wm. J. Mayo collected 1000 operations done by six surgeons, and in not 1 case did stones re-form. Kocher has seen stones recur in 3 out of 31 cases of cholelithiasis after ideal cholecystotomy (suturing the gall-bladder after removing stones). The operation of incision, removal of the stone, and suture of the gall-bladder is known as *ideal cholecystotomy* or *cholecystendysis*. It is not a

[1] On the "Gall-bladder and Bile-ducts."

[2] Robson's treatise, from which the above is taken, is a valuable exposition of the surgery of the gall-bladder and bile-ducts.

[3] "Boston Med. and Surg. Jour.," Sept. 5, 1901.

proper procedure, as it does not cure the diseased mucous membrane and stones are apt to re-form. *Cysticotomy* is incision of the cystic duct. If calculi exist in the common duct, it may be possible, after celiotomy, to manipulate them back into the bladder and extract them from that viscus by a scoop, but this maneuver is impossible unless the cystic duct is dilated. In some cases the gall-bladder is incised, a fistula is made, and the duct and bladder are frequently irrigated. In other cases the stone may be crushed by the fingers manipulating the duct and the concretion within it (*choledocholithotrity*). Robson points out that crushing of the stone is apt to leave fragments which may cause trouble, and it should be done only when the stones are soft. It is wrong to endeavor to force a stone from the common duct into the duodenum. The attempt will fail, and in some cases the patient will be placed in a worse condition by the stone lodging in Vater's diverticulum.[1] The duct may be opened, and after the removal of the stone closed by sutures (*choledochotomy*) or drained for a time (*choledochostomy*), strands of gauze being carried down to the opening and in some cases a tube being carried up a dilated duct toward the liver. If the stone is impacted near the outlet of the duct, it may be necessary to incise the duodenum in order to remove the stone (*duodenocholedochotomy*). A dilated common bile-duct may be anastomosed to the bowel (*choledocho-enterostomy*) or to the surface (*choledochostomy*). The obstruction may be side-tracked by anastomosing the gall-bladder to the bowel (*cholecystenterostomy*) (see page 1127). Cholecystenterostomy affords drainage, but does not remove the cause of trouble, and infection is apt to be received from the bowel. In some rare cases of common duct obstruction, in which the gall-bladder is distended and the condition of the patient is desperate, anastomose the gall-bladder to the colon (Robson). In some cases of diseased gall-bladder the viscus is removed (*cholecystectomy*). Wm. J. Mayo and others have pointed out that a danger in operations on the common duct is a sudden fall in blood-pressure when the duct is being manipulated. All operators have observed it. Ransohoff maintains that it arises only when the portal vein is compressed.

Carcinoma of the Gall-bladder.—In 405 operations on the gall-bladder and biliary passages the Mayo brothers found malignant disease 20 times (5 per cent. of cases). (See Wm. J. Mayo, in "Med. News," Dec. 13, 1902.) Malignant disease may be primary or secondary. In primary carcinoma calculi are always present, and are apparently the cause of cancer by maintaining chronic irritation. Stones are seldom present in secondary malignant disease.

Carcinoma of the gall-bladder can usually be palpated. It is hard and nodular, and seldom accompanied by much abdominal rigidity. There will be a long history of attacks of biliary colic and of recent or comparatively recent grave loss of flesh. Sooner or later jaundice arises, deepens, and persists.

Cholecystectomy has been employed for this condition, but offers but little hope. In 2 cases in which I opened the abdomen without suspecting malignant disease of the gall-bladder the liver was hopelessly involved. In 1 case in which I operated for a supposed impacted stone in the common duct an inoperable cancer of the common duct was found.

Injuries and Diseases of the Pancreas

Injuries of the Pancreas.—The pancreas is very rarely ruptured alone, although this sometimes occurs as the result of blows or crushes. In the majority of cases in which the pancreas is damaged other organs are involved; for instance, the stomach, the spleen, and the liver. A gunshot-wound of the pancreas is almost certain to injure the left kidney, the stomach, or the

[1] See A. W. Mayo Robson, in "Lancet," April, 12, 1902.

vertebral column. It will be remembered that in the case of President McKinley the bullet passed through the stomach, damaged the left kidney, and injured the pancreas. Becker reported an isolated gunshot-wound of the pancreas, the only case on record (Stephen H. Watts). Garré ("Beiträge zür Klinische Chirurgie," xlvi, No. 1) collected 30 cases of subcutaneous rupture of the pancreas, and in only 8 of these cases was the pancreas alone damaged.

Symptoms.—When the pancreas is injured alone, hemorrhage is not usually severe; but if adjacent organs are also damaged, it is sure to be profuse. Hence when adjacent organs are damaged immediate symptoms of severe intra-abdominal hemorrhage appear; but profound collapse is not often present when the pancreas alone is injured. In fact, symptoms may not arise for a considerable length of time after injury of the pancreas. A diagnosis at this stage is impossible without exploratory operation. Wohlgemuth and Noguchi claim that within a few hours of a pancreatic injury there is an increase of diastase in the blood and urine ("Berlin. klin. Wochen.," xlix, 1912). If this observation is correct we have a very valuable diagnostic test. Severe injury of the pancreas is usually, but not invariably, fatal. After slight damage of the gland the patient may completely recover; but, as a rule, he partly recovers, and, after a number of weeks, a smooth enlargement, palpable in the epigastric region, is formed. When operation is performed this mass is found to be back of the stomach. It contains a quantity of fluid blood, clot, and pancreatic fluid. Such a fluid collection is in the lesser peritoneal cavity and is called a cyst, though it is not a true cyst of the pancreas. It is a pseudocyst. Robson and Moynihan, in their valuable treatise on "Diseases of the Pancreas," explain the formation of this collection of fluid as follows:

The injury lacerates the posterior layer of the lesser sac of the peritoneum and the pancreas, to which it is adherent. Blood and pancreatic fluid enter the lesser peritoneal sac. Peritonitis follows. The foramen of Winslow becomes blocked by adhesions; and the lesser peritoneal cavity, being now a closed sac, is distended by a serous exudate mixed with blood and pancreatic fluid. Collections of this character form very rapidly, and several pints may gather in a few days. Other results of injury to the pancreas are abscess, pancreatitis, and true cyst formation. A fistula may follow operation for rupture of the pancreas. Such a fistula is very troublesome, often refuses obstinately to heal, and the pancreatic fluid macerates the skin severely.

Treatment.—Operation is imperatively demanded, although the prospects are bad. Garré collected 8 cases, 3 were operated upon, and all died. He reported a successful case of his own (Loc. cit.). The pancreas was torn in two and the pieces were separated. The splenic vessels were uninjured. The two portions of gland were sutured together. This stopped the bleeding. Gauze-packing was introduced. Mikulicz ("Proceedings of Amer. Surg. Soc.") in 1903 collected 21 wounds and 24 crushes of the pancreas. Twelve of the wounds were due to bullets and 9 were stabs. Five of the 12 gunshot-wounds were operated upon, with 2 deaths. All unoperated upon died. The 9 patients who had been stabbed were all operated upon and only 1 died. In a gunshot-wound of the abdomen, when exploration leads the surgeon to surmise that the pancreas has been injured, this organ should be approached by dividing either the gastrocolic omentum, the transverse mesocolon, or the gastrohepatic omentum. Accessory injuries must be carefully noted, and if a bullet has penetrated the posterior wall of the stomach, the pancreas is almost certain to be damaged. One should remember that, as Park says, even after opening the abdomen it is difficult to explore the pancreas, especially in a stout person. If there is no evidence of posterior perforation of the stomach by a foreign body, one may

assume that the pancreas has escaped. When the pancreas is exposed, if it is found to be bleeding, the bleeding vessels should be ligated and the tear in the gland should be sutured with catgut, care being taken not to puncture the main duct of the gland. If this duct has been cut, it should be carefully sutured. In some cases of gunshot-wound it is necessary to resect a portion of the gland. At the termination of an operation upon the pancreas posterior drainage, preferably at the costovertebral angle, should always be obtained. It is necessary to carefully drain away all escaping pancreatic fluid, as it tends to cause necrosis of tissue with which it comes in contact.

In cases of crush with pancreatic injury the associated injury to other structures usually proves rapidly fatal, but in a less severe case the abdomen may be opened for exploration, and if this is done, the surgeon should proceed as previously directed.

The question of excising a lacerated portion of the pancreas is one of great interest. It is known that dogs have lived for some time after complete excision of the pancreas. Four-fifths of the pancreas can be removed from a dog without producing permanent glycosuria, but if more than this is removed the dog develops saccharine diabetes and eventually dies of it. In man, quite large-sized pieces of the gland have been removed and recovery has followed. Hence it is justifiable to excise a hopelessly damaged portion, bearing in mind Park's caution that the chief danger in excising a portion of the pancreas is injury to the splenic artery.

Wounds of the Pancreas During Operations on the Stomach and Spleen.—In the performance of gastrectomy, partial or complete, the pancreas will be injured if the growth or ulcer is adherent to it. Such an accident is held by most operators to greatly increase mortality. The Mayos report 448 resections of the stomach for benign and malignant disease. The average mortality was 10 per cent. In 8 per cent. of these cases the pancreas was injured, and the average mortality of such cases was only 11 per cent. (Wm. J. Mayo, in "Annals of Surgery," August, 1913). The injuries reported by the Mayos were superficial at the point the stomach adhered. In no case was the main duct opened. It was noticed in these cases that local peritonitis had caused the formation of a fibrous capsule. Bleeding was controlled by suture-ligatures of catgut. The pancreatic wound was not sutured. As stated on page 1085, if the pancreas is wounded during pylorectomy, the closed end of the duodenum is placed in the pancreatic wound and the anterior peritoneum and adventitious sheath is sutured to the anterior portion of the duodenum. If an ulcer of the posterior wall of the stomach is adherent to the pancreas, transgastric excision removes considerable pancreatic tissue. Such a wound is not sutured, but the gap is filled by a mobilized bit of gastrohepatic or gastrocolic omentum (Wm. J. Mayo, Ibid.). In 2 of my cases of splenectomy I damaged the pancreas, tying off a bit of the tail with the splenic vessels. In 1 case leakage occurred and death followed in spite of anterior drainage. In the other case there was profuse drainage for several days, which was carried off by a posterior drain. This patient recovered. Both were cases of Banti's disease.

Pancreatic Fistula.—A fistula may follow a wound of the pancreas. It is a very troublesome condition, often refuses most obstinately to heal, and the pancreatic secretion causes maceration and violent irritation of the adjacent skin. The usual treatment is to keep the way open for easy drainage. Wohlgemuth's plan is promising ("Berliner klin. Wochen.," 1908, No. 8). He reported 5 successful cases. I have had 1. The treatment consists in feeding upon strict antidiabetic diet and in giving large doses of bicarbonate of soda before and after meals. By cutting off carbohydrates a powerful stimulus to the flow of pancreatic juice is removed. The bicarbonate of sodium lessens the acidity of the stomach contents. The more acid the contents which enter

the duodenum, the greater the flow of pancreatic juice; the less acid, the less the flow.

Displacement of the Pancreas.—In cases of splanchnoptosis the pancreas may become considerably displaced, though this condition cannot be recognized without opening the abdomen. It may be a portion of the pedicle of a movable spleen. So far, I know of no case in which fixation has been attempted, though, of course, theoretically it could be done. The pancreas has been found in umbilical herniæ. In 10 per cent. of diaphragmatic herniæ the pancreas constitutes part of the contents. Körte collected 8 cases in which the pancreas prolapsed through an abdominal wound. In several cases in which the pancreas prolapsed into an abdominal wound the protruding part has been excised. In other cases it has been restored.

Pancreatitis often leads to the production of jaundice; always to very rapid loss of weight; occasionally to the presence of fat and sugar in the urine; sometimes to the presence of fat in the stools, and frequently to the condition known as fat necrosis. Robson and Moynihan[1] point out that when there is no diarrhea and the stools contain undigested muscle-fiber, one may assume that there is a deficiency in pancreatic juice. When there is a blockage to the secretion from the pancreas, if salol is given by mouth, salicyluric acid does not appear in the urine. The test is made by putting 15 gr. of salol into gelatin capsules hardened with formalin (Sahli) and giving them with a roll and a cup of water. If pancreatic ferment is in the intestine, salicyluric acid appears in the urine in from three-quarters of an hour to one hour; if the ferment is absent from the intestine, salicyluric acid is not found in the urine because the salol is not split up and absorbed. The test for the acid is ferric chlorid, which, in the presence of the acid, turns the urine violet. The general cause of pancreatitis is infection. Often obstruction of the common duodenal outlet of the pancreatic duct and common bile-duct is followed by infection and suppuration of the pancreatic ducts and pancreatitis. Besides the general cause, which is infection, various exciting causes may be named, among which are gall-stones in the common duct and calculi in the pancreatic ducts, traumatism, cancer of the stomach or duodenum, catarrh of the stomach or duodenum, and many infectious diseases. It thus becomes evident that the infection may be by way of the blood; but, undoubtedly, in the vast majority of cases, the infection comes by way of the duct. One manner in which the disease may be produced was suggested by Halsted and Opie, of Baltimore: A stone becomes impacted in the duodenal outlet of the common duct and pancreatic duct, the pancreatic duct, where it emerges above the common duct, not being blocked. The bile and pancreatic juice are thus prevented from entering the duodenum, and the bile flows back into the pancreatic ducts. Swelling of the papillæ could act in the same way. So could a plug of mucus. It is thought that overacid gastric juice may enter the duct and produce pancreatitis. Pancreatitis is predisposed to by obesity and arteriosclerosis (Balch and Smith, "Publications of the Mass. Gen. Hosp.," Oct., 1911). Deaver is of the opinion that some infections reach the pancreas through the lymphatics ("Annals of Surgery," August, 1913).

That strange condition known as *fat-necrosis* is often present in pancreatitis. In fat-necrosis the fat is decomposed into fatty acids and glycerin. The glycerin is absorbed, but the fatty acids unite with calcium salts and remain in the tissues, forming patches of yellowish-white color and varying size. These patches are found in the fat beneath the peritoneum, in the omentum, and in the mesentery, and even in distant parts (for instance, the pericardium).[2] It is an undoubted fact that fat-necrosis is not uncommonly found after diseases and injuries of the pancreas; and many assume that it is produced by the entrance of the ferment of the pancreas into the

[1] Robson and Moynihan, on "Diseases of the Pancreas." [2] Ibid.

fatty tissue. How the ferment gets there is a matter of some doubt. In the case of a wound of the pancreas one can understand the flow of the secretion and its imbibition by adjacent parts; but in other cases one must assume that it has been absorbed by the lymphatics and distributed to more distant parts. When one reflects that in some conditions of the pancreas there is no fat-necrosis, while in others this condition arises, it is presumable that the pancreatic conditions associated with it are such as to permit the fat-splitting ferment to diffuse into neighboring tissues.

In pancreatic disease *hemorrhage* into that organ is common. The hemorrhage is not, of necessity, fatal, but frequently is so. Occasionally death takes place as the result of sudden pancreatic hemorrhage in a person apparently in excellent health. It is thought by Robson and Moynihan that during the existence of cancer of the pancreas there is a strong tendency to excessive hemorrhage after any operation. In 1 case of my own the patient bled to death after the performance of cholecystostomy for obstructive jaundice. The oozing of blood in this case was from the margins of the gall-bladder and the adjacent peritoneal surfaces. We, therefore, conclude that in certain conditions of the pancreas there is a tendency to local hemorrhage in that organ; and that there may also be a tendency to the development of a general hemorrhagic diathesis, the general hemorrhagic tendency being much increased if jaundice exists. During acute inflammation of the pancreas hemorrhage is almost certain to occur into that gland; in other varieties of inflammation hemorrhage may occur or may be absent. In degenerative lesions of the pancreas a material like unfermented pentose is frequently present in the urine. When the reaction for this material is obtained we speak of it as the *Cammidge reaction,* after its discoverer. (For Cammidge's improved method, see "Brit. Med. Jour.," May 19, 1906.) The Cammidge reaction is not by any means conclusive proof of organic pancreatic disease. It may be found in a great variety of other conditions (gall-stones, cholecystitis, gastric carcinoma, burns, etc.). In most patients who exhibit it there is arteriosclerosis and, of course, this condition might effect pancreatic secretion (Watson, "Brit. Med. Jour.," April 11, 1908). My own views coincide with those of Swan and Gilbride ("New York Med. Jour.," April 23, 1910). They believe a positive reaction indicates disturbed pancreatic function, but not, of necessity, organic disease.

Forms of Pancreatitis.—This disease is divided by Robson and Moynihan into the acute, the subacute, and the chronic forms; and they say that recorded cases demonstrate the fact that three distinct classes of inflammation may arise: (1) Cases that die within forty-eight hours of the beginning of the trouble. In this group hemorrhage is usually found, and if fat-necrosis is present, it is limited in area. (2) Those that live for some weeks after the beginning of the trouble. In these cases the pancreas may become necrotic or suppuration may occur. Fat-necrosis is usually widespread. (3) In the third class of cases long-continued inflammation or repeated attacks produce sclerosis of the pancreas.

Acute Pancreatitis.—In this condition the pancreatic secretion is infected and is blocked up in the ducts. It digests or ruptures the walls of the small ducts and diffuses through the gland, producing necrosis of gland tissue, exudation into gland tissue, necrosis of the blood-vessels, and, in consequence, hemorrhage (Balch and Smith, in "Publication of Mass. Gen. Hosp.," Oct., 1911). It is known that normal pancreatic juice will not digest living pancreas. It seems probable that trypsin is activated by bacteria and material from the duodenum (Polya, in "Pflüger's Archiv," cxxi, Heft 9 and 10). A part of the gland or the entire gland may be involved. Fat-necrosis occurs. The entire pancreas may become gangrenous.

The *symptoms* of this condition come on suddenly and consist of violent pain in the epigastric region, but seldom marked tenderness, usually vomiting, constipation, weakness of the circulation, slow or moderately rapid pulse, cold extremities, and collapse, with a great fall in blood-pressure. The temperature is normal or moderately elevated. Some maintain that collapse is due to trypsin; others, that it results from the absorption of toxic products from the gland. The pain is extremely violent and is intensified in paroxysms, and there is rigidity of the epigastrium. In some cases there is appreciable tenderness. The patient vomits the contents of the stomach and then bilious matter. Distention soon becomes distinct in the upper portion of the abdomen. The patient presents the appearance of one suffering from peritonitis. This condition is not unusually mistaken for intestinal obstruction, but in acute pancreatitis the constipation is not absolute; the patient passes gas, and may even have a bowel movement as the result of the administration of an enema. The condition is usually fatal within a few days, but in very rare instances recovery takes place. In acute pancreatitis from stone in the common duct there is no leukocytosis (Murphy). In some cases of pancreatitis from other causes there is high leukocytosis.

The *diagnosis* cannot be made with certainty and is merely an inference. Reginald Fitz told us that the existence of this disease should be suspected when a person previously in good health, or who has complained only of occasional attacks of digestive disorder, is suddenly seized with severe pain in the epigastric region, followed by vomiting and collapse; and when, within twenty-four hours or more, there appears a circumscribed swelling in the epigastrium which is resistant or tympanitic. Visible oil in the stools, a Cammidge reaction, or sugar in the urine add probability to a diagnosis of pancreatitis. When an exploratory incision is made in the abdomen, if fat-necrosis is detected, the diagnosis becomes certain. The peritoneal cavity may contain thin, bloody fluid.

Treatment.—Operation was suggested by Naunyn in 1903. The exploratory operation is carried out in front, and the earlier it is made the better. Robson operates at once, even in shock. It is quite true that the patient might, if let alone, pass through the acute stage, and that a local abscess might then form, the treatment of which would be obvious. But the danger of waiting is too great to justify delay, and if suppuration should occur it might not remain local, but might spread widely in the retroperitoneal tissues. When observation after exploratory incision into the greater cavity of the peritoneum suggests the existence of acute pancreatitis, the infected area should be exposed, preferably above the stomach, through the gastrohepatic ligament. The pancreas should be incised, hemorrhage should be arrested by ligation or packing, the gauze pack emerges above the lesser curvature, an incision should be made at the costovertebral angle, and posterior drainage should be made from the lesser peritoneal cavity. One should follow the rule laid down by Rosswell Park, and explore in every case in which the disease is suspected to exist. Of Körte's 16 cases operated on during the first week 11 recovered ("Annals of Surgery," 1911, vol. lv). Of Balch and Smith's cases ("Publication of Mass. Gen. Hosp.," Oct., 1911), 11 were operated upon within three days, and 3 recovered. The two authors just quoted state that the Massachusetts General Hospital records for twenty-one years show only 1 victim who recovered without operation.

Subacute pancreatitis comes on suddenly, with violent pain, vomiting, and constipation, but there is far less exhaustion and weakness than in the acute form. The vomiting is less marked and the swelling in the epigastric region is not so rapid. The symptoms are similar to those of the acute form, but not so violent nor so rapidly progressive. The temperature frequently rises higher than in the acute form, and it may become irregular or chills may occur.

In many cases the patient seems to grow better after a time, the violent pain abating, though distinct pain may remain; but he does not gather strength and continues to lose flesh, and there is usually albumin and there may be sugar in the urine. In rare instances fat is found in the urine. In subacute pancreatitis abscess is prone to form. The abscess may make a distinct swelling in front, and may lead to the development of a subphrenic or of a perirenal abscess. In rare cases an abscess of the pancreas tracks its way for a long distance in the subperitoneal tissue; occasionally it opens into the stomach or bowel. Cases of subacute pancreatitis usually die, but occasionally recover after a long illness.

Treatment.—Exploratory incision. Expose the pancreas, preferably by dividing the gastrohepatic ligament; determine its condition; remove purulent matter and necrotic areas; arrest hemorrhage with packing, and insert posterior drainage at the costovertebral angle. Leave the anterior wound open for the emergence of the gauze packing.[1]

Wm. J. Mayo[2] reports a successful operation for subacute pancreatitis. The patient was a man of fifty-two years, who, seven days before Mayo saw him, had developed violent pain in the epigastrium, collapse, distention, and other signs of intestinal obstruction; but some slight movements had taken place from the bowels as the result of medication. On admission, the abdomen was tympanitic. An ill-defined mass the size of a fist could be palpated to the right of and above the umbilicus. The pulse was 120 and very weak; the temperature between 101° and 102° F.; and there were slight jaundice, restlessness, and hiccup. A diagnosis of gangrenous cholecystitis was made. The abdomen was opened, and the omentum was found to be studded with thick, adherent, infiltrated round spots, the size of a pea or larger. There were some similar spots in the mesentery, and the peritoneal cavity contained bloody fluid. On palpation the pancreas felt like a pudding in a tight sac, and on aspiration a little blood was obtained. The gall-bladder was opened, a stone was removed, and some pus was evacuated. Drainage was inserted into the gall-bladder, and eighteen days later there was an enormous flow of bloody fluid, containing bile and pancreatic juice, from the drainage-tube. The patient recovered. This plan of treatment—free drainage of the pancreas by the performance of cholecystostomy—is to be taken into consideration.

Chronic Pancreatitis.—There are many causes of chronic pancreatitis, viz., syphilis, alcohol, bacteremia, block of the common duct (stenosis, stone, etc.), extension of inflammation from the bile-ducts, and ascending infection from the duodenum. It usually results from disease of the bile-passages and is often associated with gall-stones. In 2200 operations performed by the Mayo brothers on the gall-bladder and bile-ducts, the pancreas was found diseased 141 times (6.4 per cent.).

In 168 cases of pancreatic disease on which they operated 81 per cent. were caused by or, at least, associated with gall-stones. In operations upon the common or hepatic ducts the pancreas was diseased in 18.6 per cent. of cases. It was diseased in 4.45 per cent. of cases of operation upon the gall-bladder. Chronic pancreatitis produces enlargement of the organ, and the enlarged area is hard and feels like a malignant growth. This condition is more common than the acute or subacute form. Robson and Moynihan have operated upon 30 cases. This disease is frequently associated with gall-stones or with stones in the pancreatic duct, and occasionally with ulcer of the stomach or of the duodenum. In some cases symptoms of the condition come on acutely. Pain, nausea, and vomiting occur, and jaundice develops rapidly, as it does after the

[1] Roswell Park, "Annals of Surgery," December, 15, 1901.
[2] "Jour. Am. Med. Assoc.," Jan. 11, 1902.

passage of a gall-stone. It is noted, however, that the pain is not in the region of the gall-bladder, but is in the middle of the epigastrium, and it passes to the left rather than to the right. The tenderness, too, is in the middle of the epigastrium and not in the gall-bladder region. There is either constipation or diarrhea. A series of these attacks may occur, the jaundice growing worse after each attack. In some cases, however, the condition comes on gradually and insidiously, the pain slowly developing, but no violent seizures taking place. There are rigidity of the rectus muscles, rapid loss of flesh, anemia, sometimes bronzed skin, usually vomiting, and considerable flatulence. The gall-bladder is enlarged and commonly palpable.

In some cases it is possible to palpate the inflammatory mass. There may be irregular fever and chills with episodes of subnormal temperature. None of the above indications are conclusive signs of disturbed pancreatic function. Signs of disturbed function of the gland are of great importance in making the diagnosis, and these signs are glycosuria and impaired power of digesting fats and proteins (Walko, in "Arch. f. Veranungskrankheiten," 1907, xiii). Fatty stools containing unsaponified neutral fat are very significant.

The jaundice in chronic pancreatitis results from compression of the duct by the hyperplastic mass, or blocking of the duct by a stone. Stenosis of the duodenum may occur. In jaundice from chronic pancreatitis capillary hemorrhage is particularly common (Robson). Mayo Robson attaches much importance to the Cammidge reaction. In the Jefferson Hospital we regard it as often of decided use, but we do not as yet attach as much importance to it as do some other clinicians. This reaction, when present, indicates degenerative disease of the pancreas. It is obtained when the urine contains a substance having the characteristics of unfermented pentose.

Treatment.—Exploratory incision, opening and draining the gall-bladder; or the performing of cholecystenterostomy.

Pancreatic Calculi.—When the pancreatic secretion is blocked, stones tend to form; and the blocking may be due to inflammation of the duct of Wirsung, or may result from chronic pancreatitis. The stones may be single or multiple.

Symptoms.—There is pain in the epigastric region, which usually comes on in paroxysms that resemble those due to gall-stones, though they are not so violent. Pain is accompanied by vomiting, exhaustion, and sometimes actual collapse, and may be followed by rigors. Portions of stone are sometimes recovered from the feces, and sugar is occasionally found in the urine. Fat has also been noted in the stools in some cases. Sometimes jaundice develops because the calculus presses upon the common duct. Pancreatic calculi are composed of lime salts and can be skiagraphed.

Treatment.—Pancreatic calculi have, in rare instances, been removed by operation; and this is the proper procedure when the diagnosis can be made. The diagnosis is, however, possible only after exploratory incision. As a rule, no operation is performed until a cyst results or an abscess forms; and when the cyst or abscess is opened fragments of stone may be found in the fluid, and stones may subsequently come away in the resulting fistula. My colleague, Prof. Nassau, removed successfully a pancreatic calculus.

Pancreatic Cysts.—Many forms of cyst may develop in the pancreas; the following are set forth by Robson and Moynihan: (1) Retention cysts; (2) proliferation cysts, including cystic adenoma and cystic epithelioma; (3) hydatid cysts; (4) congenital cysts; (5) hemorrhagic cysts; (6) pseudocysts. What we speak of as pseudocysts have already been considered in discussing effusions into the lesser peritoneal cavity. They result from lacerations of the pancreas (see page 1055). Retention cysts are due to blocking of the

pancreatic duct. Congenital cystic disease is extremely rare. Hemorrhagic cysts result from hemorrhage into the substance of the pancreas itself.

Symptoms.—Cysts are somewhat more common in men than in women. A cyst of the pancreas proper is more often met with in the head of the organ than in its body or tail. The cyst may be single or multiple. In its growth it either destroys the substance of the pancreas or it grows away from the pancreas and damages it but little. In some cases the cysts grow to a very large size; and Robson and Moynihan refer to a case in which the cyst attained the size of a man's head, and to another in which it was the size of a full-term pregnancy. A pancreatic cyst is smooth, round, elastic, and rather tense (Robson and Moynihan). The contained fluid varies greatly. As a rule, it is brownish-red in color; in 1 case upon which I operated it was clear yellow; in some cases it is milky, and in others it is nearly black. The fluid is always albuminous. Urea may be present, and in many cases pancreatic ferments are found. In most cases the cyst adheres so closely to the surrounding structures as to render extirpation practically impossible. A pancreatic cyst of considerable size causes epigastric discomfort, pain during digestion, and frequently vomiting. In some cases the pain is trivial, in others it is very violent. As a general rule, the patient is constipated, but sometimes diarrhea occurs, and the movements may even contain blood. If the tumor presses upon the common bile-duct, jaundice will develop. The patient loses flesh markedly and with considerable rapidity, and he becomes very weak. In rare instances fat is present in the stools, and in other unusual cases sugar is found in the urine. A test should always be made with salol, to see whether pancreatic ferment is present in the intestine (see page 1057). In the beginning the pancreatic cyst is behind the stomach; but it enlarges and, as a rule, pushes the stomach upward and to the right side, and the transverse colon downward. The cyst approaches the surface of the abdomen below the greater curvature of the stomach (Robson and Moynihan). The same authors tell us that in rare cases the cyst appears at the upper border of the stomach, and that in others it inserts itself between the layers of the transverse mesocolon. In a case upon which I operated it had worked its way through the subperitoneal tissue into the right loin, and was looked upon by Professor Montgomery and myself as a hydronephrosis. As a rule, the pancreatic cyst is immovable, but in rare instances it is movable. When a hand is placed in the loin and another on the abdomen, ballottement may be appreciated. If the distended stomach or colon overlies the tumor there will be a tympanitic percussion-note, but when the tumor reaches the abdominal wall there will be a dull percussion-note. On inquiring into the history of these cases it will be found frequently that there has been a severe injury to the upper abdomen.

Treatment.—Exploratory incision makes the condition clear. In the majority of cases the cyst is incised, emptied, and stitched to the wall of the abdomen. This operation may be done in two stages—first, exposing the cyst and fixing it to the abdominal wall; second, when adhesions have formed, opening it. As a rule, however, it is performed in one stage, the abdominal cavity being carefully protected by gauze. Some authors advocate exposing the cyst, opening and evacuating it through the abdominal wound, and draining through the loin. Complete extirpation is usually impossible because of the adherence of the cyst. If the cyst is movable, extirpation may be carried out, but the safest operation consists of incision and drainage.

Tumors and Other Growths of the Pancreas.—The pancreas may be affected with sarcoma, carcinoma, adenoma, tuberculous disease, or syphilis. Primary tumors are very rare. Billroth in 1884 removed an adenocarcinoma. Finney reported 1 case and collected 16 from literature which came to

operation ("Annals of Surgery," June, 1910). He says the diagnosis can only be made by exclusion and that in 25 per cent. of cases the mass is not fixed, but is movable. In Finney's series of cases there were 9 recoveries and 8 deaths. Wm. J. Mayo reports the successful removal of a cyst with sclerosed pancreatic tissue (Ibid., August, 1913).

Treatment.—Attempts have been made to remove tumors of the pancreas. After an exploratory incision has determined the condition the pancreas is exposed at the point at which the tumor projects. This is usually done by opening through the gastrocolic omentum. If the tumor is in the tail of the pancreas, however, the exposure may be effected in the flank. When the tumor has been exposed an attempt may be made to enucleate or resect it. Coffey ("Annals of Surgery," Jan., 1911) shows that ligation of the duct does not occlude it permanently. Tumors of the splenic portion of the pancreas have been removed. Total pancreatectomy or complete resection of the head of the gland should not be attempted.

In a large tumor of the head of the pancreas palliate the condition by cholecystenterostomy. Villar reports 13 cases of partial resection of the pancreas for tumors, with 5 recoveries from operation (French Surgical Congress of 1905). Finney's paper deals with 17 cases (see above).

Injuries and Diseases of the Spleen

Wounds of the Spleen.—A considerable wound of the spleen causes great hemorrhage and, if surgical aid is not soon at hand, will almost inevitably produce death. It is caused by a bullet or a stab and, as a rule, other viscera are also damaged. Immediate operation is indicated.

Rupture of the spleen (Fig. 621) is unusual if the organ be healthy, but does occasionally occur from crushes. It is rarely found unassociated with other injuries. The spleen may be dislocated as well as ruptured. An enlarged spleen is particularly liable to rupture not only from a crush, but from a kick, a blow, or a fall. Rupture of the spleen produces pain and rigidity in the left hypochondriac region and the signs and symptoms of intra-abdominal hemorrhage. There is tenderness over the spleen, pain over the heart, and great shortness of breath. The bleeding is profuse, but sometimes slow. The splenic blood contains numerous leukocytes and clots rapidly, hence the bleeding may be arrested for a time, and if it should be the patient will not bleed to death rapidly and reaction will generally occur (Ballance). The blood in some cases clots so rapidly that it gathers in the left loin, and is not commonly diffused throughout the abdomen. It gives rise to an increasing area of dulness on percussion in the left flank, which, Ballance points out, seldom shifts when the position of the patient is shifted, as it does in bleeding from other intra-abdominal structures. In some cases, however, the blood remains fluid and spreads throughout the belly, and then there is rising dulness in each flank. The cases reported by Le Dentu and Mouchet shows that the blood may remain fluid ("Bull. de l'Academie de Med.," June 16, 1903). In some cases the signs of hemorrhage are late and they may even be deferred until the fourth day (Eisendrath, "Annals of Surgery," Dec., 1902). In some cases there is violent pain in the left shoulder (*Kehr's sign*). Exploratory incision will be required to recognize the condition positively. In Elder's table there are 52 uncomplicated cases, not a case was operated upon (operation was not the rule until 1890), and 84.6 per cent. died. Eisendrath[1] has collected 50 cases operated upon: 56 per cent. recovered and 44 per cent. died. Février[2] has collected 56 ruptures of the spleen. In 46 cases operation was performed and the mortality was 50 per cent. E. Berger ("Archiv. für klinische Chirurgie," Bd. 28, Heft 3)

[1] "Jour. Am. Med. Assoc.," Oct. 25, 1902. [2] "Rev. de Chir.," Nov., 1901.

collected 168 fatal cases of rupture of the spleen: 145 died during the first day and every one of them died from hemorrhage. After the first day 23 died. In 90 per cent. of the entire series hemorrhage caused death; in 10 per cent. infection was responsible for death. Vedova collected 194 cases of splenectomy for traumatic rupture, with 65 deaths, a mortality of 33.5 per cent. ("Practical Medicine Series," vol. ii, 1913). Hemorrhage is the great danger in ruptured spleen—hemorrhage from the parenchyma rather than from the great vessels. The parenchyma is friable and contains multitudes of capillaries and veins, there is no muscular tissue, divided vessels do not tend to contract, and the capsule is thin (the elder Senn, in "Jour. Am. Med. Assoc.," Nov. 21, 1903).

Fig. 621.—Fauntleroy's case of ruptured spleen. External surface.

Treatment of Wounds and Rupture.—The treatment is evident from the previous remarks. It is as follows: Open the abdomen immediately, the patient being surrounded with hot bottles and hot salt solution flowing into a vein. Explore the spleen and other viscera. If the spleen is damaged, we may do splenectomy (total or partial), may use the suture, the cautery, or the tampon, and any other visceral injuries are, of course, attended to.

The usual operation has been total splenectomy. In partial splenectomy only the injured part is excised and the wound margins are sutured.

The arrest of hemorrhage by suture is known as *splenorrhaphy*. Lamarchia, in 1896, was the first to perform this operation. The tear or wound is sutured with catgut and the suture line is covered with omentum. Berger collected 14 cases of suturing, with 2 deaths, but these were injuries of less severity than those requiring splenectomy. In some cases the tampon can be used. Berger collected 10 cases, with 1 death. Another method is to crush the splenic structure slowly with broad forcipressure forceps and suture the crushed margins with catgut. Senn followed this plan. George Ben Johnston (paper read before Johns Hopkins Med. Soc., March 2, 1908) has collected 150 cases of splenectomy for wounds or ruptures, with 99 recoveries and 51 deaths, a mortality of 34 per cent.

Abscess of the spleen is a rare condition which is usually metastatic in origin. It may follow typhoid, may develop during pyemia, or may result from injury. Chronic suppuration may be due to tuberculosis or actinomycosis. Pain is felt, and enlargement is noted in the splenic region, and the symptoms of pyemia exist. The abscess may become adherent to the belly wall, may become encapsulated, or may rupture into a viscus or the peritoneal cavity. Fluctuation can seldom be obtained. What is known as a tropical abscess (Fontoynant and Jourdrau, in "Archiv. Prov. de Chir.," No. 11, 1902) may develop during a malarial attack as a result of severe exertion. There are severe pain in the left hypochondrium, dyspnea, and dry tongue. There may or may not be fever. The pus may be sterile.

The **treatment** of abscess of the spleen consists in incising the abdomen at the outer edge of the left rectus muscle, suturing the spleen to the abdominal

wall, opening the abscess, and providing for drainage (Tédenat[1]). If the abscess is adherent to the abdominal wall, incise it directly. Splenectomy has been performed for abscess. In 9 recorded cases of splenectomy for abscess there was 1 death (George Ben Johnston, paper read before Johns Hopkins Med. Soc., Mar. 2, 1908).

Enlargements and Tumors of the Spleen.—(See Royale H. Fowler, in "Long Island Med. Jour.," July, 1911.) The spleen undergoes hypertrophy in the course of infectious disease, from amyloid disease, from malaria, from splenic anemia, from tuberculosis, from leukemia, and from Hodgkin's disease. Secondary cancer is seen after cancer of the stomach. Genuine primary tumors are extremely rare. Fibroma, enchondroma, hemangioma, lymphangioma, angioma, and sarcoma occasionally develop. Jepson and Albert reported a case of primary sarcoma of the spleen and collected 31 others from literature ("Annals of Surgery," July, 1904). Primary carcinoma can only arise from fetal inclusion. It is usually medullary and is sometimes melanotic. Secondary carcinoma and secondary sarcoma are more common. Echinoccocus cysts, dermoid cysts, lymph cysts, serous cysts, and blood cysts occasionally develop. The spleen alone may suffer from hydatid disease. The liver is apt to be also involved. "There is but a single recorded case of a dermoid cyst. It was reported by Andral in 1830" (Royale Hamilton Fowler, in "Surg., Gynec., and Obstet.," August, 1910).

Non-parasitic cysts may be unilocular or multilocular.

A blood cyst is usually preceded by injury or an infectious disease. A serous cyst may result from a hemorrhagic cyst, and a blood cyst may be due to hemorrhage into a serous cyst (Fowler, Ibid.). There are on record 12 cases of splenectomy for sarcoma: 9 recovered and 3 died (George Ben Johnston, Loc. cit.).

Treatment.—The condition may become clear only after exploratory laparotomy. For some tumors splenectomy is indicated. A hydatid cyst is treated as is a hydatid cyst of the liver (see page 1034). A blood cyst is sutured to the incision in the abdominal wall and is drained.

Splenoptosis, or Wandering Spleen.—The spleen may wander into any part of the general peritoneal cavity. This condition is seldom met with except in women. It is most common in women who have borne children. A wandering spleen may undergo atrophy, engorgement, or axial rotation (Sir J. Bland-Sutton). The spleen may be healthy or enlarged from malaria or leukemia. As a matter of fact, it is usually diseased. The organ when displaced drags upon the stomach, producing dilated stomach; it may interfere with the bile-duct, causing jaundice; it may cause intestinal obstruction by forming adhesions, or may cause uterine retroflexion or prolapse by passing into the pelvis.

Sir J. Bland-Sutton[2] says this condition may endanger life, as it may lead to rupture of the stomach, intestinal obstruction, splenic abscess, or splenic rupture. A wandering spleen can be identified by the fact that it has a notch upon its edge, and can be pushed about the abdomen. When the spleen wanders it may be missed from its normal situation. Always examine the blood in order to determine if leukemia or malaria exist.

Treatment.—Greiffenhagen advocates suturing the organ in place (*splenopexy*). Most surgeons prefer to perform splenectomy. In a case without leukemia the operation is very successful. Splenectomy for wandering spleen is rarely followed by serious blood changes or other trouble. The reason is that a wandering spleen is usually a diseased organ, having undergone hypertrophy or fibroid change, and other structures have taken on splenic function.

[1] "Rev. de Gynéc. et de Chir. Abd.," July, August, 1901.
[2] "Brit. Med. Jour.," Jan. 16, 1897.

Splenectomy should not be undertaken if leukemia exists. In such a case surgeons usually apply a support and employ medical treatment for the existing disease, but some endeavor to suture the organ in place. If the wandering spleen were enlarged by malaria, I would perform splenectomy. If the spleen were healthy I would surround it with gauze exactly as is done with the kidney in a case of movable kidney. If the spleen were enlarged by leukemia I would not operate at all.

Operations Upon the Abdomen

Abdominal Section (*Celiotomy; Laparotomy*).—There are many different methods of opening the abdomen. The plan selected depends upon the nature and the situation of the disease, and upon the inclinations and the custom of the operator. The abdomen may be opened to attack a recognized seat of disease or injury or to determine what the disease or injury is and where it is situated. Abdominal section performed for the latter purpose is spoken of as exploratory section or exploratory incision.

An incision should not be unnecessarily lengthy, but it should be long enough to permit of thorough exploration and rapid and safe work. A very lengthy incision favors visceral prolapse and renders the patient liable to hernia. Again, a lengthy incision requires longer to suture than a short one, and so operation is prolonged. James E. Moore protests against too small incisions, which are often made as a matter of pride ("Jour. Am. Med. Assoc.," Sept. 16, 1911).

Of recent years exploratory operations have become extremely common, and many abdominal conditions would be unrecognized without such exploration, or would be recognized at so late a period as to be beyond the reach of surgery by the time the diagnosis had been made. This is notably true of the surgical diseases of the stomach. The wise surgeon will not be too radical in employing exploratory operations. The fact that he can explore with such comparative impunity does not release him from the obligation to endeavor by every proper method to make a diagnosis before resorting to operation. I fancy that of recent years the belief that it is almost waste of time to make prolonged efforts to diagnosticate many intra-abdominal troubles because the solution is so much easier by section, has become so common as to have led young and unskilled operators to perform section in cases in which the diagnosis might have been made without this procedure.

Before opening the abdominal cavity for exploratory purposes or to gain access to some area of abdominal or pelvic disease the patient is carefully prepared as for any other operation. In an appendicitis case the patient is moved with the utmost care and is prepared for operation most gently, because of the possible danger of rupturing an abscess. In an emergency case no prolonged or complicated method of cleansing can be employed. The abdomen and loins are scrubbed carefully with soap and water, special attention being given to the umbilicus; the pubic region is shaved, the soapsuds are washed away with sterile water, the surface is gently scrubbed with alcohol and then with a hot solution of corrosive sublimate (1 : 1000), and is covered with gauze wet with the sublimate solution. In emergencies the iodin method can be used after dry shaving (see page 68). As previously stated (see page 67), we no longer regard it as necessary to "prepare" the abdomen the day before. The patient can be prepared antiseptically the morning of the operation, or can be shaved just before etherization, and be cleaned when under ether. The instruments required depend upon the nature of the case. Have at hand an electric light and appliances for throwing salt solution into a vein. Always have the instruments, sponges, and pads counted twice by two people, write down the number, and have two people count them twice after operation. This rule is adopted so that no instrument, sponge, or pad

will be left in the abdomen. Some surgeons do not use abdominal pads and sponges when dry, believing that dry gauze injures the peritoneum and favors the subsequent development of adhesions (Sanger). Believers in this hold that pads and sponges should be wrung out in hot normal salt solution before being used. I find moist pads and sponges satisfactory, but moist packs cannot be satisfactorily adjusted. If dry packs are used, dry pads and sponges may as well be.

Operation.—An anesthetic is given. In some cases the patient is placed recumbent; in others, is put in the *position of Trendelenburg* (Fig. 622). In the Trendelenburg position the pelvis is elevated, the intestines fall toward the epigastrium, are removed from the necessity of being handled and from the danger of being bruised, the pelvis is thoroughly exposed, and pelvic work becomes easier and safer. This position should not be used if there is myocardial disease, as the increased pressure in and flow of blood from the inferior cava may cause fatal acute dilatation of the heart (Kraske, of Freiburg, in "Proceedings of German Surg. Congress," 1903). The position is of little use in very fat people (Trendelenburg), and in such subjects may cause intestinal obstruction (Kraske). When this position is employed, the table should be lowered as soon as possible, because gastric hemorrhage may occur (von Eiselsberg). The normal position should not be suddenly assumed, as this may cause intestinal obstruction, the omentum being mixed with coils of intestine, pulling the colon down (Pasteau, in "Bulletins and Mém. de la Soc. Anat. de Paris," July, 1905). The position should not be used in a pelvic abscess (König), as it may lead to a flow of pus from the pelvis into the far more dangerous regions above.

Volvulus or kinking of the ileum and of the large intestine have followed the use of the position. If the Trendelenburg position was employed, before closing the belly return the omentum to its proper position and spread it out (Lauenstein). In every abdominal operation the patient is to be carefully protected from cold, the extremities and the chest are covered with blankets, and sterilized sheets are placed well around the field of operation. The skin is sterilized anew immediately before operating. The surgeon steadies the skin of the belly with the fingers of his left hand, and, holding the knife free in the right hand, makes an incision. For purposes of exploration the incision is made about 2 inches in length, and it is lengthened if it is found necessary. The abdomen may be opened in the median line above or below the umbilicus. This incision is advantageous for operations on the pelvis, for general exploration, and for certain procedures upon the stomach, the intestines, and the left lobe of the liver. The closure of such an incision, however, lacks strength, as compared with the closure of an incision where strong muscles will overlie the scar through the peritoneum and the transversalis fascia. Incision through the semilunar line is practised by a number of operators. A favorite incision is through the rectus muscle. The fibers of this muscle are separated, the structures beneath it are divided, and, after the completion of the operation, the deeper structures are sutured and the parts of the separated muscle are allowed to fall together. The scar resulting from such an incision is well supported and solid, hence the likelihood of hernia developing is diminished. A favorite method with some is to open the sheath of the rectus muscle, retract the entire muscle aside, incise the posterior portion of the sheath and the structures back of it, and, when the operation has been completed, allow the entire muscle to come back into place, thus strengthening the deep-seated scar. When the abdominal trouble is in a region that

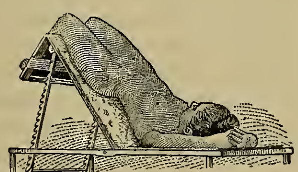

Fig. 622.—The Trendelenburg position.

admits of it, I almost invariably go through the rectus muscle or retract the entire muscle. Besides these methods, there are special incisions, suitable for particular cases: An incision along the costal margin, for reaching the gall-bladder; an incision shaped like the italic letter *f*, for the same purpose; special incisions for certain operations upon the stomach, for abdominal nephrectomy, etc. Some operators have even used a transverse incision in certain pelvic operations. (A full discussion of abdominal incisions will be found in an article by R. E. Farr, "The Journal Lancet," Nov. 1, 1912).

In an operation through the median line the first cut goes to the aponeurosis of the external oblique muscle. Clamp the vessels. Do not hunt for the linea alba below the umbilicus, but go right through or between the recti muscles. Above the umbilicus the linea alba is very distinct and the surgeon often cuts through it. Divide the transversalis fascia, beneath which is a little fat, and expose the peritoneum. The latter structure is recognized by its glistening appearance, by the ease with which it can be pinched up between the finger and thumb, and by the readiness with which its opposed surfaces may be made to glide over each other. On identifying the peritoneum, catch it at each side of the incision with forceps, raise a fold, nick it with a knife, and open the layer by scissors to the length of the external wound. To prevent stripping of the peritoneum a good plan is to anchor it to the belly wall with a stitch on each side of the incision. Through the wound thus made the abdomen and its contents are explored, the trouble located, and determination made as to whether or not further operation is advisable, and, if it is advisable, what form it shall take. It may be necessary to enlarge the wound. This is done by placing the index and middle fingers of the left hand in the belly, with their pulps against the peritoneum, in the line where the surgeon will cut, to serve as supports to the scissors and as guards to intraperitoneal structures. The scissors are introduced and the wound is enlarged upward or downward, going around the umbilicus if necessary. As soon as the incision is complete for work in the lower abdomen or pelvis it is a good plan to push a large pad into Douglas's pouch and leave it there until the operation is finished, when it must be removed. Slender adhesions are stripped off with the finger or are pushed off with gauze; firm adhesions are tied in two places and cut between the ligatures.

The *toilet of the peritoneum* is important after the operation is completed. Following a clean laparotomy, when but little blood has flowed into the cavity, flushing is not required; if much blood has flowed or if septic matter has passed into the peritoneal cavity, after removing the pad from Douglas's pouch flush the belly thoroughly with hot normal salt solution. In a clean case empty out most of the fluid, but let a pint or more remain in the abdomen. In flushing the abdomen bear in mind Monks's observations as to the mesentery. It is a sort of shelf. If we follow down the left side of it with the finger the finger must enter the left iliac fossa; if we follow down the right side of it the finger must enter the right iliac fossa. Hence in order to flush the right cavity carry the nozzle down the right side of the mesentery to its root, and in order to flush the left fossa carry it down the left side of the mesentery to the root (Monks, "Annals of Surgery," Oct., 1903). The retention of the saline fluid in the belly minimizes shock. It is absorbed with great rapidity after the operation if the patient is placed with his head lower than his feet, because in this position the saline fluid gravitates to the diaphragmatic region, where absorption is very active; in fact, in one hour the peritoneal cavity can absorb from 3 to 8 per cent. of the body weight. If there is widespread infection with stomach contents or feces, eviscerate, wipe out the peritoneum with pads soaked in hot normal salt solution, and wipe the intestines carefully, slowly returning them as they are wiped. Extravasated septic matter is apt to collect in the peritoneal

fossæ and between the liver and diaphragm, and these regions must be carefully wiped and irrigated. In cases of septic and purulent peritonitis, flushing, evisceration, and wiping with gauze are not advisable (see page 1024). In some cases it is desirable to drain through a lumbar incision. Rutherford Morison has pointed out that a lumbar opening into the right kidney pouch will drain a fossa which holds over a pint of fluid, and which, when the patient is recumbent, is the most dependent portion of the peritoneal cavity. In some cases a drainage-opening is made through the linea alba, through one side or on each side of the belly, or above the pubis or through the vagina. In septic cases it may be advisable to drain with several pieces of iodoform gauze instead of inserting tubes. After most laparotomies drainage is not needed, but it should be used when stomach contents were extravasated, and it must be used if feces or urine were extravasated, in certain recent septic cases, and when hemorrhage has been severe. We may drain by a rubber tube, strands of gauze, a cigarette drain, or a glass tube. If a glass tube is used, it is introduced at a lower angle of the wound and reaches the bottom of the pouch of Douglas. The tube is repeatedly emptied during the progress of the case by means of a syringe. Before closing the wound arrest hemorrhage and ask for the count of the instruments and pads in order to know that nothing foreign has been left in the belly.

It is highly important that an abdominal incision shall be accurately closed, for any failure of neat approximation will, in all probability, result in the formation of a hernia through the cicatrix. Various methods have been employed. Probably the majority of operators use layer sutures. sewing up the peritoneum with a continuous suture of catgut, and the aponeurotic layers with the same material or with chromicized catgut, and closing the skin with either interrupted sutures of silkworm-gut or a subcuticular stitch of catgut, silkworm-gut, or silver wire. Other operators close the peritoneum with a continuous suture of catgut, then pass silkworm-gut sutures through all the other structures, leaving them for the time untied; put in and tie layer sutures of catgut or of chromicized catgut, and then tie the silkworm-gut sutures. A layer suture makes a beautifully neat approximation, and is frequently quite satisfactory; but I have become persuaded that the dead space, so often left unobliterated when this method of suturing is employed—a space in which blood and inflammatory exudate may gather—is a danger to the future integrity of the wound. The combination of a dead space with catgut, a material that is always somewhat uncertain, is an unfortunate one from the surgical point of view. I have returned in many cases to the use of the through-and-through suture, applied according to the method of the late Dr. Joseph Price. This suture is inserted with the straight needle, is composed of silk or of silkworm-gut, is put in close to the margin of the skin, gathers up a great deal more muscle than skin, and then passes close to the margin of the cut peritoneum and transversalis fascia. When these sutures are adjusted the peritoneal edges are brought into accurate and firm apposition, the peritoneal surface is overlaid with abundant muscle, the skin edges are brought into neat approximation, and the formation of a dead space is rendered impossible. When passing the sutures have a gauze pad under the wound and be very careful not to include bowel or omentum in the stitches. It is necessary to tighten and tie most carefully to prevent omentum being caught in the loop of the stitch. After closing a laparotomy wound, dress with aseptic gauze and apply a flannel binder. In badly infected cases the wound is often kept open.

If a 2-inch incision has been closed without drainage and primary union has taken place, the patient can usually get out of bed in seven or eight days. A large incision offers greater danger of subsequent hernia, and the patient should be kept in bed for two or three weeks. If the wound has been kept open

for drainage, a prolonged retention in bed may be necessary. I get patients up at an earlier period than used to be my custom, but I do not get them up as do Kümmell and others in from one to three days (Kümmell, in "Zentralblatt f. Chirurgie," 1908). To get them up reasonably early lessens constipation, favors an early return of appetite and strength, and diminishes the risk of postoperative thrombosis and embolism and of bronchitis. We must bear in mind that if there is myocardial degeneration very early getting up may prove disastrous or even fatal, and that in septic diseases there is often myocardial degeneration (E. W. Foote, in "Progressive Medicine," June, 1909). In a case in which an incision of considerable length has been made, an abdominal support should be worn for a variable time. It limits the movements of cough, laughter, etc., and *reminds* the patient of the necessity of caution in lifting, hurrying, etc.

The **after-treatment** depends somewhat on the case, but certain general rules can be laid down. The late J. Greig Smith said many wise things, and among them this: "A golden rule in the treatment of cases of celiotomy is to let the patient alone. Everything approaching to meddlesomeness is to be condemned. The patient must not be upset by fussy applications of tentative therapeutics; when an emergency arises, it is to be met, promptly and decisively, by a method which has been approved trustworthy" ("Abdominal Surgery"). In many cases immediately after the operation the patient must be treated for shock by methods previously set forth. The treatment of vomiting resulting from the administration of an anesthetic is discussed on page 1202. If vomiting persists during the third or fourth day it may be due to acidosis, but is probably due to the development of inflammation which has caused intestinal paresis; and if it is so produced, medicine is practically useless. In this condition there is usually marked tympanitic distention, and vomiting is, in a sense, a relief. Nothing should be given by the mouth and the patient should be fed entirely by enemata. The insertion of a rectal tube and its retention for a considerable time may afford relief. Lying on the side is more comfortable than recumbency. Washing out the stomach from time to time gives great comfort and is often of real service.

In the average case of celiotomy, in which persistent vomiting does not occur, the question of feeding is of much importance. Usually, for the first twelve or twenty-four hours, nothing is given by the mouth but small quantities of hot water. The day after the operation, if everything is satisfactory, food is given to the patient. In many cases, however, food is not given by the stomach for forty-eight hours and the patient is fed by the rectum during the wait. He should not be given milk because it will not be easily digested, may lead to nausea, and causes flatulence. Peptonized milk, if the patient will take it, does not possess these hurtful qualities. At first albumin-water or liquid beef peptonoids should be given, and later meat-juice, beef-jelly, broth, etc. Food is given every third or fourth hour, and stimulants are administered if required. After the first twenty-four or forty-eight hours considerable quantities of plain water or Poland water should, if possible, be taken, to favor elimination by the kidneys. Hot coffee is not only a stimulant, but is an excellent diuretic. The urine is always scanty after an abdominal operation, and a normal daily amount is not voided for ten days or more. Solid food is not given for seven or eight days. The patient is apt to suffer greatly from thirst, in spite of the hot water given during the first twelve to twenty-four hours. He seldoms takes and should never have any great amount of hot water, and iced water and ice are inadmissible and tend to induce nausea and vomiting. Sucking ice or sipping water draws air into the stomach and causes distention. Thirst can be much mitigated by enemata of salt solution. J. Greig Smith recommended an enema composed of from 4 to 20 oz. of tepid

water and some brandy. Usually, after the first twenty-four hours, a sufficient amount of liquid can be given to keep the patient free from actual distress.

The bladder must be watched to see that retention does not occur. If retention occurs, a clean catheter must be used at regular intervals. If tympanitic distention occurs after forty-eight hours, a saline purgative should be given and it should be followed by an enema of turpentine. The rectal tube is frequently of signal service in such cases. If obstruction develops, it is treated as directed on page 989.

In any ordinary case after operation the bowels should be moved after forty-eight hours as a prophylactic measure against distention, peritonitis, and obstruction. From four to eight 1-dram doses of Epsom salts are given, in hot water, the solution having been filtered through gauze. The saline is followed by the administration of an enema consisting of soap, water, and $\frac{1}{2}$ oz. of castor oil. Should opium be given? Never as a routine, and not to secure sleep; but if the patient is in pain which not only harasses him, but causes him to turn and shift in torturing restlessness, one or possibly two hypodermatic injections each containing $\frac{1}{4}$ gr. of morphin can be given with confidence that the good will overbalance the harm.

Operation for Appendicitis.—Before operating try to locate the situation of the appendix, and the relation the area of infection bears to the ascending colon. The incision should be over the seat of disease. In the rare left-sided cases and in median cases the incision is median. In some cases in which the appendix is posterior the cut may be in the loin. In 1 case I opened a purulent collection through the rectum. In the vast majority of cases the incision is made in the right iliac region.

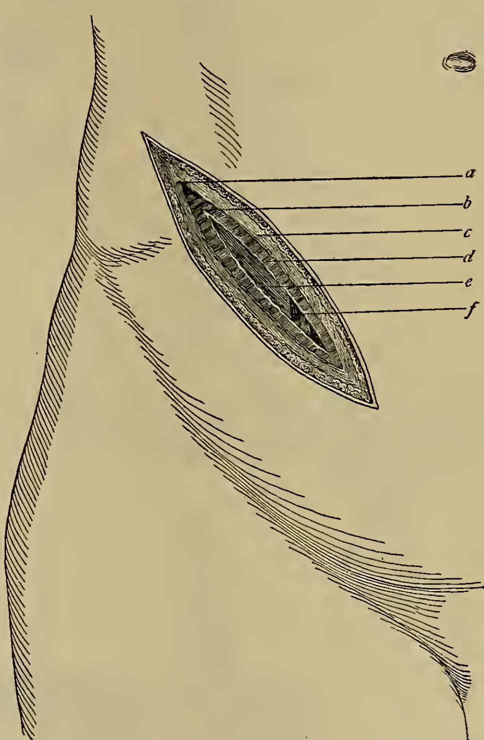

Fig. 623.—Resection of the vermiform appendix, incision through the abdominal wall: *a*, External oblique muscle; *b*, internal oblique muscle; *c*, aponeurosis of external oblique; *d*, aponeurosis of internal oblique; *e*, peritoneum; *f*, outer border of rectus abdominis muscle (under it the deep epigastric vessels) (Kocher).

In acute appendicitis, when there is not thought to be a distinct abscess, the incision usually made is 2 inches internal to the anterior superior iliac spine and perpendicular to a line drawn from the spine to the umbilicus (Fig. 623). The skin incision is usually 3 inches in length, the upper third of the incision being above the omphalospinous line; the incision in the peritoneum is about 2 inches in length, but if there are many adhesions, it may be necessary to make it much longer. The oblique incision may be carried out as advised by McBurney, the muscles being separated by blunt dissection. By this method very few nerve-fibers are divided, and hence the operation is not followed by marked muscular wasting, a condition which strongly predisposes to hernia.

Further, as Van Hook[1] points out, the oblique incision enables the surgeon to reach freely all the ordinary areas of appendix trouble, the wound is parallel with the lines of traction of the abdominal muscles, and does not tend to gape widely. In an acute case I make an oblique incision, but cut the muscles

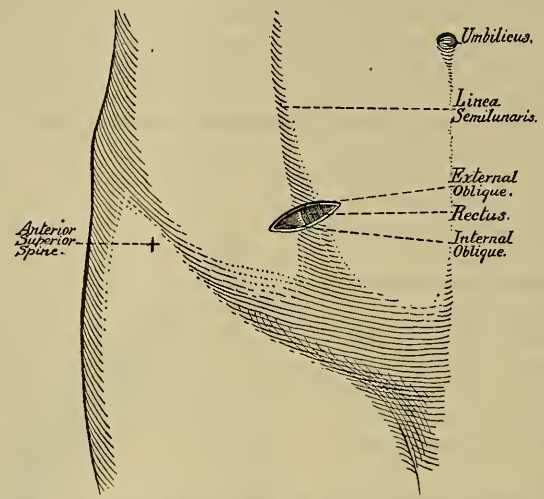

Fig. 624.—Davis's small transverse incision for simple cases.

(Fig. 623). In an interval case I separate the muscular fibers. Battle's incision at the outer edge of the rectus muscle is preferred by many surgeons. The anterior layer of the rectus sheath is opened longitudinally, the rectus is drawn

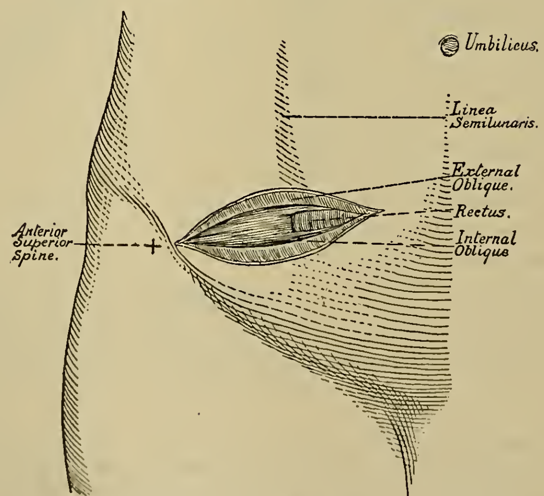

Fig. 625.—Davis's large transverse incision for difficult cases.

inward, and any existing portion of the posterior rectus sheath with the transversalis fascia and peritoneum is incised.

I have used *Davis's transverse incision* (Figs. 624 and 625) in many interval cases with entire satisfaction (Gwilym G. Davis, in "Annals of Surgery," Jan.,

[1] "Jour. Amer. Med. Assoc.," Feb. 20, 1897.

1906). This incision does not divide arteries, but it divides the deep muscles in the direction of the nerves, hence the nerves are not injured. The center of this incision is almost over the base of the appendix. Davis describes his incision as follows:

"*For easy cases* the incision is made directly transverse, $1\frac{1}{2}$ inches long. Its center is to be on the semilunar line on a level with the anterior superior spine. The aponeurosis of the external oblique is divided in the line of the skin incision, but obliquely to the direction of its fibers. The fibers of the internal oblique and transversalis muscles are parted—not cut—in the same line as the structures above. The peritoneum is then opened and the incision is carried inward, first through the anterior layer of the sheath of the rectus. A blunt retractor $\frac{3}{4}$ inch wide is then inserted and the muscle drawn toward the median line. This exposes the transversalis fascia and peritoneum posteriorly, which are then also divided. Thus is obtained a triangular opening with its base of $\frac{3}{4}$ inch and two sides of about 1 inch long, which is ample for simple cases.

"*For Difficult Cases.*—If the case is a difficult one, the outer end of the incision is prolonged to the anterior spine or even above and inwardly through the sheath of the rectus to within 1 inch of the median line. This will give an opening 4 to 5 inches long, according to the size of the patient, sufficiently large to insert the hand if necessary and through which the appendix can be extracted under almost all circumstances."

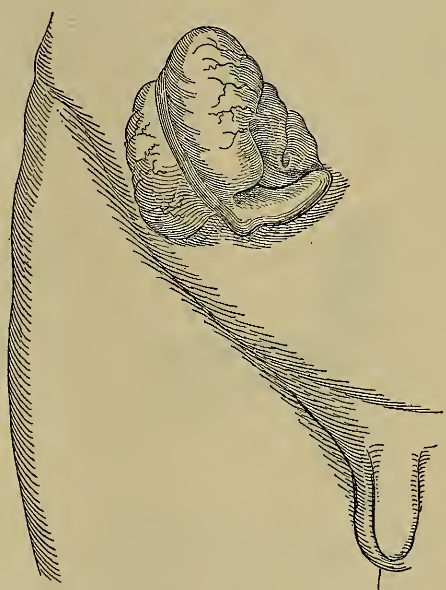

Fig. 626.—Radical operation for appendicitis (Kocher).

After opening the peritoneum examine very gently to detect the situation of the appendix, and if there are or are not adhesions. In a very recent case and in a very acute case there will probably be no adhesions unless there have been previous attacks. Surround the region of infection with packs of plain gauze, each strip being $2\frac{1}{2}$ inches wide, 15 inches long, and four layers in thickness. The edges of the wound should be lifted up by retractors and the strips inserted around the cut, between the parietal peritoneum and intestines and to a distance of 3 inches from the wound. Strips of gauze are passed, when possible, below the appendix to prevent entrance of infected material into the pelvis, and a piece is pushed upward toward the liver (Van Hook). Over the packing gauze, which it may be necessary to leave in place after the operation, other pads are packed. The appendix is sought for by finding the colon. The colon is found by following the parietal peritoneum with the finger. The course of the finger is first outward, next backward, and finally inward; the first obstruction it encounters is the colon. The fact that it is the colon can be confirmed by finding the longitudinal bands. The anterior longitudinal band leads directly to the appendix. Pass the finger down to the head of the colon, find the appendix, usually posterior and internal, and lift it and the head of the colon into the wound. In many cases it will be advisable to deliver the head of the colon from the belly (Fig. 626); in other cases this will not be

necessary, in some it will not be possible. If adhesions exist, they must be gently and carefully separated. Barker's method (Fig. 627) is a very satisfactory mode of removing the appendix. It is done as follows: Turn up a cuff of peritoneum, pull down the other coats, ligate at the base, cut through the tube, let the musculomucous stump retract, and tie or suture the peritoneal cuff over the stump. Another method, which is the one I usually employ, is as follows: Pass a ligature through the meso-appendix, as shown in Fig. 628, *A*, tie the ligature, and cut off the meso-appendix below the threads. Crush the stump of the appendix with strong straight hemostatic forceps. This divides the mucous membrane, submucous tissue and muscular coat, and leaves the peritoneal coat undivided. Remove the forceps. Surround the appendix with a catgut ligature and tie the ligature in the groove produced by the crushing. When the ligature is tied, peritoneum is brought against peritoneum. Cut off the appendix between the ligature and a clamp by the cautery, a knife, or scissors. Disinfect the stump of the appendix by pure carbolic acid. The stump beyond the ligature contains mucous membrane and muscle, which are lifted out with forceps and scissors. Suture the fringe of the meso-appendix, invert the stump into the wall of the colon, and suture a portion of the wall over it by inversion stitches. Figure 628 shows an older method still used by many. The meso-appendix is

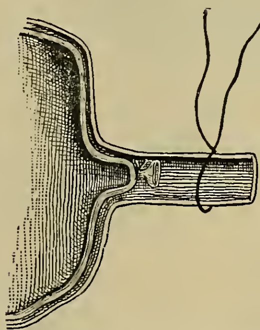

Fig. 627.—Barker's technic of operation for removal of the appendix.

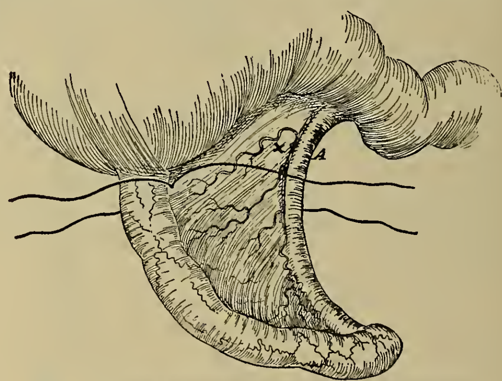

Fig. 628.—Ligation of appendix and meso-appendix.

tied off by one ligature, the appendix is not crushed, but is tied off by another ligature, and both structures are cut off below their respective ligatures. The stump is disinfected with pure carbolic acid or the cautery, inverted, and the fringe of the meso-appendix is sutured. This method does not entirely remove the appendix, but inverts glandular tissue into the wall of the bowel. The stump may not be completely asepticized by the carbolic acid and hence may lead to postoperative abscess, dense adhesions or fecal fistula, or the undestroyed lymphoid structure may cause further trouble, even persistent ill health (Joseph Price). Some remove the appendix by an elliptical incision around its base, and close the colon wound by Lembert sutures. This method, of course, removes the appendix completely. Dawbarn surrounds the appendix with a continuous Lembert purse-string suture of silk. This is inserted in the superficial layers of the cecum, $\frac{1}{2}$ inch from the appendix. The appendix is divided so as to leave a stump never shorter than $\frac{1}{2}$ inch. The lumen of the stump is gently stretched by inserting a pair of mouse-toothed forceps and opening the blades. The stump is then invaginated into the cecum, that is, it is turned "outside in." The sutures are tightened, and while this is being done, the mouse-tooth forceps used in effecting inversion are withdrawn. Finally, the sutures are tied (Robt. H. M. Dawbarn, in "Internat. Jour. of

Surg.," May, 1895). In this method the stump is not ligated and hemorrhage is liable to take place into the gut. Deaths from such hemorrhage are on record. The retained bit of appendix drains into the colon. I believe it is a mistake to trust to simple ligation and to fail to bury the stump left after appendectomy. If a surgeon follows this plan in any large number of cases he will now and then have a case in which the ligature slips and feces pass into the peritoneal cavity, or cases of temporary fecal fistula, or cases of intestinal obstruction from adhesion of some portion of the bowel to the exposed stump (Murat Willis, in "Annals of Surgery," July, 1908). I do not believe that a a buried stump increases postoperative pain.

If there is no pus and no extravasated feces, if the peritoneum is not seriously affected, if the appendix is not gangrenous or perforated, and if there is no pus within the appendix, remove the pads which were inserted last, irrigate with hot salt solution, remove the strips of gauze which were inserted first, and close the wound. If any of the above conditions were found, remove the infected pads, but leave in place the strips which were first inserted in order to limit infection and secure drainage. Pass sutures through wound edges, tie some of them and leave some untied until gauze is removed at a later period (Van Hook).

If an operation is performed in a distinct interval, pus is absent and the surgeon can proceed without apprehension. If there is any question of the presence of pus, surround the region with gauze, as suggested above, before breaking down adhesions and liberating the appendix. An interval operation should not be performed until three weeks after an attack. In an interval case McBurney proceeds as follows: He makes the skin incision in the direction of the fibers of the external oblique muscle, separates the fibers of this muscle by blunt dissection, retracts them, separates the fibers of the internal oblique and the transversalis muscles in the same way and retracts them, and opens the transversalis fascia and peritoneum. No muscle-fibers are cut and hernia is not apt to follow. Such a wound is closed as follows: a continuous catgut suture for the peritoneum, sutures of chromic gut for the transversalis fascia, the muscles are restored to place, the aponeurosis of the external oblique is sutured with chromic gut, and the skin is closed by interrupted sutures of fine silk or silk-worm gut or by a subcuticular stitch.

If an *abscess* is believed to exist, make an incision parallel with Poupart's ligament and over the area of dulness on percussion (Willard Parker's oblique incision). If the abscess is adherent to the anterior abdominal wall such an incision will not enter the free peritoneal cavity. If, after opening the abdomen, an abscess is thought to exist, although it is not adherent to the anterior abdominal wall, surround the abscess with gauze before opening it, as directed under acute appendicitis. The gauze is placed under the margins of the incision in the peritoneum all around the appendix area; a piece is carried toward the pelvis and another piece toward the liver. Overlay this gauze with gauze pads (Van Hook). Adhesions are broken through with the finger, and when pus appears it is at once wiped away. Remove the appendix in most cases, but not in all. If the appendix lies loose in the abscess cavity, if it is sloughed off or but loosely attached to the abscess wall, remove it. If the appendix is firmly fixed in the abscess wall and must be dug out of a mass of inflammatory material do not remove it. To remove it under these circumstances may rupture the wall and disseminate the pus into regions not protected by pads and gauze. Deaver and others tell us always to remove the appendix. I do not believe this to be a safe rule to follow. To insist on removing the appendix may cause death. When the appendix is left it usually sloughs away. It is true, a fecal fistula may result, but this is in the large bowel and usually heals spontaneously. Even if a fecal fistula forms and does not heal, the surgeon acted properly in not removing the appendix, be-

cause a fecal fistula may be remedied by another operation. It is rarely that secondary abscess forms, and there are not a great many cases recorded in which an appendix has subsequently given serious trouble when left after operation. In fact, in many cases the appendix is destroyed or obliterated by inflammation. In some cases, however, a secondary operation will be required because of a fecal fistula, a persistent sinus, or an acute inflammatory attack. When Deaver decides to remove such an appendix, he makes an incision in the median line of the abdomen, packs around the periphery of the abscess with gauze, opens the abdomen by another incision, removes the appendix, disinfects, inserts drainage, and then removes the surrounding gauze and closes the median incision. In every abscess case search for fecal concretions and remove them if found. Irrigation should not be employed in appendicular abscess. The force of the stream may break down barriers of lymph and spread infection. After the evacuation of the pus, whether the appendix was removed or not, take out the pads, but leave the long strands of gauze first placed to keep the wound open. Introduce iodoform gauze into the abscess cavity and insert a rubber tube, partially suture the wound, and dress with dry gauze. In forty-eight hours all the strands of gauze are removed and fresh pieces are inserted for drainage. After this period the gauze drain is changed daily. Morris maintains and proves that large pieces of gauze sometimes cause intestinal obstruction and iodoform gauze sometimes causes iodoform-poisoning, but the risk, it seems to me, should be taken. An interval case should be up and about in from ten days to two weeks after operation. An abscess case may require a much longer time for complete recovery. A fecal fistula sometimes results in cases in which the appendix was not removed, and occasionally forms when it was removed.

If on opening the abdomen pus is found, unlimited by adhesions but widespread in the peritoneal cavity, remove the appendix, and then bear in mind Murphy's wise counsel as to how to treat general peritonitis (see page 1025). Put a drainage-tube into the pelvis and one in the appendix region, place the patient in Fowler's position, and administer salt solution by continuous proctoclysis at a low pressure. The after-treatment of an ordinary appendix operation is that advised after celiotomy (see page 1070).

Mortality After Operations for Appendicitis.—The interval operation is practically without mortality. In over 1000 cases Treves had 2 deaths. In 446 cases of chronic appendicitis the Mayos had 1 death ("Report of St. Mary's Hospital for 1912"). In grave acute cases the mortality is large. In 100 consecutive cases of this character collected by Hearn and operated upon in the Jefferson Hospital by Keen, Hearn, and DaCosta, there were 8 deaths. As previously stated, Maurice H. Richardson reported a death-rate in such cases of 18 per cent. in 750 cases. Deaver reports from the German Hospital 144 cases, with a mortality of 17.8 per cent. He eliminates 1 death from diabetes, 1 from pneumonia, and 1 from phthisis, and estimates his personal mortality at 15.9 per cent. (Deaver and Ross, in "Jour. Am. Med. Assoc.," Oct. 5, 1901). In 124 cases (including all chronic cases and those acute cases in which the inflammation had not extended beyond the peritoneal coat) there was 1 death. In 347 cases of acute and suppurative appendicitis operated upon in the Mayo clinic in 1912 there were but 2 deaths ("Report of St. Mary's Hospital for 1912"). I fancy most of these cases came from a distance and hence the proportion of violent and rapid cases must have been less than is usually the rule in a great city In Burgess's 500 consecutive operations there were 40 deaths ("Brit. Med. Jour.," Feb. 24, 1912). When infection was limited to the appendix the mortality was .74 per cent (135 cases); when there was circumscribed abscess it was 4.64 per cent (213 cases); when there was diffuse spreading peritonitis it was 19.07 per cent. (152 cases). The usual causes of death are

intestinal obstruction, septic peritonitis, septic endocarditis, pylophlebitis, hepatic suppuration, metastatic abscesses, endocarditis, and gangrene of the bowel. In a further report from September 1, 1902, to September 1, 1903, Deaver reports 566 cases in the German Hospital, with an aggregate mortality of 5 per cent. In cases with diffuse peritonitis the mortality was 31 per cent. In abscess about a necrotic and perforated appendix it was 12 per cent. In early appendicitis or when disease was confined to the appendix it was 0.8 per cent. In 107 cases of circumscribed abscess in which Burgess removed the appendix the mortality was 1.86 per cent. In 106 cases in which he did not remove the appendix it was 7.54 per cent. ("Brit. Med. Jour.," Feb. 24, 1912).

Appendicostomy (Weir's Operation).—This operation was devised by Weir, of New York, in 1902. It consists in opening the abdomen, finding the appendix, fastening this structure to the skin, closing the rest of the wound, opening the appendix to see that it is patent, and applying a temporary ligature to prevent leaking. The temporary ligature is removed in a day or two, and a few days later the adherent and open appendix is used as a route for the introduction of irrigating fluids. The operation is of the greatest value in chronic ulcerative colitis, as it enables us to irrigate thoroughly the large bowel. Daily a large tube is passed into the rectum and a small tube into the appendix. The fecal matter is washed out of the bowel through the rectal tube by salt solution, and then a 1 : 5000 solution of silver nitrate or

Fig. 629.—Eye of the calyx-eyed needle.

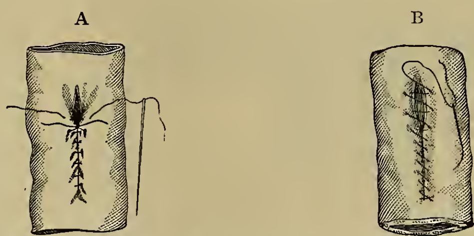

Fig. 630.—Enterrorrhaphy: A, Lembert suture; B, Dupuytren's suture.

bismuth and starch water (1 dram to 1 oz.) is used to irrigate the colon. It is injected by way of the appendix and it runs out of the rectal tube. It is used for the same purpose in some cases of tuberculous rectal or anal fistulæ. A most extraordinary suggestion is that appendicostomy be performed in epileptics, so that the opening may be used to flush the bowel, a suggestion which I will not act upon. When the fistula exists, it does not leak to any appreciable degree. When we wish to close it we insert within the lumen of the tube the Paquelin cautery at a red heat. This destroys the mucous membrane and the fistula closes (Robt. Weir, in "Med. Record," August 9, 1902).

Enterorrhaphy, or Suture of the Intestine.—Surgical opinion has greatly altered in regard to this operation since the day when John Bell wrote his famous attack on Benjamin Bell. John Bell said: "If in all surgery there is a work of supererogation, it is this operation of sewing up a wounded gut." To-day we know that if in all surgery there is a proceeding of imperative necessity, it is the sewing up of a wound in the intestine. To perform this operation take fine sterile silk and thread a thin, round, straight, calyx-eyed needle with it (Fig. 629). The needle is very useful, as it can be threaded rapidly by pushing the calyx eye down upon the silk thread while the latter is kept taut. *Lembert's suture* (Figs. 630, A, 631, and 632) was devised in 1823. Lembert used it on animals, but never on man. It is inserted at right angles to the wound. It goes down to, but not through, the mucous membrane. It is formed by picking up a fold of the intestine ($\frac{1}{12}$ to $\frac{1}{8}$ inch wide) $\frac{1}{8}$ inch from

the edge on one side of the wound, passing the needle through, picking up a fold on the opposite side of the wound, and passing the needle through. On tying

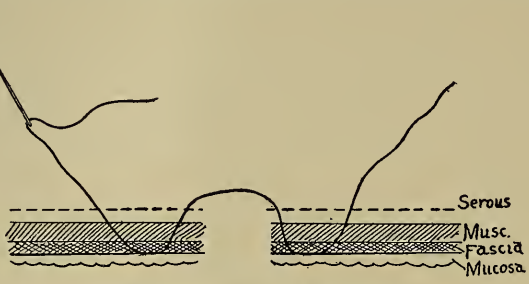

Fig. 631.—Lembert's suture.

the threads the serous membrane is inverted and peritoneum is brought into contact with peritoneum. For many years it was taught that this suture

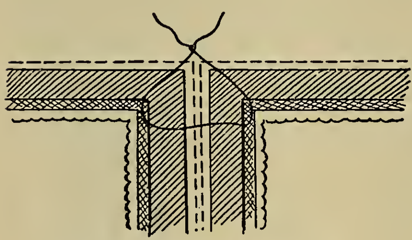

Fig. 632.—Lembert's suture closed.

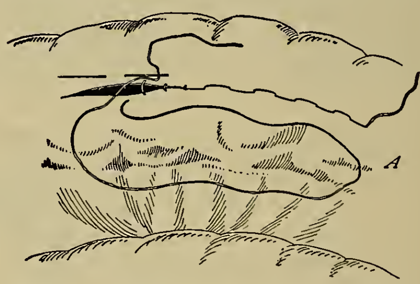

Fig. 633.—Cushing's right-angled suture (Senn).

should include only the serous coat, but Halsted, in 1887, showed that it must include the tough submucous coat. The submucous coat is strong and will hold a suture. The other coats are thin, tear easily, and will not hold a suture.

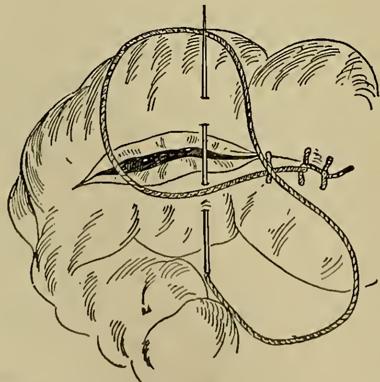

Fig. 634.—Ford's stitch, showing a Lembert insertion and the needle passed so as to tie a single knot by drawing it on through.

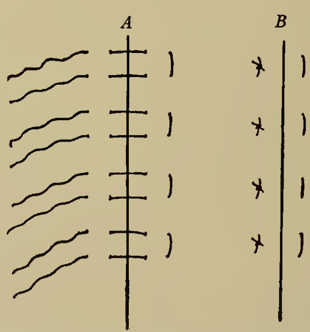

Fig. 635.—*A*, Halsted sutures untied; *B*, Halsted sutures tied and serous surface inverted.

So thin are the coats that a surgeon could not suture the serous coat alone were he to try. Sutures which include only the muscular and serous coats tear out easily. *Dupuytren's suture* (Fig. 630, B) is simply a continuous Lembert

EXPLANATION OF PLATE 11.

Intestinal suture, all knots inside (Connell).

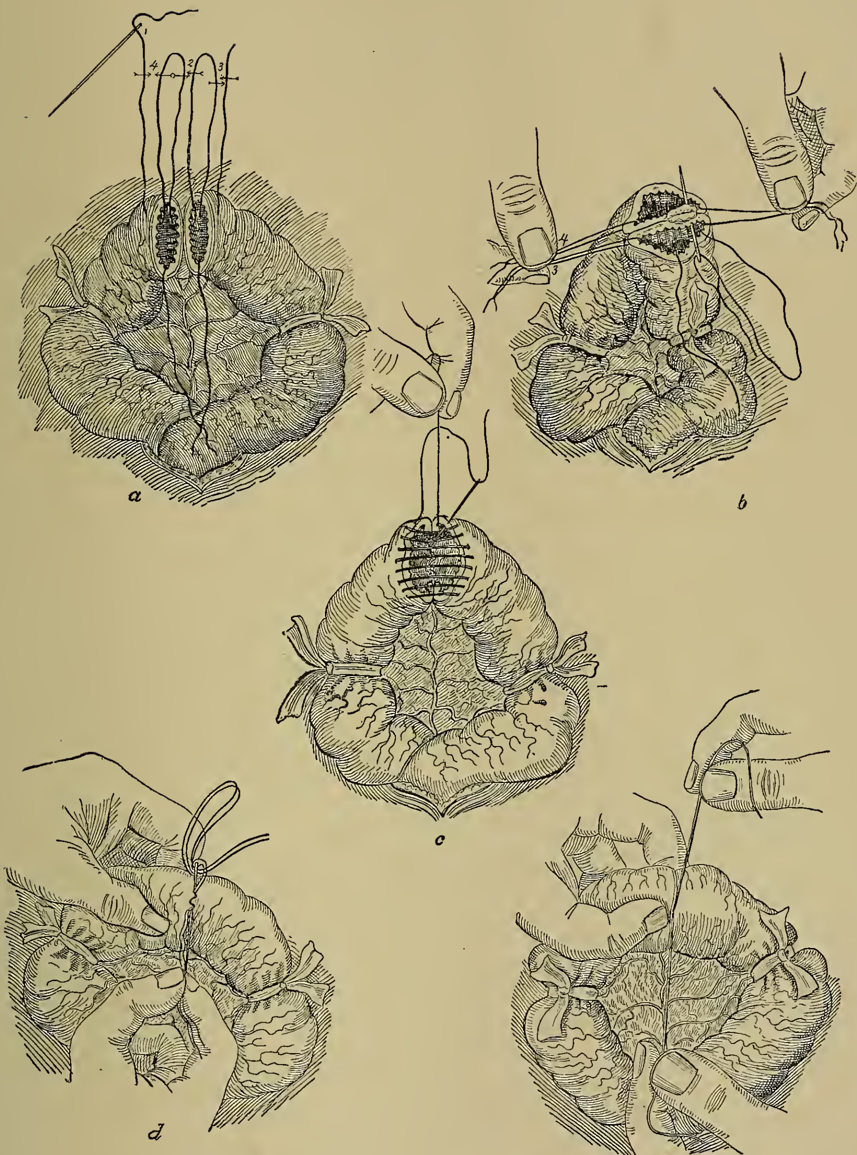
a, Suspending loops 2, 3, and 4 are made with one thread inserted at a point two thirds of the distance from mesenteric to convex border. The needle with suture is passed through the four walls of the cut ends, and that portion of suture within each lumen is drawn up to a sufficient length, then cut, and the contiguous threads tied at the points indicated by the arrows; thus having as a result four suspending loops dividing the circumference of each cut end into thirds. Instead of employing four suspending loops which divide the circumference of the bowel into thirds, we may use but two loops, and thus divide the circumference into halves; or, if available, the "holder" devised by Dr. E. H. Lee can be recommended highly, and will be found a most efficient aid in maintaining the cut edges in apposition. (The description of the instrument will be found in the "Annals of Surgery," January, 1901.)

b, Loop 2 has been cut away, and loop 1 takes its place in one hand of the assistant, with loops 3 and 4 held in the other hand, thereby bringing into apposition that portion of the walls to be included in the second third of the suture. The operator continues the suture to the points of insertion of loops 3 and 4, where again a back stitch is taken, to fix the suture and prevent a purse-string contraction of the same. The white elevation in the center of illustration, representing mesentery, shows that that portion of the intestinal wall not covered by peritoneum, at the mesenteric border, has been secured in the suture.

c, The needle, after having entered the lumen, is passed out again on the same side ⅛ inch distant; then over to the opposite cut end, where it is inserted from without in, and again emerges from within out, on the same side. This step—the taking of a bite—is repeated alternately on opposing margins until the necessary number of stitches have been inserted. It will be observed that when the needle enters the lumen the last time, it makes what might be termed a half-stitch, as it does not return again *through* the wall; but having reached the point where the suture was commenced, the free end and the needle end will complete the last stitch, when tied, on the mucosa. The needle at this point is then brought out of the lumen at the angle of wound alongside of the free end of the suture. The cross-over stitches are next carefully drawn up, thus bringing into contact the opposing serous surfaces at every point except where the suture ends still protrude.

d, The eye-end of threaded needle is made to emerge alongside of the suture ends, and is then withdrawn a little, which causes its thread to form a loop, through which the assistant passes the ends of the suture. The operator next withdraws the threaded needle, at the same time bringing with it the suture ends, and they present externally at the point of withdrawal of the needle. The serous coats throughout the entire circumference are now in apposition, and the suture ends can be tied.

e, By slight traction on the suture ends the opposing mucous surfaces are brought in close contact; the suture ends are then tied firmly, and deep between the serous coats, thus tying the knot upon the mucous coat, and the ends then cut off short.



a

d
e

suture running obliquely across the wound. *Cushing's right-angled suture* (Fig. 633) is a continuous suture catching up the submucous coat and serving to invert the serous layer. Ford, of San Francisco, employs a continuous inversion suture, which is tied in a single knot each time it is drawn through (Fig. 634). *Halsted's mattress* or *quilt suture* is shown in Fig. 635. Each stitch picks up the submucous coat. Mattress sutures do not tear out easily, they appose evenly considerable surfaces, and do not constrict the tissue as much as Lembert stitches. The *Czerny-Lembert suture* is a suture passed through the serous membrane on one side of the wound, made to perforate the mucous membrane, and to emerge at a corresponding point of the serous membrane. A Lembert

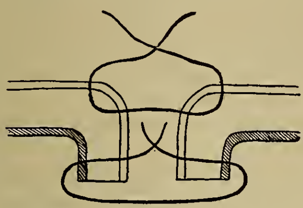

Fig. 636.—Czerny-Lembert suture.

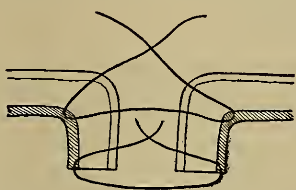

Fig. 637.—Czerny-Lembert suture as at present used.

suture is added (Fig. 636). As at present used, the Czerny suture is carried to, but not through, the mucous membrane (Fig. 637). *Gussenbauer's suture* is similar to the Czerny-Lembert suture, except that it applies the Czerny and the Lembert with one suture, and this suture does not pass through the mucous membrane (Fig. 638). In *Connell's suture* (F. Gregory Connell, in "Phila. Med. Jour.," Jan., 1899) the knots are placed within the lumen of the bowel (Plate 11). Connell's very useful and ingenious stitch seems to be a modification of a stitch described by Frederick Holme Wiggin ("Med. Record," Nov. 19, 1898). *Wölfler's suture* unites broad layers of the serous coat, the knots being tied internally (Fig. 639). Senn says that after suturing a large wound of the stom-

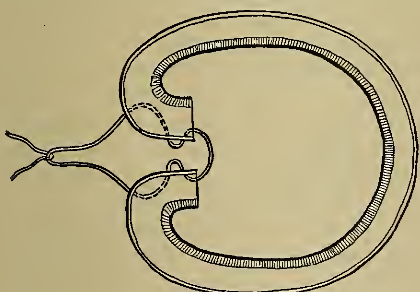

Fig. 638.—Gussenbauer's suture.

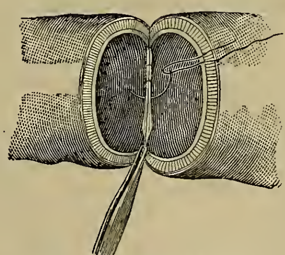

Fig. 639.—Wölfler's suture.

ach or of the intestine a strip of omentum ought to be laid over the wound and fastened by catgut sutures (*omental graft*). These grafts adhere and are a safeguard against leakage. (For other methods of enterorrhaphy see Intestinal Resection and Anastomosis.)

Operations Upon the Stomach.—A patient must be carefully prepared for an operation upon the stomach. The Johns Hopkins method, founded on the researches of Harvey Cushing regarding sterilization of the stomach, is to be used. During the two or three days immediately preceding operation clean the mouth and teeth several times during the day with a carbolic solution. Give only sterile water and sterile liquid food by the mouth,

and for twelve hours before operation give no food whatever. During the two or three days before operation wash out the stomach with boiled water night and morning. I do not wash immediately before operation, as it sometimes leads to annoying vomiting and thus may interfere with anesthetization. After operation give no food whatever for thirty-six hours. Small quantities of hot water are allowed as soon as the patient recovers from ether. During the first twenty-four hours give an enema of hot salt solution and coffee every five hours and then alternate nutritive enemata with salt enemata. After thirty-six or forty-eight hours usually begin to give food by the mouth—at first small doses of albumin-water, and, if this is tolerated, broth and milk. Solid food should not be given for two weeks.

If the patient is advanced in emaciation and much exhausted we should not wait for thirty-six hours to feed him, but should give milk and broth as soon as the patient recovers from ether. The bowels should be moved by enema the day after the operation. If the enema fails, calomel is given (3 or 4 gr.).

Digital Dilatation of Pylorus for Cicatrical Stenosis (Loreta's Operation, or Pylorodiosis).—Place the patient recumbent and administer ether. Make a vertical incision in the linea alba or through the right rectus muscle. The median incision begins 1 inch below the ensiform cartilage. The cut in either case should be 5 inches in length. When the peritoneum has been opened the stomach is drawn out of the wound, any adherent omentum is separated, and the pylorus is carefully examined. The stomach, after being surrounded with gauze pads, is opened near the center of its anterior surface, "but rather nearer to its pyloric end" (Jacobson).

Insert the index-finger through the stomach wound and into the pylorus, and follow that with the middle finger. The pylorus can be well dilated by separating the fingers. If the stenosis is so tight as to prevent the entry of a finger, first introduce a pair of hemostatic forceps and open the blades a little when they are within the lumen of the constricted area. The wound in the stomach is closed by a continuous silk suture of the mucous membrane and two layers of Halsted sutures, to invert and approximate the peritoneal surfaces. After closure of the stomach wound the abdominal wound is sutured.

Divulsion by the fingers or by an instrument is no longer practised, because experience has shown that the constriction is sure to return.

Pyloroplasty (Heineke-Mikulicz Operation).—The first operation was performed by Heineke in 1886. Early in 1887 Mikulicz, not knowing of Heineke's antecedent operation, did the same thing. Open the abdomen in the middle line or, better, through the right rectus muscle. Draw up the pylorus as well as possible, and pack warm moist gauze pads around it; make an incision through the stricture and in a direction corresponding to the long axis of the stomach and bowel (Fig. 640). Catch an aneurysm-needle under the upper margin of the incision and draw it up, and an aneurysm-needle under the lower margin and draw it down. The effect of traction is to convert the longitudinal wound into a transverse wound. The sutures are applied so as to maintain the wound in a vertical line (Fig. 641). The mucous membrane is sutured with a continuous suture of silk, and interrupted Lembert or Halsted sutures of silk close the peritoneal and muscular coats (Figs. 641 and 642). Do not drain. A. W. Mayo Robson inserts a bone bobbin and then applies the sutures. The operation of pyloroplasty shows a mortality about the same as or slightly less than gastro-enterostomy. In some cases it is a very satisfactory procedure, but there are objections to it, and in 30 per cent. of cases it fails to give relief (Wm. J. Mayo). The outlet is not at the most dependent part of the stomach, hence the stomach may not empty itself. Further, as Finney points out, it cannot be performed if there are firm adhesions or active ulceration, and the scar may contract and give rise to stenosis. Again, it is

difficult to suture the wound so as certainly to provide against leakage. The Mayos reported 21 pyloroplasties without a death, but 7 cases required sec-

ondary operations ("Annals of Surgery," Nov., 1905). Pyloroplasty has been abandoned by many surgeons; J. Rutherford Morison still advocates it. Finney has devised an operation to correct the objections to pyloroplasty.

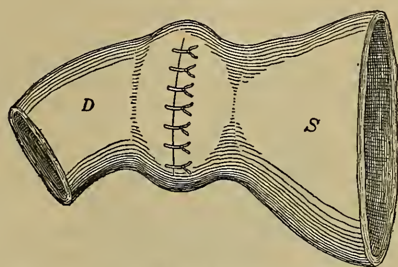

Fig. 642.—Heineke-Mikulicz's pyloroplasty: After tying the sutures.

Gastroduodenostomy by Finney's Method.—This operation is usually called a method of pyloroplasty, but it is rather a gastroduodenostomy. The operation was described in the "John's Hopkins Hospital Bulletin," July, 1902, and was then called pyloroplasty. It is performed as follows: Thoroughly free the first portion of the duodenum and the pyloric end of the stomach by dividing the posterior layer of peritoneum 1 inch to the right side of the duodenum. This step is known as mobilization. Insert three retractor sutures (Fig. 643) and draw upon them. Suture together, as far

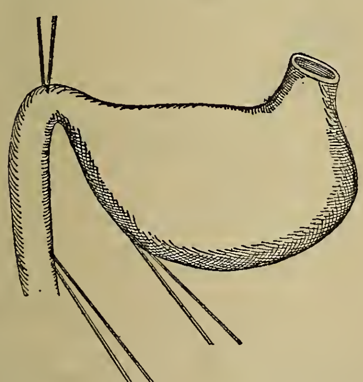

Fig. 643.—Finney's pyloroplasty: The retractor sutures.

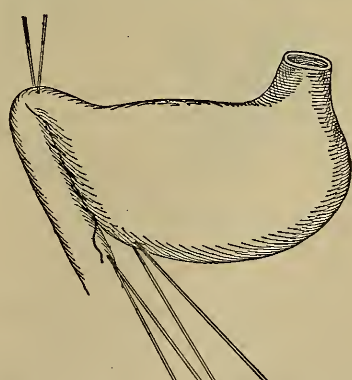

Fig. 644.—Finney's pyloroplasty: Suture of greater curvature of stomach to duodenum.

posterior as possible, the peritoneal surface of the duodenum and the peritoneal surface of the stomach along its greater curvature (Fig. 644). Then

insert an anterior row of mattress sutures, but do not tie them as yet (Fig. 645). Make a horseshoe-shaped incision (Fig. 646); arrest bleeding; excise as much scar-tissue as possible on either side of the incision, and trim off the redundant mucous membrane. Insert a continuous catgut suture on the posterior side of the incision and carry it through all the coats (Fig. 647). Straighten out

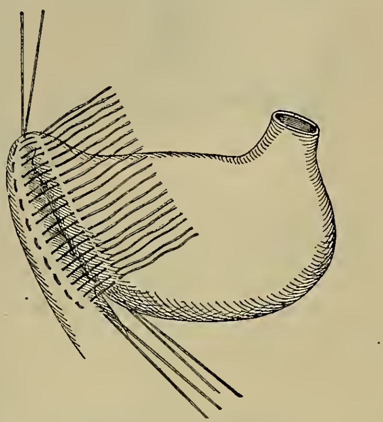

Fig. 645.—Finney's pyloroplasty: Shows the three retractor sutures, the posterior line of sutures tied and the anterior line of sutures untied.

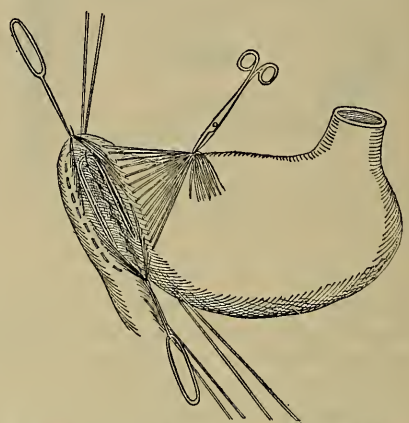

Fig. 646.—Finney's pyloroplasty: The anterior sutures gathered and lifted.

the anterior sutures and tie them (Fig. 648). The Mayos reported 58 Finney operations, with 4 deaths and 2 secondary operations (Wm. J. Mayo, in "Annals of Surgery," Nov., 1905).

The mortality is greater than after gastro-enterostomy, due probably to the necessity of separating adhesions and setting the duodenum free. The opera-

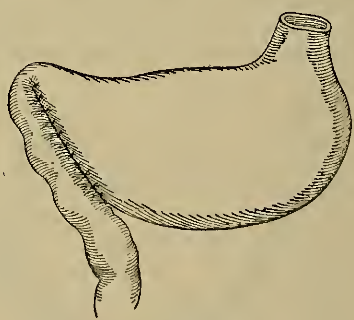

Fig. 648.—Finney's pyloroplasty completed by tying the anterior sutures.

tion should be restricted to cases in which adhesions are not widespread and firm and in which the gastrohepatic omentum is of fair length. In properly selected cases it is a very valuable operation.

Pylorectomy (Excision of the Pylorus).—The removal of a portion of the stomach is a partial gastrectomy, and pylorectomy is a partial gastrectomy in which the pylorus and also a portion of duodenum are removed.

The experiments of Gussenbauer and von Winiwarter on dogs in 1876 led them to suggest the operation. It was first performed by Péan in 1879. It was next performed by Rydygier in 1880. Billroth did the first successful pylorectomy in 1881. The operation is seldom performed for anything but cancer, but sometimes is done for pyloric ulcer and its results. In many cases of pyloric cancer the abdomen is opened only after a palpable tumor is detected, and when a palpable tumor is detectable it is usually too late to perform pylorectomy.[1] The lesson is to explore suspected cases earlier than has been our custom.

I agree with Hemmeter that stenotic symptoms, even when no tumor is palpable, call for exploratory laparotomy; if the stomach is dilated, if there is cachexia, if there is no free hydrochloric acid in the gastric juice, if there is an excess of lactic acid in the gastric juice, if the patient is at or beyond forty years of age, when there is vomiting of blood, when the Oppler bacillus is present, when blood examination shows a diminution in red corpuscles and hemoglobin, and also shows that there is no increase in white corpuscles after a full meal. After the abdomen has been opened the stomach is examined, and if a tumor exists, the surgeon must decide between the performance of pylorectomy and gastro-enterostomy. If the tumor is not very extensive, if there is no glandular involvement or only involvement which can be removed, and if adhesions are not extensive, pylorectomy is chosen; otherwise gastro-enterostomy is selected.

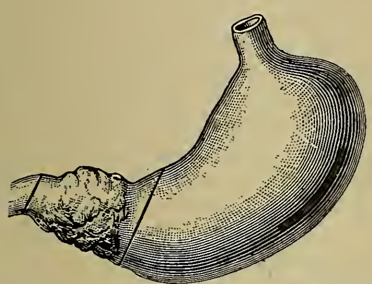

Fig. 649.—Billroth's method of pylorectomy.

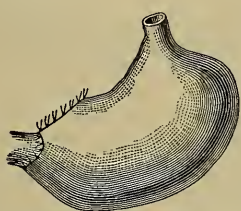

Fig. 650.—Pylorectomy.

Until very lately the mortality from pylorectomy was estimated to be 25 per cent., even in favorable cases. In 9 complete pylorectomies, with closure of both the stomach and duodenal ends, communication being reëstablished by the performance of gastrojejunostomy, Mayo reported 1 death, and in 14 pylorectomies and partial gastrectomies he reported 2 deaths, or 14 per cent. (Wm. J. Mayo, in "Annals of Surgery," Aug., 1902) (see page 1085). Prepare the patient for pylorectomy as for any stomach operation. The best incision through the abdominal wall is a vertical one in or near the median line. A small incision is first made to permit of exploration, and if the growth is found to be removable, the incision is enlarged. In some cases it will be found necessary to divide the rectus muscle by a transverse cut.

Method of the Mayos.—This is the best operation. The Billroth method, which was long employed, does not remove enough of the stomach if there is malignant disease, the opening left in the stomach is much larger than the duodenal opening, and in suturing so as to make the two openings of equal size an angle is left which is apt to leak. Billroth's operation is shown in Figs. 649 and 650. In the Mayo method, after the stomach has been exposed the gastric artery is ligated close to the stomach, the lesser omentum is tied in several segments close to the liver and then divided, and the pyloric artery is tied. Two clamps are applied to the duodenum 1 inch apart, and the duodenum is divided by means of the cautery (Fig. 651).

The right end of the duodenum is closed by means of a continuous catgut

[1] Keen's "Cartwright Lectures for 1898."

suture, the clamp is removed, and the closed end of the duodenum is inverted by a purse-string suture (Fig. 652). A hand is passed from above back of the stomach and lifts the great omentum forward. The right gastro-epiploic artery is tied close to the stomach. The left gastro-epiploic artery is tied distinctly to the left of any enlarged glands in the great omentum. The great omentum is tied in several segments. The great omentum is divided, leaving any enlarged glands attached to the portion of the stomach it is the intention to remove. The stomach is to be divided to the left of all lymphatic glands into which the cancerous region drains. The clamps are applied as shown in Fig. 651. The stomach is divided between the clamps by a cautery, and as the division is being carried out the stump is caught here and there by hemostatic forceps to prevent it slipping through the clamps. Slipping is disastrous and will cause leaking and entrance of air into the stomach, and entrance of air is apt to be followed by pulmonary difficulty. A row of locking stitches is passed through all the coats of the stump. The stitches are tied and a second row is passed and tied (Fig. 652). The clamp is removed and the stump is buried by Cushing's right-angled suture or Dupuytren's suture. A gastrojejunostomy is then performed to the posterior wall of the portion of stomach which remains.

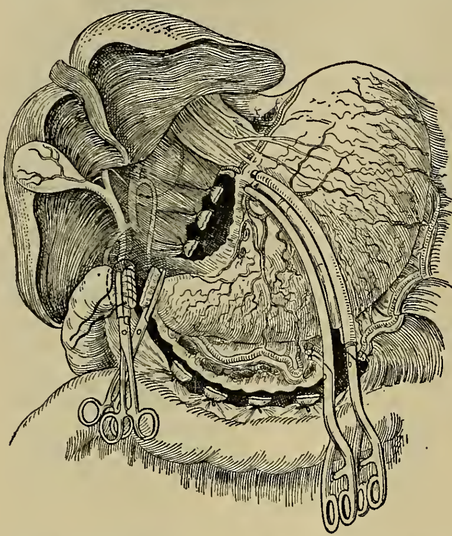

Fig. 651.—Pylorectomy by the Mayo method: Clamps applied, duodenum divided, and continuous catgut stitch introduced (Mayo).

Such a patient is usually much dehydrated, and if he is, salt solution should be given intravenously during the operation, and an enema of warm salt solution should be administered every six hours for several days after the operation. Active stimulation is usually necessary and 8 oz. of coffee should be given by rectum at the completion of the operation. The patient must be placed erect or semi-erect in bed as soon as the effects of the ether pass away. Twelve hours after operation begin to give small amounts of hot water by the mouth. Nourish by the rectum from four to six days, when fluid food may be given by the mouth, starting with small doses of albumin-water, and,

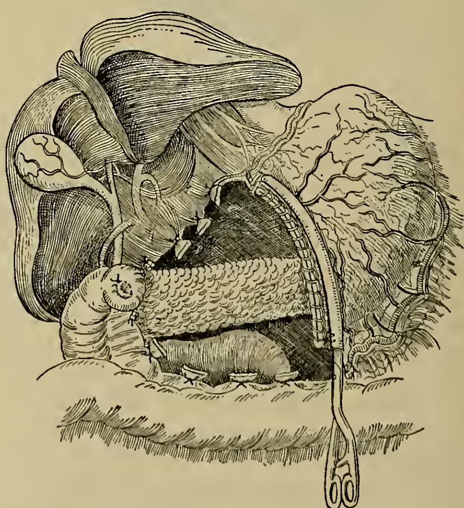

Fig. 652.—Pylorectomy by the Mayo method: End of divided duodenum buried by a purse-string suture. Row of lock stitches inserted in stomach stump (Mayo).

if this is tolerated, giving dessertspoonful doses of peptonized milk every hour. During 1912 the Mayos did 46 pylorectomies for cancer, with 5 deaths ("Report of St. Mary's Hospital"). They did 13 for ulcers and benign tumors without a death (Ibid.). If during the operation the pancreas is wounded the closed end of the duodenum is applied directly to the pancreatic wound, as Willy Meyer suggested ("Trans. of Am. Surg. Assoc.," 1910). "The anterior peritoneum and adventitious sheath of the pancreas is then sutured to the anterior surface of the duodenum." This plan prevents leakage from the duodenum and pancreas (Wm. J. Mayo, in "Annals of Surgery," August, 1913).

Total Gastrectomy.—The entire stomach was first removed by Conner, of Cincinnati, in 1883. The first successful operation was performed by Schlatter, of Zürich, in 1897. Total gastrectomy will rarely be required, but in certain unusual cases it will be proper to perform it. In some cases the duodenal end can be sutured to the divided esophagus; in others it will be necessary to close the end of the divided first portion of the duodenum, and anastomose the esophagus to the jejunum.

The cases suitable for total gastrectomy are those in which the entire viscus, or almost the entire viscus, is cancerous, the stomach being still freely movable, and the glands not so much implicated as to forbid attempts at removal. It is a remarkable fact, first demonstrated in Schlatter's case, that an individual can digest food very well without a stomach. This statement is true only if the stomach function has been gradually abolished by disease. During this period the functions of the stomach have been assumed to a greater or less degree by other parts. In a recent injury of the stomach complete removal would almost certainly be followed by death, as in such a case other parts would have had no chance to learn how to assume gastric duties. The reported cases of total gastrectomy show 10 deaths out of 27 cases, but, as Robson truly says, if all cases were reported, the mortality would probably be found to be 50 per cent. Trinkler ("Archiv. für klin. Chir.," Berlin, xcvi, No. 2) reports 1 case (which died on the eighth day) and gathers 25 from literature; 13 recovered. When the duodenum was stitched to the esophagus the mortality was 57.1 per cent. When the jejunum was stitched to the esophagus the mortality was 28.5 per cent.

I have done the operation once. The patient died on the third day.

Gastrotomy.—This term is used to designate the operation of opening the stomach for the accomplishment of some purpose, and immediately closing the incision in the gastric wall when that purpose is accomplished. Gastrotomy may be performed to permit of the removal of foreign bodies, of exploration of the stomach and its extremities, of divulsion of the pyloric orifice, of the treatment of bleeding of an esophageal stricture or a stricture of the cardiac orifice of the stomach, or of the removal of a foreign body lodged in the esophagus. The first case on record was in 1602, when Florian Mathias, of Brandenburg, removed from the stomach of a juggler a knife which had been accidentally swallowed. When Evelyn was in Leyden in 1641 he saw a knife which had been removed by gastrotomy. He says (Evelyn's Diary): "I was showed the knife newly taken out of a drunken Dutchman's guts by an incision in his side, after it had slipped from his fingers into his stomach. The picture of the surgeon and his patient, both living, were there."

The patient is prepared as for pylorectomy. The incision may be vertical in the middle line or identical with the incision for pylorectomy. If a large foreign body can be felt, the incision is made directly over it. When the peritoneal cavity is opened, the surgeon decides as to the point where the stomach is to be incised, and draws this portion out through the wound, packing gauze pads under and around it. The stomach is opened by means

of scissors, the cut being at a right angle to the long axis of the viscus (Jacobson). Bleeding vessels are ligated with catgut. The purpose for which the stomach was opened is now to be carried out, the interior of the stomach and the surface of the extruded portion are irrigated with hot salt solution, the mucous membrane is sutured with a continuous suture of silk, and two rows of Halsted sutures are inserted. The abdominal wound is closed, drainage being employed for twenty-four hours.

Gastrostomy is the making of a permanent gastric fistula, through which opening the patient can be fed. Gastrostomy was first proposed by Egebert in 1837 and was first performed by Sédillot in 1849. In 1875 Sydney Jones operated upon the twenty-ninth case and obtained the first recovery (Keen). Up to 1884 the estimated mortality was 80 per cent. At present the mortality in malignant cases is from 20 to 25 per cent., and in non-malig-

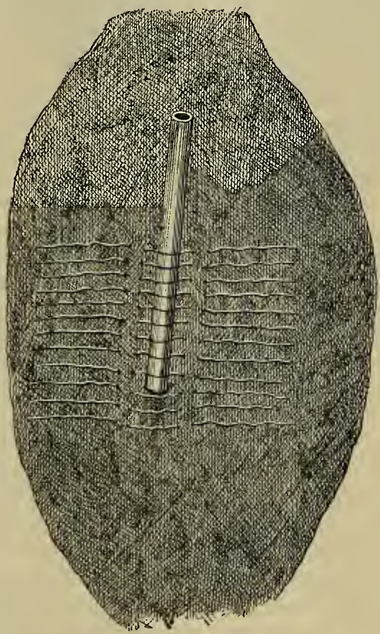

Fig. 653.—Witzel's method of gastrostomy, showing application of sutures in wall of stomach, embedding tube obliquely therein.

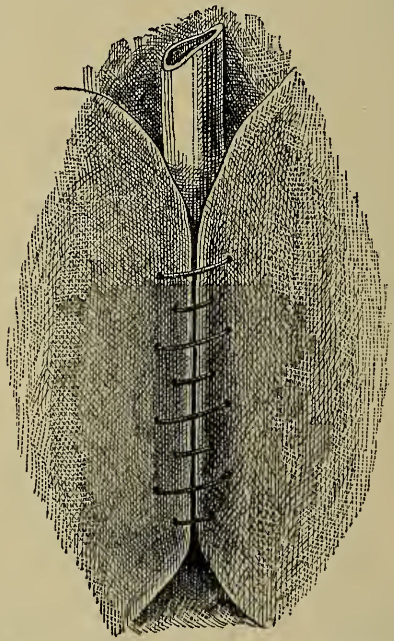

Fig. 654.—Sutures tied, completely embedding tube obliquely therein.

nant cases from 8 to 10 per cent. Gastrostomy is employed in cases of esophageal obstruction or obstruction of the cardiac end of the stomach. In many cases of malignant disease the operation is performed too late, and if performed when the patient is greatly emaciated and exhausted the operation has, of course, a high mortality. An early operation is far safer and confers the maximum of relief. The operation should be performed, as Mikulicz advises, when the patient is steadily losing weight and there is beginning to be difficulty in swallowing semisolids or liquids. The surgeon must endeavor to perform an operation which will not permit of leakage. Prepare the patient as for any stomach operation, except as to washing out the stomach, which is usually impossible.

Witzel's Method.—This operation was first practised in 1891. Make an incision 4 inches in length, running to the left from the middle line, just below the border of the ribs. After opening the peritoneal cavity seize the stomach,

bring it out of the wound, and pack gauze around it. Introduce a rubber tube into the stomach and enfold it by a double row of Lembert sutures (Figs. 653, 654). This tube should be 5 inches long and of the same diameter as a No. 25 French bougie. The opening is made in the stomach toward the

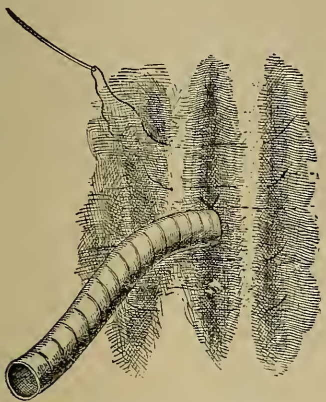

Fig. 655.—Kader's method of gastrostomy: Tube in place and first row of sutures inserted.

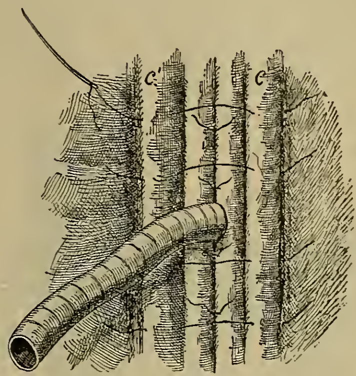

Fig. 656.—Kader's method of gastrostomy: First row of sutures tied and second row inserted.

cardiac extremity, the tube is placed parallel with the belly wound, and the outer end of the tube emerges in the median line. The tube is retained in place by a catgut stitch carried through the tube and the stomach wall. The stomach is returned and is stitched by three sutures to the abdominal wall. The abdominal incision is sutured and a clamp is placed on the tube. When the patient is fed, a funnel is slipped into the tube, the clamp is removed, and liquid food is poured into the funnel. After the wound heals it is not necessary to retain the tube permanently. It is passed when the patient desires food.

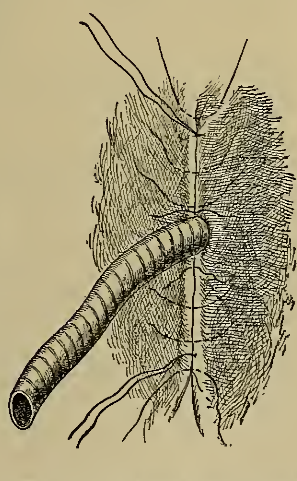

Fig. 657.—Kader's method of gastrostomy: Second row of sutures tied.

Kader's Method.—This operation was devised in 1896. It is a modification of Witzel's method. A small incision is made in the stomach and a tube is introduced and fastened to the stomach by one catgut stitch. Four Lembert sutures are passed so as to form a fold on each side of the tube and turn the stomach wall inward around the tube (Fig. 655). Lembert sutures are inserted in the furrow on each side of the tube. Two more folds are formed over the first two (Figs. 656 and 657). The stomach wall is stitched to the parietal peritoneum and sheath of the rectus muscle (Willy Meyer).

The Ssabanajew-Frank Method.—This operation is preferred by many surgeons. I usually employ it if the stomach is not so shrunken as to render the pulling out of a sufficient cone impossible. It was first performed by Ssabanajew in 1890 and was performed independently by Frank in 1893. Fenger's incision is made (a curved incision at the margin of the costal cartilages of the left side). A cone of the stomach is pulled out of the wound and is passed under a bridge of skin which has been prepared for it. The stomach is fixed above the margin of the ribs and opened (Figs. 658, 659).

Von Hacker makes the gastric fistula through the left rectus muscles, and Hahn between two of the rib cartilages (Willy Meyer).

The Younger Senn's Method.—Emanuel Senn devised the following method: A cone of the stomach is pulled out of the abdominal wound, and this cone is puckered by the insertion of two drawing-string sutures of chromicized catgut. A cuff of gastrocolic omentum is sutured by silk around the neck of the puckered cone. The stomach is sutured to the belly wall with silk, the sutures including the omental cuff, the serous and muscular coats of the stomach, and the structures of the belly wall, except the skin. The skin is partly sutured. The stomach may be opened at any time.

Gastro-enterostomy or **gastrojejunostomy** is the establishment of a permanent fistula between the stomach and the small intestine, in order to side-track the pylorus. The operation is performed for cancer of the pylorus, for non-cancerous stenosis of the pylorus, in some cases of ulcer of the stomach, and for tetany. Anterior gastro-enterostomy was proposed by Nicoladoni in 1881 and was first performed by Wölfler the same year. In Wölfler's early operations the jejunum was so placed that the proximal end was to the right of the anastomosis opening. Hence peristalsis in the stomach was from left to right and in the jejunum from right to left, and this was supposed to be responsible for the common occurrence of regurgitant vomiting. It was sought to prevent this by altering the direction of the loop (Lücke), then by entero-anastomosis (Braun), and finally by posterior anastomosis. Posterior gastro-enterostomy was first proposed by Courvoisier in 1883. His suggestion was that the posterior surface of the stomach be reached through the transverse mesocolon. His plan necessitated a transverse division of the mesocolon, but it was found that this impaired the blood-supply of a part of the colon and might lead to gangrene. Von Hacker, in 1885, devised an improved posterior operation. As a matter of fact, the transverse mesocolon has a marginal artery, unlike other parts of the colon, and the danger of gangrene from a transverse incision is probably not very great. In the earlier operations by the posterior method a long loop was used and results were not notably better than after the anterior operation. In 1890 Czerny and Peterson advised the making of the jejunal opening close to the duodenojejunal flexure. The results from this operation are vastly better than from the

anterior operation. Posterior gastro-enterostomy has been signally improved in technic by the Mayos, Moynihan, and others. In the earlier operations of anterior gastro-enterostomy the mortality was 40 per cent. In non-malignant conditions the mortality after gastro-enterostomy is now very low (under 3 per cent.), the hyperacidity of the gastric juice disappears, and the functions of the stomach are restored. In malignant cases the mortality is about 20 per cent., but even in such cases, if operation is done early, life may be prolonged and made comfortable for months. Wm. J. Mayo makes the following report upon 421 cases of gastrojejunostomy: "Benign, 307 cases, 19 deaths (6.18 per cent.). In the last 140 there were 4 deaths, a mortality of 2.85 per cent.; the last 80 gave but 1 death. Malignant, 114 cases, with 21 deaths (18.5 per cent.). Of these 114 cases, 63 were in connection with pylorectomy and partial gastrectomy, with 8 deaths (12.6 per cent.). The very unfavorable cases of cancer obstruction were subjected to gastro-enterostomy, so that this operation gives a higher mortality than radical excision. In the last 40 gastrojejunostomies for malignant disease the mortality was 8 per cent. In the 421 gastrojejunostomies there were 21 reoperated cases (5 per cent.)" ("Annals of Surgery," Nov., 1905). During 1912 the Mayos did 40 gastro-enterostomies for chronic ulcer of the stomach, with 2 deaths, and 31 for cancer of the pylorus, with 2 deaths. They did the operation 187 times for chronic and subacute ulcer of the duodenum with 1 death ("Report of St. Mary's Hospital for 1912"). In about 5 per cent. of cases of gastro-enterostomy for benign disease secondary operation has been required. In Krönlein's clinic, 51 cases of malignant disease subjected to gastro-enterostomy showed an average duration of life of 192 days; 470 days after operation 17 cases were living. The causes of death, according to Wm. J. Mayo, are: exhaustion, exhaustion with vomiting, pneumonia, and detachment of the anastomosed intestine.

Treatment After Gastro-enterostomy.—On returning the patient to bed at once establish continuous proctoclysis with one-half strength salt solution, the reservoir being only 6 inches above the level of the bed. As soon as the patient is out of ether place him semi-erect. Mayo begins in from sixteen to twenty hours to administer by the mouth 1 oz. of hot water every hour, and if it is well tolerated the amount is quickly increased, and in thirty-six hours liquid food is given, and if tolerated, is continued.

Complications Following Gastro-enterostomy.—Among them are *lung complications*. These are not due to the anesthetic, for they tend to occur even when local anesthesia has been employed. They are not due to the epigastric incision interfering with cough and expectoration, for they are not nearly so common after operations upon the gall-bladder (Wm. J. Mayo). Mayo says that the latest theory is that some of the venous blood returning from the stomach does not pass through the liver, and infected emboli are deposited in the lungs. The *suture line* may *leak* after gastro-enterostomy because of imperfect suturing, or the anastomosed intestine may become *detached;* 20 per cent. of the deaths among Mayo's cases resulted from this cause. *Contraction* of the *anastomosis opening* may gradually take place. This has been held by some to be particularly common in cases of dilated stomach, shrinking of the stomach being the efficient cause, but evidence upon this point is not conclusive. In cases in which the pylorus is not obstructed shrinking often occurs, but it rarely takes place when the pylorus is obstructed. In some cases after operation a *spur* forms in the jejunum because of angulation; in other cases adhesions produce obstruction; and in rare instances ulceration takes place in the jejunum. The most common complication after gastro-enterostomy is *persistent vomiting*, which may or may not be expressive of the formation of a vicious circle.

Peptic Ulcer of the Jejunum.—The first case was reported by Braun in 1899.

The first English case was reported by Mayo Robson in 1903. Herbert J. Paterson reported a case and collected reports of 61 other cases (A. W. Mayo Robson, "Brit. Med. Jour.," Jan. 6, 1912). F. Gregory Connell has collected 38 cases and reported 1 of his own, 39 in all ("Surg., Gynec., and Obstet.," Jan., 1908). He points out that in many of the reported cases acute perforation occurred. Most of the reported cases suffered from non-malignant trouble and had hyperacid gastric juice. It very seldom occurs after operations for cancer. Most of the reported cases happened after the anterior operation and when the anastomosis was very near to the pylorus. It has happened, however, in 9 cases after the posterior operation, and cases have been reported following both the anterior and posterior methods associated with entero-anastomosis. It is probable that more cases seem to follow the anterior method because until late years it has been the operation commonly performed. In most of the reported cases the ulcer was single; in 3 out of 24 cases it was multiple. It is usually in the distal loop, but may be in the proximal loop. It may be situated at the anastomosis level, a little way below it, or even 5 or 6 inches below it. The ulcer may appear a few days after the operation, weeks after, months after, or even years after. The condition results from hyperacid gastric juice passing directly into the jejunum before it has been neutralized by admixture with bile and pancreatic juice. It is possible that the condition is predisposed to by a twist in the jejunum and by such a small anastomosis opening that hyperacidity was not corrected.

There may be no symptoms at all until there is a severe hemorrhage or perforation, or symptoms similar to those which called for the gastro-enterostomy may return. Connell's table shows that acute perforation took place in 14 of the 39 reported cases. Pain is to the left of the umbilicus, comes on two or three hours after eating, and is relieved by food. There may be tenderness and may be rigidity of left rectus muscle (Robson, Loc. cit.). In chronic cases treatment is first medical; if this fails, operation is indicated. If on opening the abdomen it is found that the original pyloric or duodenal ulcer has healed, but there is an ulcer in the jejunum, separate the bowel from the stomach, close the stomach opening, excise the jejunal ulcer, and close the wound in the bowel. If there is stenosis of the pylorus or duodenum we must have a gastro-enterostomy, so we make another after closing the original opening (Robson). Very extensive ulceration may call for resection. If the patient is greatly weakened or if the ulceration is extensive, jejunostomy (see page 1105) may be done (Robson). In perforation, operation must be immediate.

The Vicious Circle and Regurgitation.—Vomiting may occur after the performance of gastro-enterostomy. It may soon cease, may be productive of disastrous consequences, and may be expressive of an existing complication of great gravity. In some cases of gastro-enterostomy vomiting arises because the anastomosis has been made high up on the anterior gastric wall and the stomach is not drained. In other cases ether induces vomiting, and the mechanical efforts force the contents of the duodenum and even of the jejunum into the stomach. The true "vicious circle" is a condition in which the contents of the stomach pass through the anastomosis opening into the duodenal side of the loop of intestine, mix with the duodenal secretions, and return to the stomach (Fowler, in "Annals of Surgery," Nov., 1902). The following conditions are often classified under the same head, but each is called by Fowler a regurgitation or reflex: (1) When the duodenal secretions pass back into the stomach through a permeable pylorus (as in cases of gastroptosis, non-cancerous pyloric stenosis, and gastric dilatation); (2) when the duodenal secretions enter the stomach through the anastomosis opening; (3) when the contents of the jejunum pass into the stomach, because of efforts at vomiting or as a result of reversed peristalsis. In some cases the contents of the jeju-

num may pass into the afferent loop of intestine and distend it. It was long thought that the vicious circle was due purely to bile passing into the stomach from the proximal (afferent) loop of the jejunum. Dastre's experiments on dogs show that bile in the stomach does not impair either digestive power or the general health, and Moynihan has confirmed these experiments by clinical observation. It has been held that the cause of this condition is the making of an anastomosis with a long loop between the duodenojejunal flexure and the anastomotic opening into the jejunum, the loop being unable to propel its contents downward and tending by its weight to produce a bend or kink at the seat of anastomosis. This is a very doubtful theory.

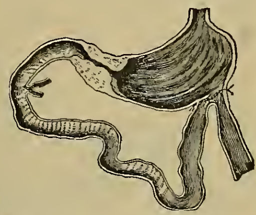

Fig. 660.—Billroth's method of gastro-enterostomy.

Persistent vomiting may be due to spur formation, which deviates stomach contents into the duodenal side of the loop. It is in some cases due to kinking or twisting of the distal loop; in others, to failure of peristalsis in the proximal loop; in still others, to contraction of the opening in the stomach wall (Chlumsky on "Gastro-enterostomy" in the Breslau Clinic; article by Charles L. Gibson, in "Annals of Surgery," Aug., 1908). I cordially agree with the statement of Herbert J. Paterson, viz.: "Most, if not all, fatal cases of regurgitant vomiting are due to mechanical obstruction at the afferent opening" ("The Hunterian Lectures," delivered before the Royal College of Surgeons of England, Feb. 19, 21, and 23, 1906). In order to lessen the danger of vomiting after gastro-enterostomy, do the operation under a local anesthetic whenever possible; and in order to prevent regurgitant vomiting take every care in the operation to prevent the formation of a spur on the mesenteric border of the jejunum (Herbert J. Paterson, Ibid.).

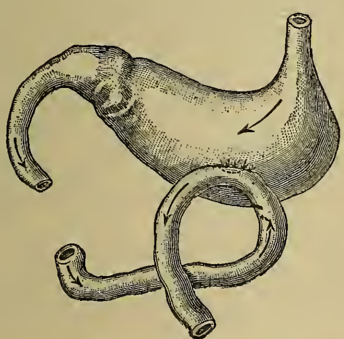

Fig. 661.—Gastro-enterostomy (after Lücke).

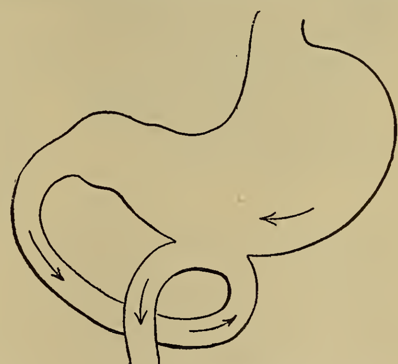

Fig. 662.—Wölfler-Lücke method of gastro-enterostomy.

After Billroth's operation (Fig. 660) and in all the earlier methods the contents of the duodenum certainly pass into the stomach, mix with the stomach contents, and usually, but not always, pass into the efferent loop. In all these operations there is great danger of the development of a vicious circle.

Lücke devised an operation with the idea of preventing such a complication. In the Lücke operation the direction of peristalsis in the efferent loop is the same as in the stomach (Fig. 662). McGraw points out that the crossing of the loop which is effected is dangerous. The Wölfler-Lücke operation is shown in Fig. 661. Wölfler also devised the operation pictured in Fig. 663. Von Hacker's posterior operation is thought by some to be less apt

than the anterior method to be followed by the vicious circle (Fig. 664). Kocher devised an operation in which a valve is formed, but, as Fowler points out, this valve does not prevent filling of the duodenum and imbibition of the material by the stomach; and, further, that the valve does not work when the parts become cicatricial (see Fig. 668).

The combination of gastro-enterostomy with entero-anastomosis does tend to prevent the vicious circle. This operation is shown in Figs. 665 and 666.

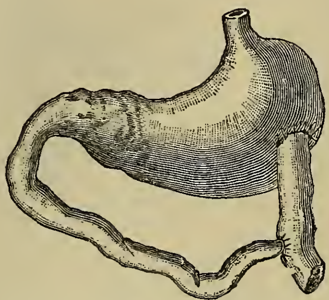

Fig. 663.—Implantation of duodenum into jejunum and jejunum into stomach (after Wölfler).

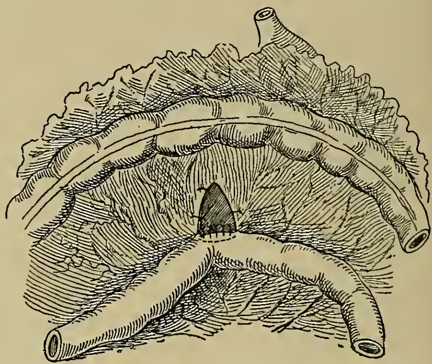

Fig. 664.—Von Hacker's posterior gastro-enterostomy.

I do not believe it should ever be a primary operation. It permits acid gastric juice to flow directly into the jejunum and keeps away the bile which would normally protect mucous membrane. Hence such an operation exposes the patient to the danger of jejunal ulceration. Another defect in such an operation is that there is still a communication between the stomach and the efferent loop. Fowler's operation (see Fig. 672) closes the jejunum and corrects the defect inherent in Braun's and in Jaboulay's operation. Other operators close

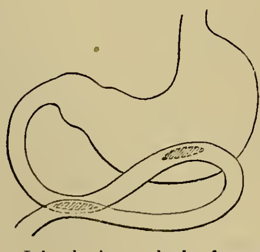

Fig. 665.—Jaboulay's method of gastro-enterostomy.

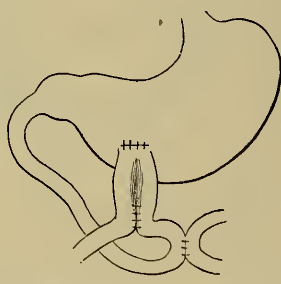

Fig. 666.—Braun's method of gastro-enterostomy.

the pylorus. McGraw's operation (see Figs. 669 and 670, which show entero-anastomosis) tends to prevent the formation of a vicious circle. It seems certain that the danger of the formation of a vicious circle is greatest after a long-loop anterior operation and least after a short-loop posterior operation. The shorter the loop, the less the danger, hence the latter is the operation of choice. The safest operation of all is the short-loop operation of Moynihan or Scudder (see page 1099) or the "no-loop" operation of the Mayos (see page 1101).

Treatment of Persistent Vomiting After Gastro-enterostomy.—If vomiting persists in spite of gastric lavage and rectal feeding following the operation of gastro-enterostomy with a long loop without entero-anastomosis, open the

abdomen again and perform anastomosis between the afferent and efferent loops of intestine. This was suggested by Braun in 1892, and both he and Jaboulay performed it in the same year. The operation has saved lives. In a short-loop operation we should assume that the jejunum has been twisted, should open the abdomen, and endeavor to correct the condition. Herbert L. Paterson ("Hunterian Lectures," before the Royal College of Surgeons of England, Feb. 19, 21, 22, 1906) points out that slight cases of regurgitant vomiting not immediately following an operation may be due purely to constipation, and may be recovered from if care is taken to secure daily a free bowel movement. In Paterson's opinion constipation causes reversed peristalsis, and as both the duodenal "siphon-trap and the pyloric sphincter are put out of service," regurgitation takes place from the efferent loop into the stomach.

Anterior Gastro-enterostomy.—*Senn's Method.*—A median incision is made through the abdominal wall, from below the xiphoid cartilage to the umbilicus. An opening is made in the lower part of the anterior wall of the stomach in the direction

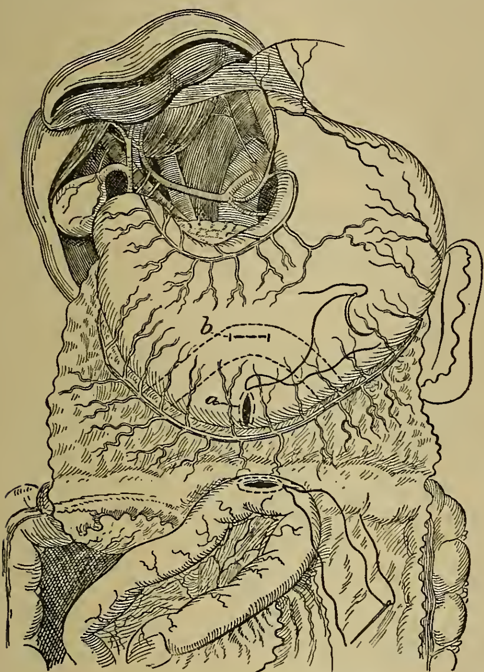

Fig. 667.—Mayo's method of anterior gastro-enterostomy, showing proper and improper locations of openings: *a*, Proper position, leaving no pouch; *b*, usual position, forming intragastric pouch ("Annals of Surgery").

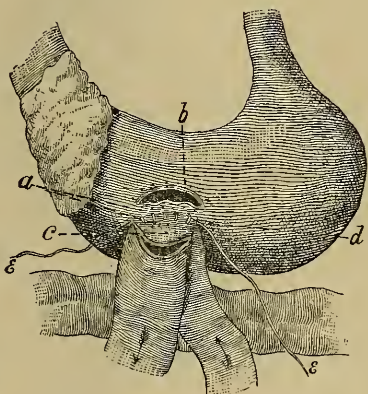

Fig. 668.—Kocher's method of gastro-enterostomy: *a*, Places of posterior annular suture through entire wall of stomach and intestine; *b*, places of anterior annular suture through the entire wall; *c*, valve at the jejunum by arch-formed incision; *d*, posterior annular suture of the serosa; *e*, thread ends for continuing anterior suture of the serosa.

of the long axis of the viscus, and its edges are stitched by a continuous catgut suture. The contents of the jejunum are forced along to below the point where an incision is to be made. The duodenal loop of jejunum should be from 12 to 14 inches in length. A rubber tube is fastened around the bowel above this point, and another below it; an incision is made in the long axis of the bowel, and the margins of the wound are sutured in the same manner as the stomach wound. Bone plates are introduced into the stomach and intestine, and the ligatures are tied as in intestinal anastomosis. Catgut rings or rubber rings may be used.

Mayo's Anterior Method (Fig. 667).—Open the abdomen, and pick up the small intestine and find a point of jejunum about 14 inches from the point at which it emerges from under the mesocolon. Effect the union to the inferior

border of the stomach close to the greater curvature and at the lowest portion of the stomach pouch. When the anastomosis is completed the stomach pouch is funnel shaped. The usual custom has been to place the opening higher on the anterior wall. It sometimes led to the formation of a pouch on the anterior wall, did not drain the stomach, and caused vomiting. After the performance of gastro-enterostomy the edges of the omentum are caught upon each side of the anastomosis and are sutured to each other and to the stomach wall 1 inch above the opening. The edges are then united to each other in a downward direction for about 3 inches so as to form an apron over the anastomosis, yet not connected with it. Catgut is used for suturing. If leakage occurs, the omentum is adjacent and "available." If it does not occur, the omentum soon returns to its normal position (Wm. J. Mayo, "Annals of Surg.," Aug., 1902).

Kocher's Method (Fig. 668).—After opening the abdomen lift up the omentum, pull up a loop of intestine, and find the point where the jejunum

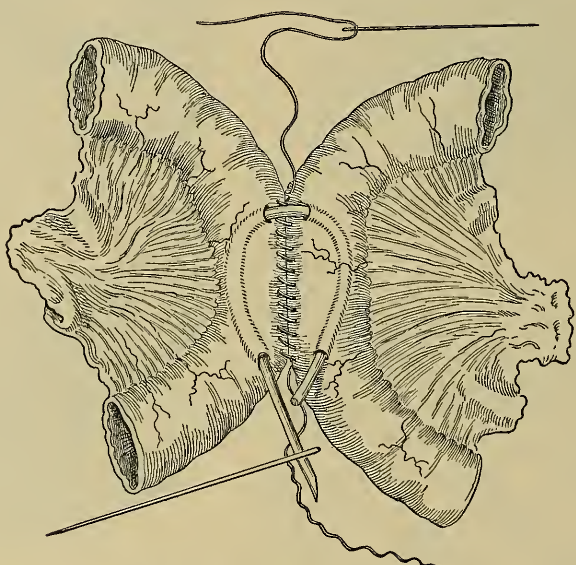

Fig. 669.—McGraw's method of lateral anastomosis: The elastic ligature is introduced (Walker). Gastro-enterostomy is done by the same plan.

appears from under the mesocolon. Select a loop 16 inches from the origin of the jejunum and prepare to attach it to the stomach. Wölfler believed that the intestine should be applied to the stomach in such a manner that the direction of peristalsis in the bowel would correspond to the direction of the stomach-tide. This can be accomplished by having the proximal portion of gut to the left, and the distal portion to the right. The operation is to be so performed that after its completion the stomach contents pass into the distal portion of the gut, and intestinal contents do not tend to enter the stomach (see Fig. 662). In order to accomplish this Kocher hangs the intestine to the stomach wall in such a manner that the proximal portion of the loop is posterior and ascending, and the distal portion is anterior and descending. The bowel is hung to the stomach by a continuous serous suture of silk, the ends of which are left long. The intestine is opened by a curved incision, the convexity of which is downward. The stomach is opened so that the convexity of the cut is upward. The valve-like portion of the bowel wall is sutured to the stomach below the incision in that viscus. The two openings are well approximated by sutures.

Operation by McGraw's Elastic Ligature (Figs. 669–671).—The elastic ligature was introduced by Silvestri in 1862, and was first used in intestinal anastomosis by the same surgeon. McGraw perfected the operation in 1891.

Fig. 670.—McGraw's method of lateral anastomosis: One tie of the elastic ligature with a strong silk ligature underneath ready to fasten the elastic ligature where it is drawn taut (Walker).

(See Dudley Tait, in "Annals of Surgery," Feb., 1906.) The operation may be anterior or posterior. The intestine and stomach are sutured together by

Fig. 671.—McGraw's method of lateral anastomosis: The operation completed (Walker).

Lembert stitches. The elastic cord, which is 3 to 5 mm. in diameter, is passed through the stomach and then the bowel, in the long axis of each, and is tightly tied, and the knot is fastened with a silk thread. Another row of Lembert

sutures buries the elastic cord from sight. The cord cuts through in from forty-eight to seventy-two hours and makes the anastomosis. Thus the danger of infection is greatly lessened, for when the anastomosis opening is formed it is completely encompassed by firm adhesions. Further, the danger of the formation of a vicious circle is greatly lessened, because there is no communication between the stomach and bowel for between forty-eight and seventy-two hours, the period in which vomiting of the type previously described is most apt to occur. The method is not suitable for absolute pyloric occlusion. In this condition it is imperative to give nourishment early, and, again, an ordinary gastro-enterostomy allays auto-intoxication and this operation cannot until the ligature cuts through. It is particularly valuable in the performance of lateral intestinal anastomosis. The cuts show the operation of lateral anastomosis of intestine, but gastro-enterostomy is performed in the same manner.

Jaboulay's Gastroduodenostomy.—This operation was devised by Jaboulay in 1892. It aims to obviate some of the objections to pyloroplasty and at the same time to retain the advantages this operation possesses over gastro-jejunostomy. Jaboulay's gastroduodenostomy has never become popular with surgeons, and Finney's method is much more satisfactory (see page 1081).

Posterior Gastro-enterostomy (see page 1088 and Fig. 664).—In a thin subject with a long mesocolon posterior gastro-enterostomy is to be chosen, but if the mesentery is short or contains much fat, or if the vascular loop coming from the superior mesenteric artery, and which supplies the transverse colon with blood, is small, so that on opening the posterior layer of the gastrocolic omentum it would be close to the artery, the anterior operation is employed (Wm. J. Mayo, in "Annals of Surgery," Aug., 1902). If a Murphy button is used, the posterior operation is selected. Posterior gastro-enterostomy is commonly performed as follows: After the abdomen has been opened the stomach and omentum are raised; a portion of the upper jejunum is seized, emptied, and a site selected for the clamp. This site must be within 5 inches of the flexure. If there is a broad mesocolic band preventing a near approach to the flexure the band must be divided. A clamp is applied on the side opposite the mesenteric attachment. A spot is selected on the transverse mesocolon where there are no vessels, and an opening is made through the mesocolon with a blunt instrument. The posterior wall of the stomach is pulled into the opening and sutured to its edges. This prevents downward displacement of the stomach and obstruction of the loop of gut. A portion of the posterior wall of the stomach is pulled out into a cone and clamped. Openings are made and the sutures applied as directed on page 1088. Regurgitation is less common after posterior than after anterior gastro-enterostomy. In 250 posterior operations in Czerny's clinic there was not one case of regurgitant vomiting; 170 cases were button operations and 45 were by sutures alone (Peterson). Von Hacker had one instance of regurgitation in 60 posterior operations.

Operation by the Murphy Button.—Gastro-enterostomy may be quickly performed by the use of a large-sized Murphy button. Murphy says that in some reported cases the button has slipped back into the stomach, but this accident can be prevented by the use of an oblong button and by making the anastomosis on the posterior stomach wall. The same surgeon advises us to scarify the peritoneum in order to hasten union, and says supporting sutures about the button are not required, except when considerable tension exists. There is no question that an anastomosis on the anterior wall, accomplished by a Murphy button, can be speedily performed. Anastomosis on the posterior wall cannot be performed so speedily, and it sacrifices to some extent the great advantage of the button operation—that is, speed. In spite of the reported cases we can positively assert that the danger of the button producing grave trouble is slight. In some cases it drops into the stomach and remains there, but seems to do no

harm. In other cases it takes a long time to pass. In 1 of the author's cases it did not pass until the eighty-sixth day. In one of Keen's cases it has been retained for years. If it does not pass in four weeks, the rectum should be explored by the finger from time to time to see if it is lodged in that region. The x-rays will determine whether the button is in transit. If the wall of the stomach is thick, the incision should be made in the stomach wall before the suture is passed, and this suture should pick up only a small portion of the stomach wall, otherwise the button may be retained in place for a very long time (Wm. J. Mayo). "In many cases in which the button passes, vomiting with symptoms of obstruction may appear during the second or third week while it is in transit. Gastric lavage and rectal feeding for a day or two cause these symptoms to subside" (Wm. J. Mayo, in "Annals of Surgery," Aug., 1902). Mayo long ago maintained that the suture operation is as good as the button operation, and that the results are about the same. Mikulicz says that in the suture operation entero-anastomosis is necessary, but not in the button operation, because the button, while in place, prevents angulation. The last-named surgeon uses the button in malignant cases and the suture in benign cases. Czerny is an advocate of the button. Every button should be tested before it is used. Mayo finds nearly 20 per cent. of buttons imperfect and dangerous.

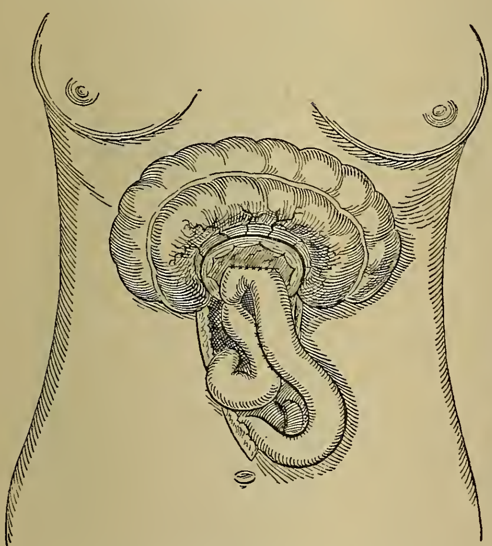

Fig. 672.—Fowler's method of gastro-enterostomy.

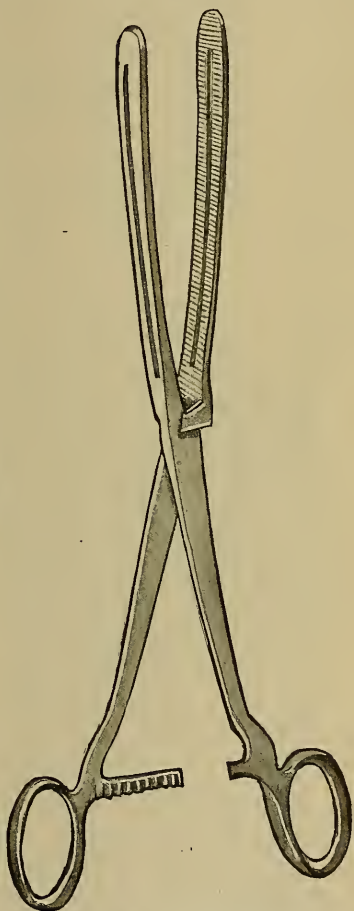

Fig. 673.—Moynihan's clamp for gastric and intestinal operations (made by Down Brothers, London).

Fowler's Method (Fig. 672).—Anastomose the posterior wall of the stomach to the jejunum and do an entero-anastomosis between the afferent and efferent loops of jejunum. Pass a No. 20 silver wire two or three times around the afferent loop of jejunum and draw it sufficiently tight to occlude the lumen without strangulating the wall of the gut. The ends are twisted, cut short,

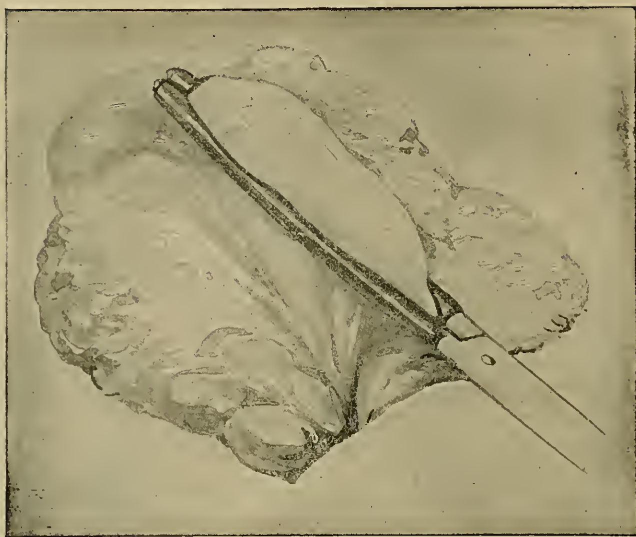

Fig. 674.—Moynihan's method of gastro-enterostomy: The oblique application of the clamp to the stomach (Moynihan).

rolled into a flat coil, the cut ends being in the coil. (See Geo. Ryerson Fowler on the "Circulus Vitiosus" following gastro-enterostomy, "Annals of Surgery,"

Fig. 675.—Moynihan's method of gastro-enterostomy: The strip of gauze between the clamps (Moynihan).

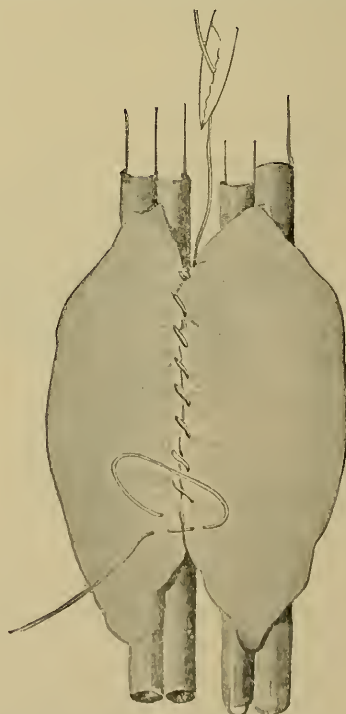

Fig. 676.—Moynihan's method of gastro-enterostomy: The first layer of serous suture (Moynihan).

Nov., 1902). This operation positively prevents the entrance of material from the duodenal loop into the stomach and also drains that loop.

Moynihan's Method.—This plan I have employed repeatedly. It is easy, rapid, and clean: Make a 4-inch incision 1 inch to the right of the middle line and above the umbilicus. Open the anterior sheath of the rectus and separate it from the front of the muscle as far as the middle line. Draw the entire muscle outward, open the posterior portion of the sheath, and then open the belly. Inspect and feel the entire stomach. Lift the omentum and transverse colon out of the abdomen and make the mesocolon taut by raising the stomach and colon with the left hand. Find "a bloodless spot in the arch of the middle colic artery," pick up a bit of the under surface of the mesocolon by a pair of hemostatic forceps, lift it from the posterior stomach

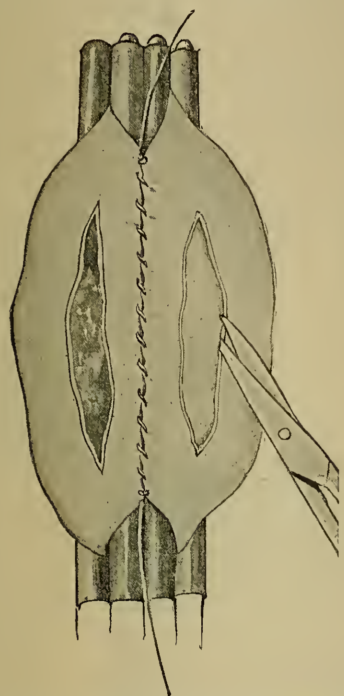

Fig. 677.—Moynihan's method of gastro-enterostomy: Removal of the ellipse of mucous membrane (Moynihan).

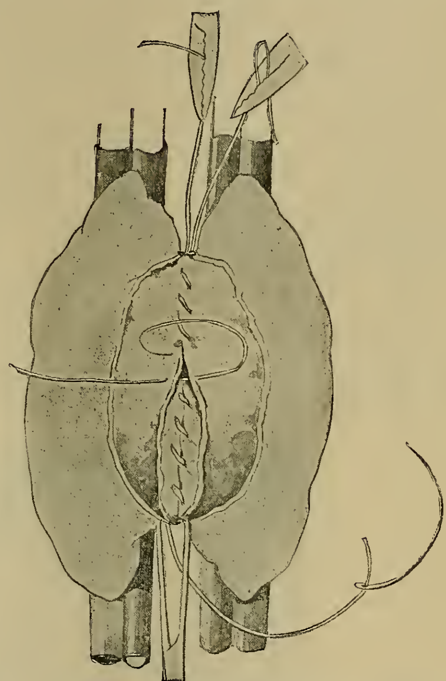

Fig. 678.—Moynihan's method of gastro-enterostomy: The inner suture continued (Moynihan).

wall, and open the lesser sac of peritoneum by the scissors. Enlarge the opening by dilatation or tearing until it admits three fingers. Inspect and feel the posterior stomach wall. Place the stomach in its natural position, mark with the thumb the lowest part of the posterior stomach wall, and again turn the viscus over. From the spot marked by the thumb a fold is raised. The fold is oblique and its upper end is to approach the cardia and lesser curvature. A stomach clamp (Fig. 673) having a rubber tube bent over each blade is applied obliquely so as to grasp the base of this fold. In applying the clamp the tip should point to the right shoulder and the handle of the outer side of the left hip, and the lowest portion of the stomach is grasped in the tip of the blade of the clamp (Fig. 674). The clamp is now put in a horizontal position. The duodenojejunal flexure is found by the finger, the jejunum is identified and its natural position is noted. The jejunum is picked up

and "drawn tight" and a spot is noted which reaches the greater curvature of the stomach when the jejunum is in its natural position. The point noted is 5 inches from the flexure and the anastomosis is made to the jejunum above the spot. The clamp is applied in the side of the gut opposite the mesentery. The surgeon must be sure that the jejunum is not twisted around its longitudinal axis. If it is, the clamps are not rightly applied, and they must be placed so that after the anastomosis the jejunum lies in its natural position without a twist. The clamped gut is placed by the side of the clamped stomach, a bit of gauze being put between them (Fig. 675). The stomach (except the clamped portion), the omentum, and transverse colon are returned to the abdomen and the clamps are surrounded by gauze. Each clamp holds a fold $3\frac{1}{2}$ to 4 inches in length. Pagenstecher's celluloid thread is used for suturing. The first line of sutures is passed as shown in Fig. 676. In front of these sutures an incision is made into the stomach and another into the jejunum, the serous and muscular coats being first divided, and an ellipse of mucous membrane being removed (Fig. 677). The next row of sutures is inserted as shown in Fig. 678. When this row is completed the clamps are removed and the long suture of the first row is picked up again and the operation is completed (Fig. 679). Finally, the edges of the mesocolic opening are sutured to the jejunum. The parts are cleansed with salt solution,

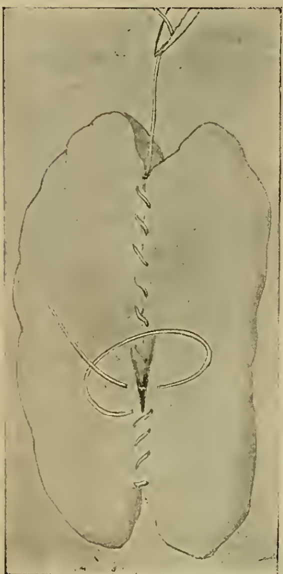

Fig. 679.—Moynihan's method of gastro-enterostomy: The serous suture resumed (Moynihan).

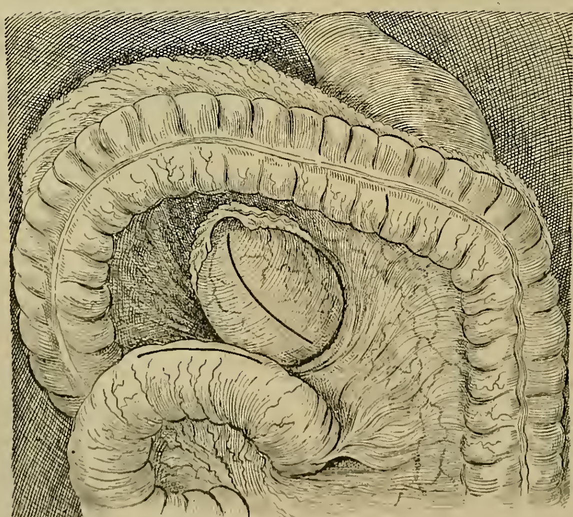

Fig. 680.—Mayo's method of gastro-enterostomy: Showing posterior wall of the stomach drawn through a rent in the transverse mesocolon. Note slight separation of gastrocolic omentum from its attachment to the stomach, permitting anterior wall of stomach to appear, and insuring drainage at lowermost level. Black lines mark site of proposed anastomosis; the jejunum shows at its origin.

the suture line is inspected, the parts are returned to the belly, and the abdomen is closed. (See Moynihan's "Abdominal Operations.")

The No-loop Operation of the Mayos.—(Figs. 680–682).—It is this operation I usually perform. By it the gastric opening, which is placed in the line advised by Moynihan, extends $\frac{1}{4}$ or $\frac{1}{2}$ inch into the anterior wall

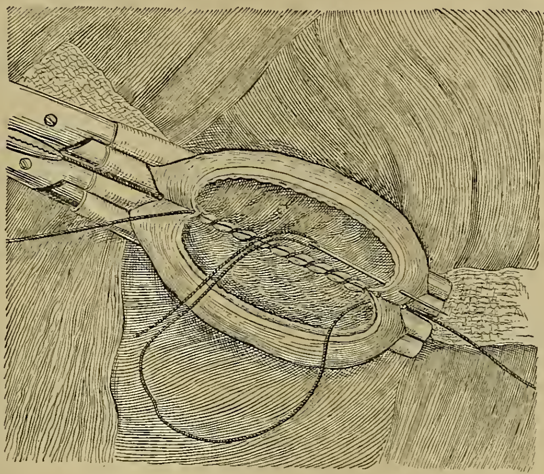

Fig. 681.—Mayo's method of gastro-enterostomy: Forceps in place and anastomosis half completed by suture.

of the stomach, and thus the lowest part of the opening will be the lowest part of the stomach (Fig. 680). The incision in the intestine begins from 1 to 3 inches from the origin of the jejunum, the measure being made on the anterior surface (Fig. 680).

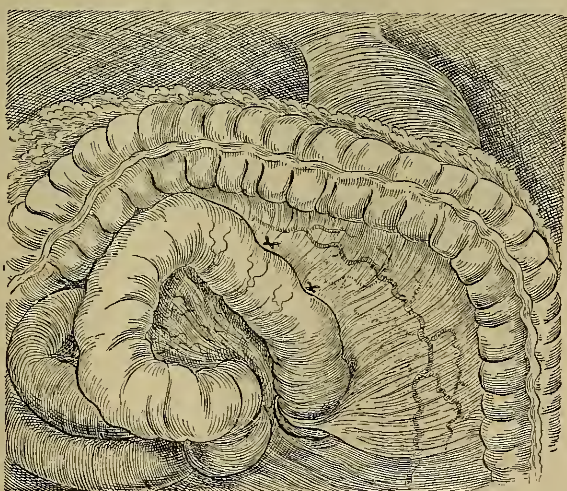

Fig. 682.—Mayo's method of gastro-enterostomy: Completed operation from behind. Margin of torn mesocolon attached by several interrupted sutures to line of union.

The object is to get as short a piece of jejunum as can be attached without tension. The operation is described as follows (Wm. J. Mayo, in "Annals of Surgery," Nov., 1905):

"(*a*) The abdominal incision is made 4 inches in length, $\frac{3}{4}$ inch to the right of the middle line, the fibers of the rectus muscle being separated. The lower end of the external wound lies opposite the umbilicus. This opening also enables inspection of the duodenum and gall-bladder and is reliable against hernia when closed.

"(*b*) The transverse colon is pulled out and the mesocolon made taut by traction upward and to the right, in this manner bringing the jejunum into view at its origin.

"(*c*) About 3 to 4 inches of the jejunum opposite the mesentery are drawn into a slightly curved clamp. The handles of the clamps should be to the right, to enable a short grasp on the intestine. Three-fourths of the circumference of the bowel is pulled through; the posterior border is not included, to prevent entanglement of the suture with the redundant posterior mucous membrane. The holding clamps are applied sufficiently tight to check hemorrhage and prevent extravasation of intestinal contents.

"(*d*) The ligament of Treitz is a short muscular mesentery covered by a variable peritoneal fold (too variable for a reliable landmark) extending upward from the origin of the jejunum on to the mesocolon. This peritoneal fold lies at the base of the arterial loop of the middle colic artery which supplies the transverse colon. The mesocolon is opened within the vascular loop and the posterior inferior border of the stomach pushed through. A small separation of the greater omental attachment to the stomach enables the anterior gastric wall to be drawn out posteriorly. The posterior gastric wall is drawn into a clamp, with the handles to the right, in such a manner as to just expose the anterior wall at the base.

"(*e*) The two clamps are laid side by side and the field carefully protected by moist gauze pads. With fine celluloidal linen thread on a straight needle the intestine is sutured to the stomach from left to right by a Cushing suture at least $2\frac{1}{2}$ inches.

"(*f*) The stomach and intestine are incised $\frac{1}{6}$ inch in front of the suture line and the redundant mucous membrane excised flush with the retracted peritoneal and muscular coats. With a No. 1 chromic catgut on a straight needle the posterior cut margins of the entire thickness of the gastric and jejunal wall are united by a buttonhole suture from right to left; at the extreme left the suture changes to one which passes through all the coats, of each side alternately, from the peritoneal to the mucous, then directly back on the same side from the mucous to the peritoneal. This acts as a hemostatic suture, and also turns the peritoneal coats into apposition. It passes around the anterior surface and is tied to the original end, which has been left long for the purpose. If silk or linen is used for this suture it may hang *in situ*, suppurating for months.

"(*g*) The clamps are now removed and the linen thread continued around until it is tied to the original end, firmly catching the blood-vessels in sight along the suture line. The parts are carefully cleansed and inspected. If necessary, a suture or two is applied to accurately coapt or to check the oozing.

"(*h*) The margins of the incised mesocolon are now united to the suture line by 3 or 4 interrupted sutures, and the parts returned into the abdomen." In this operation the greatest care must be taken to avoid twisting the gut around its longitudinal axis.

Gastro-anastomosis or **gastrogastrostomy** is an operation performed for hour-glass contraction of the stomach, a condition which occasionally ensues on the healing of an ulcer. In this operation an anastomosis is effected between the pyloric and cardiac pouches. It was devised and practised by Wölfler in 1894. I have performed it twice with success. Watson folds the two stomachs over each other, using the narrow isthmus as a hinge;

sutures the pouches together and leaves the ends of the sutures long. He incises the anterior wall of the anterior stomach in order to obtain access to the double septum between the two pouches. He makes an anastomosis opening through the double septum, sutures the edges, and closes the wound in the anterior wall of the anterior stomach. Wölfler made a vertical cut in each pouch and united these openings to make an anastomosis. The best plan is to apply clamps on each side of the isthmus and operate as we would for gastro-enterostomy (Fig. 684).

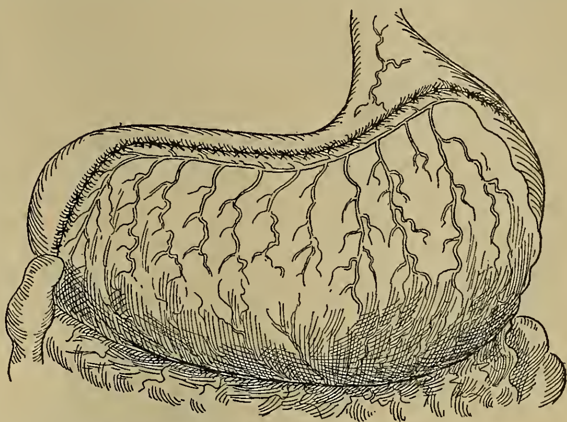

Fig. 683.—Bircher's method of gastroplication.

Gastroplication (Brandt's Operation of Stomach-reefing for Dilated Stomach).—Apply sutures in the anterior wall so as to form reefs, then tear through the great omentum and apply sutures in the posterior wall.

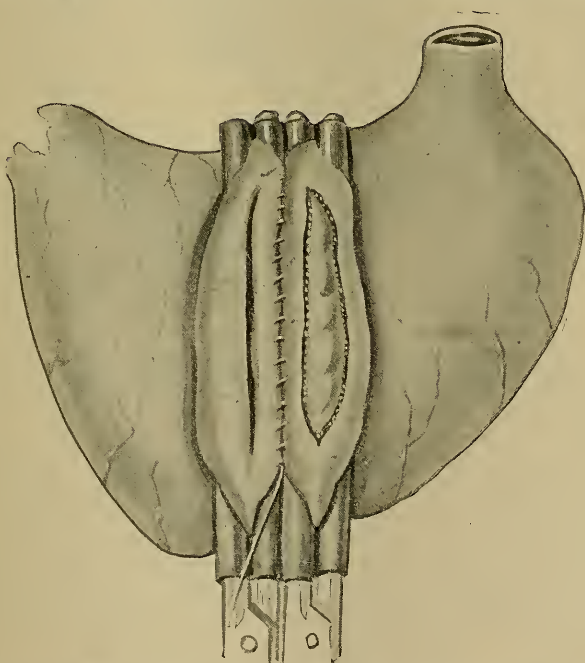

Fig. 684.—Hour-glass stomach. The application of clamps and the method of suture in gastrogastrostomy. The details are the same as in the operation of gastro-enterostomy (Moynihan).

The sutures pass through the serous and muscular coats. A continuous suture may be used on the anterior wall and another on the posterior wall, or numerous interrupted sutures may be inserted. This operation is of ques-

tionable value, and must never be used if stenosis of the pylorus exists, and stenosis of the pylorus is the most common cause of gastric dilatation.

Bircher's method of gastroplication is shown in Fig. 683.

Gastropexy (Duret's Operation for Gastroptosis).—It has been shown by Duret that dyspepsia of a peculiarly severe type may be produced by prolapse or downward displacement of the stomach. In this condition he advised the following operation: Perform a median laparotomy, but do not incise the peritoneum in the upper portion of the wound. Expose the stomach and fix it by means of a silk suture to the undivided but exposed peritoneum. The suture should be parallel to the lesser curvature and near the pylorus should be horizontal.[1] Rovsing, too, fixes the stomach to the abdominal wall. So do Hartmann and Eve. The operations of Duret, Rovsing, Hartmann, and Eve, of London, fix and distort the stomach. This seems to me an objectional procedure and liable to be followed by pain. To fix an organ which

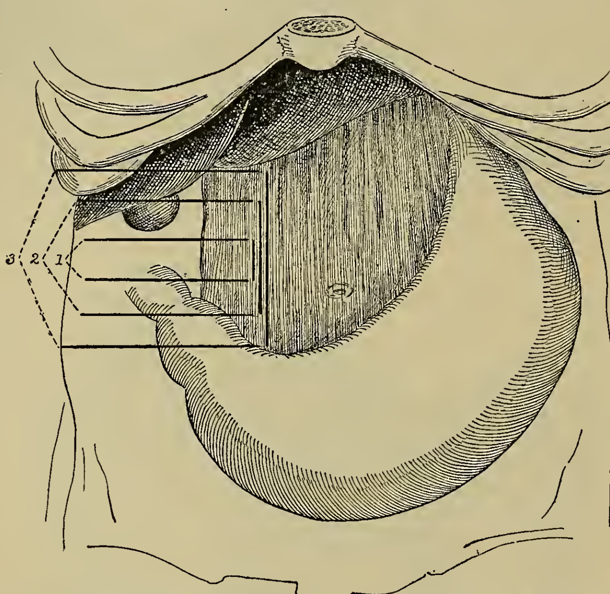

Fig. 685.—Beyea's operation for gastroptosis: 1, Position of one suture of first row; 2, one suture of second row; 3, one suture of third row. Others of each row introduced at intervals to and including the gastrophrenic ligament.

undergoes active peristalsis must surely be productive of difficulty. Byron Davis advises the suturing of the gastrohepatic omentum near its attachment to the lesser curvature to the stomach wall as high as possible. Beyea has devised an operation which is free from the objections which may be urged against Duret's operation. Sometimes gastro-enterostomy is also performed.

Beyea's Operation for Gastroptosis.—Insert three rows of interrupted silk sutures through the gastrohepatic omentum and the gastrophrenic ligament. Each suture is passed from above downward and the row begins at the right and passes to the left (Fig. 685). When the sutures are tied, a fold or plication is formed in the ligaments, the supports of the stomach are shortened, and the viscus is elevated to a normal position without any disturbance of its physiological mobility ("Univ. of Penna. Med. Bull.," Feb., 1903).

Ransohoff's Omentopexy for Gastroptosis.—Ransohoff ("Medical Communications of the Mass. Med. Soc.," 1912, vol. xxiii) points out that

[1] "Rev. de Chir.," June, 1896.

Beyea's operation is insufficient because only the right and left borders of the gastrohepatic omentum act as supports. He uses the omentum to raise and fix the stomach, and at the same time raises and fixes the transverse colon. He makes spaces between the fascia and peritoneum as advised by Coffey and sutures the omentum into these spaces. If necessary he also does gastroplication, or coloplication, or reefs the mesocolon or separates bands and adhesions, or shortens the round ligament of the liver.

Duodenostomy and Jejunostomy.—It has been suggested that one of the above operations should be performed in a case of pyloric obstruction in which neither pylorectomy nor gastro-enterostomy is feasible. Duodenostomy is said by some to be an easy operation because of the mobility of the pylorus and first part of the duodenum, and to be not only easier, but safer, than jejunostomy, because it makes the fistula above the opening of the common bile-duct ("Bull. et Mém. de la Soc. de Chir. de Paris," No. 39, 1901). Cackove advocates the operation in some cases of gastric ulcer with repeated hemorrhages and some cases of gastric cancer. In the latter cases he asserts that the mortality is about the same as from gastro-enterostomy and the prolongation of life is greater ("Arch. f. klin. Chir.," Bd. lxv, Heft 2). Hartmann's case of duodenostomy lived two months. The operation was performed for extreme cicatricial stenosis of the pylorus due to swallowing hydrochloric acid.

Jacobson disapproves of both procedures, and objects particularly to duodenostomy, because it involves a portion of the intestine which is difficult to deal with, and because important fluids escape constantly from the fistula.[1]

If duodenostomy is performed, it should be done in the same manner as gastrostomy by Witzel's method. I regard jejunostomy as an operation which is occasionally justifiable and as preferable to duodenostomy. As performed to-day there is little danger of leakage, even if the tube slips out. This operation puts the stomach at absolute rest. It is employed in very extensive ulceration, in multiple ulcers, and in some cases of cancer in which gastro-enterostomy is impossible or is contra-indicated, because the fistula would be in or too near the malignant growth. Wm. J. Mayo ("Am. Jour. Med. Sciences," April, 1912) regards the operation "as an active competitor of gastrostomy in cases of esophageal and cardiac obstruction." Mayo-Robson ("Brit. Med. Jour.," Jan. 6, 1912) advocates the operation. Mayo makes an epigastric incision, picks up the jejunum, makes a little opening at a point from 12 to 16 inches from the jejunal origin, introduces a rubber catheter (No. 9 English) "down stream" for about 3 inches, catches it to the wall of the bowel by one suture of chromic gut, infolds it for 1 inch or more as in Witzel's gastrostomy, using mattress sutures of linen, anchors the gut to the peritoneum by two or three lines of linen sutures at the lower angle of the incision, and closes the abdominal wound (Wm. J. Mayo, Loc. cit.). Food can be given at any time.

If the tube slips out it must be put back at once, as the tract might close in a few hours. When the operation has been done for cancer the fistula is permanently maintained. If for ulcer, it can be allowed to close or can be closed surgically, if it persists, as soon as the ulceration heals. Billon ("Archiv. prov. de Chir.") has collected 127 cases. The direct mortality was 29 per cent. Sixty-four of the patients lived but three months or less. A single case lived beyond a year. This is not a very gratifying showing.

Maydl does a much more formidable operation (divides the jejunum, attaches the upper end to a far-away portion of gut, and attaches the lower end in the abdominal wound). He has operated on 25 cases, with 4 deaths.

Enterectomy, or Resection of the Intestine with Approximation by Circular Enterorrhaphy.—How much of the intestine can be removed without the patient dying from lack of nutrition? The question is not settled.

[1] Jacobson's "Operations of Surgery."

It has been stated that the removal from an adult of more than 6⅝ feet produces nutritional disturbance, and that a child tolerates the removal of a piece relatively larger better than does an adult. Senn was of the opinion that excision of more than one-third of the intestine makes inanition inevitable. Certain it is that great lengths have been successfully removed, and the patients have not only lived, but have been well nourished. Ruggi removed 11 feet, Witall removed 10 feet 8 inches, Von Eiselsberg, 11 feet 8 inches, and Obulinski, 12 feet 2 inches. Brougham removed 11 feet 2 inches for mesenteric thrombosis and the patient recovered. Childe successfully removed 9 feet 6 inches of small intestine for embolism of the mesenteric artery. Hayes removed 8 feet 4½ inches from a boy ten years of age, and the patient was well eight months later. Dressman reported 26 cases in each of which more than 3 feet 3 inches had been removed (Alexander Blaney, in "Brit. Med. Jour.," Nov. 16, 1901). Blaney adds 7 cases from literature, and tells us that in 9 of the 33 cases death occurred soon after operation.

Alexander Blaney, in the previously quoted article, reviews the subject of the resection of great lengths of intestine. He tells us that how much remains after a resection is important, but uncertain. It is uncertain because, as Treves has shown, the length of the intestine varies from 15 feet 6 inches to 31 feet 10 inches.

Fig. 686.—Excision of bowel: first step (Esmarch and Kowalzig).

Fig. 687.—Excision of bowel with enterorrhaphy and stitching of the redundant mesentery: second step (Esmarch and Kowalzig).

Could end-to-end anastomosis be done as safely as lateral anastomosis it would usually be the preferred method. The great danger is infection from soiling. "Occasionally, the circular suture is the only feasible one" (Halsted, "Jour. of Exper. Med.," No. 3, 1912).

Resection of the jejunum is much more dangerous than resection of an equal length of ileum. Resection of the ileum is more dangerous than resection of the colon. If resection is employed, all diseased or injured bowel must be removed irrespective of ultimate bad consequences (Blaney). The operation is performed as follows: After opening the abdomen isolate the loop of intestine we intend to resect. Push a rubber tube through the mesentery close to the bowel, above the seat of operation, and pass a rubber tube through the mesentery below the seat of operation. Instead of tubes, strips of iodoform gauze may be used to encircle the bowel. Empty this segment of bowel by squeezing and stroking, tighten the rubber tubes, and clamp them to keep the bowel empty (Fig. 686). The diseased intestine is resected, each incision being carried through a healthy segment, and care being taken that the cuts are so arranged that at each end a blood-vessel from the mesentery reaches the edge of the cut bowel. Otherwise repair can scarcely occur. The lumen of each end of the divided gut is irrigated with salt solution. The divided surfaces are approximated by a double row of sutures—a continuous suture for the mucous membrane, and Lembert's, Dupuytren's, Cushing's suture, or Halsted's sutures

—to effect inversion. Thoroughly satisfactory approximation can be effected by one row of Halsted mattress sutures (Fig. 688). If a redundant fold of mesentery is left, it can be stitched at its raw edge (Fig. 687). Many surgeons remove a V-shaped piece of mesentery, tie the divided mesenteric vessels (Fig. 686), and introduce sutures so that no mesenteric vessel will be constricted (Fig. 688). The tubes are removed, and the wound is cleansed, closed, and dressed.

Senn effects invagination by means of a bone ring (Fig. 689).

If the two segments of bowel are unequal in size, it was formerly the custom to cut the narrow part of the bowel obliquely and the larger part transversely. To meet this complication Billroth devised *lateral implantation* (see Fig. 717). Suppose the cecum has been resected: its lower end is closed by Lembert sutures, an opening is made in the long axis of the periphery of the colon opposite the attachment of the mesocolon, and the end of the ileum is sutured into this incision. This is called *end-to-side approximation,* or implantation. It is used in the sigmoid, in the cecum, and in any intestinal segment in which the circulation is deficient. Eugene A. Smith ("Amer. Med.," May 10, 1902) sums up the advantages of end-to-side approximation as follows: The strain of peristalsis is less than in end-to-end union; the circulation of each end of the

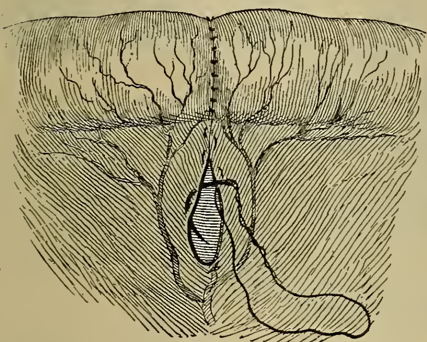

Fig. 688.—Suture of the mesentery after circular enterorrhaphy (Halsted).

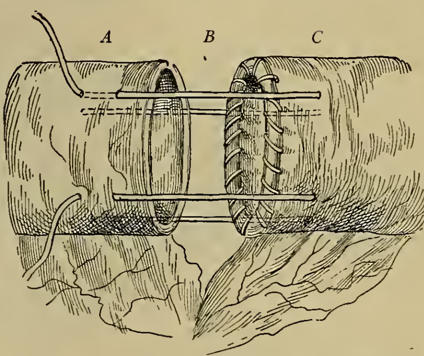

Fig. 689.—Senn's modification of Jobert's invagination method: *A*, Upper end lined with ring; *B*, invagination sutures in place; *C*, lower end.

bowel and the parts of bowel adjacent is better; each cut edge of mesentery is free to recover its circulation, and there is no dead space at the mesenteric border to lead to leakage.

Senn advised the insertion of an anastomosis ring in the ileum, the invagination of the colon as the ring is pulled into place, and firm suturing of the line of junction. By Senn's method the ileum may be implanted into the end of the colon or into a slit in the wall of the large bowel after the end of the colon has been closed. In some cases, in which one portion of bowel is larger than the other, lateral anastomosis is the preferable method. For a full week after an intestinal resection the patient is fed chiefly by nutrient enemata. During the first twenty-four hours nothing is given by the stomach but small amounts of hot water, and for the next six days only water and a little liquid food is allowed to be swallowed.

The use of *Murphy's button* (Fig. 691) permits of rapid approximation after resection (Fig. 690). This button closely approximates the portions of the intestine within its bite, rapid adhesion taking place. The diaphragm of tissue undergoes pressure-atrophy and liberates the button, which is passed per anum. It is claimed that the button-opening contracts but slightly. For end-to-end or side-to-side approximation of the small intestine a No. 3 button is used.

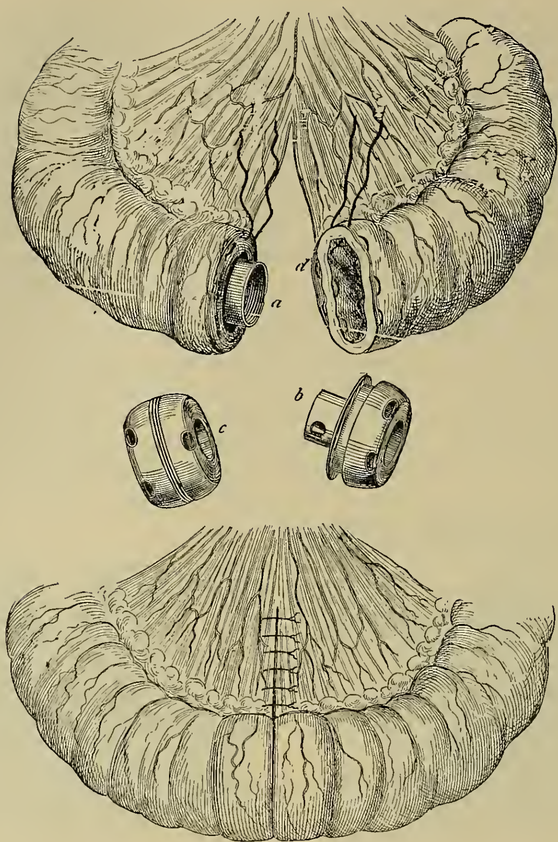

Fig. 690.—Resection of intestine: *a*, *b*, The two halves of the button; *c*, the two portions clamped together; *d*, introduction of the sutures for holding each half of the button in place. The lower figure shows the completed union of the intestine by the Murphy button; the slit in the mesentery has been closed by linear union (after Zuckerkandl).

For similar operations on the large intestine a No. 4 button is employed (Murphy). After the resection one-half of a button is inserted into each segment, and is held in place by a purse-string suture of silk which passes through all the coats (Fig. 690). The redundant mucous membrane is tucked in or clipped off, so that it will not be interposed between the serous surfaces. The serous surfaces are scratched with a needle and the halves of the button are locked (Fig. 690). It is not necessary to surround the margin of junction with sutures. Murphy says that liquid nourishment should be given as soon as the patient has recovered from the effect of the ether, and that the bowels should be moved at an early period, and frequent evacuations should be maintained. If the

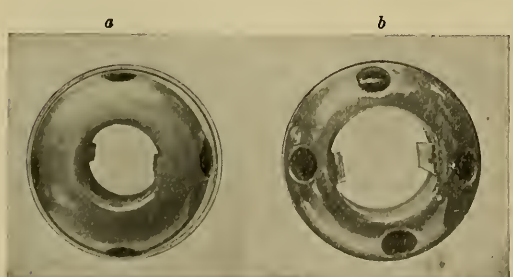

Fig. 691.—Comparison of old (*a*) and new (*b*) Murphy buttons.

button does not pass in four weeks, examine the rectum for it.[1] The situation of the button can be ascertained by the x-rays. An objection to the button is that it introduces a foreign body which must pass per rectum to complete the operation successfully. It may not pass, but trouble does not of necessity follow. In some cases its retention does lead to trouble, and intestinal obstruc-

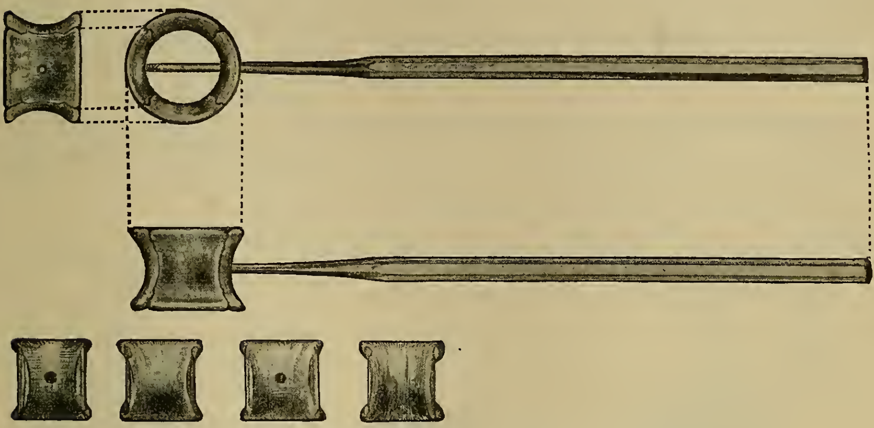

Fig. 692.—The segmented ring of Harrington and Gould.

tion ensues. If the caliber of the button blocks before dislodgment, obstruction follows, hence the rule to give saline purgatives the day after the operation.

Some surgeons have sought to make a button which would come apart and be absorbed after it had accomplished its purpose. One of these appliances is Frank's coupler, which is made of bone, the compression being

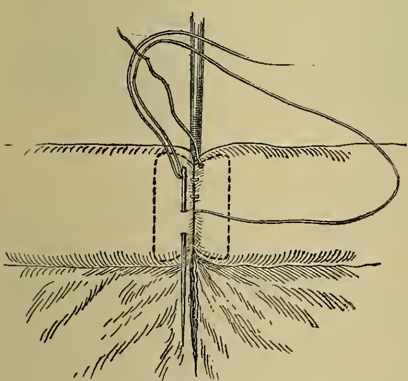

Fig. 693.—End-to-end union with aid of segmented ring. Continuous stitch beginning at one side of the handle (Harrington and Gould).

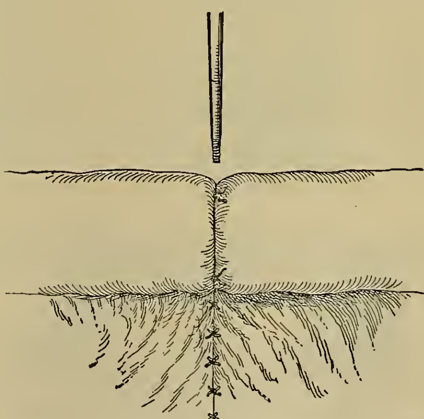

Fig. 694.—End-to-end union with aid of segmented ring. Handle unscrewed, suture completed (Harrington and Gould).

furnished by rubber. In this apparatus, however, the amount of pressure obtained is always uncertain and the rubber is apt to wear out. The button gives a lower mortality than the suture operation, and some surgeons now use it who once condemned it. Czerny is a strong advocate of the button.

[1] John B. Murphy, in "Med. News," Feb. 9, 1895.

Harrington and Gould use a *segmented aluminum ring*. This ring collapses into small segments after the anastomosis has been effected. By its use the authors believe that the operation is made more rapidly and safely ("Annals of Surgery," Nov., 1904). During the suturing the ring is held by means of a handle, which, after the anastomosis has been effected, is removed. The ring in the handle is shown in Fig. 692 and the operation in Figs. 693, 694.

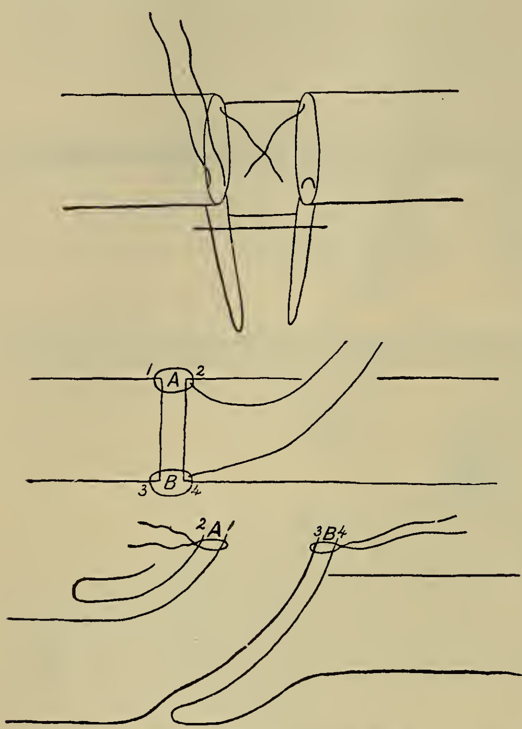

Fig. 695.—Maunsell's method of anastomosis (after Wiggin).

Maunsell has devised a most ingenious method of circular enterorrhaphy. The two portions of bowel are attached by two fixation sutures which penetrate all the coats (Fig. 695). An incision $1\frac{1}{2}$ inches in length is made through the wall of the proximal segment of gut, about 1 inch from its edge. The fixation sutures are brought through this opening, traction is made upon them, the distal portion of the bowel is invaginated into the proximal portion, and the ends emerge from the opening, their peritoneal surface being in contact (Fig. 695). Sutures of silk are passed through both sides of the area of invagination, the threads are caught up in the center, cut, and tied on each side. The fixation sutures are cut off. The invagination is reduced by traction. The longitudinal cut is closed by Lembert sutures.

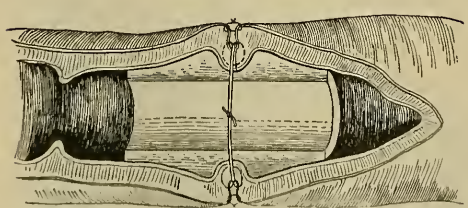

Fig. 696.—Robson's decalcified bone bobbin.

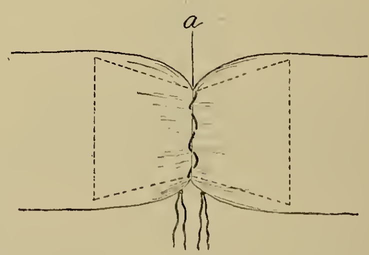

Fig. 697—Allingham's decalcified bone bobbin.

A. W. Mayo-Robson performs circular enterorrhaphy and brings the ends of the gut together over a bobbin of decalcified bone (Fig. 696). Allingham uses a bone bobbin the shape of two cones joined at their apices. The bobbin is decalcified, except an area at the center (Fig. 697, *a*). Kocher performs circular enterorrhaphy as follows: A fixation suture is introduced

through the bowel at the mesenteric attachment and another is inserted at an opposite point. The intestinal ends are approximated by a continuous silk suture, which passes through all of the coats, but which includes more of the serous than of the mucous coat. The suture-line is overlaid by a continuous Lembert suture which includes the serous and a portion of the muscular coat.

In doing an end-to-end approximation I prefer to use the clamp of Moynihan (see Fig. 673), as shown in Figs. 698–700. We thus are able to hold the parts and keep them clean, rapidly make an even and secure stitch line, and have no free-edged septum.

Some surgeons have used inflatable rubber cylinders in making an end-to-end anastomosis (Halsted, Downes, and others). The method was devised by Treves, but was subsequently abandoned by him. Halsted no longer uses the inflatable cylinders. Professor Halsted is at present developing a method which seems to be aseptic and to offer other advantages. He calls it "A Bulkhead Suture of the Intestine" ("Jour. of Exper. Med.," No. 3, 1912). He reduces the wall of the bowel by crushing its submucous coat on each side of the loop to be excised; he then finally ligates and cuts through by a cautery. There is now a diaphragm on each end of the divided gut. He invaginates the gut by paper cylinders held in wooden mandrels, redivides it (thus cutting loose the diaphragm), and sutures it.

Fig. 698.—Moynihan's method of end-to-end anastomosis (Moynihan).

Fig. 699.—Moynihan's method of end-to-end anastomosis continued.

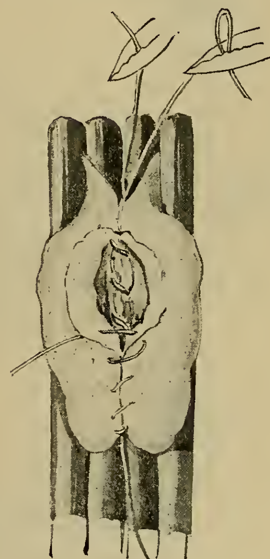

Fig. 700.—Moynihan's method of end-to-end anastomosis continued.

Connell has devised a method which places the knots in the lumen of the bowel (F. Gregory Connell, "Medicine," April, 1901). He maintains that the placing of the knots within the lumen of the gut has the following advantages: there is no foreign body; the suture passes away early; adhesions to neighboring organs are few; the serous approximation is perfect; the suture line is more secure; the septum is smaller and the danger of necrosis is less. The suture is shown in Plate 11.

Laplace has devised forceps which greatly facilitate suturing, which make it easy to obtain an even suture line, and which can be withdrawn after the suturing is finished, the small opening through which the instrument emerged

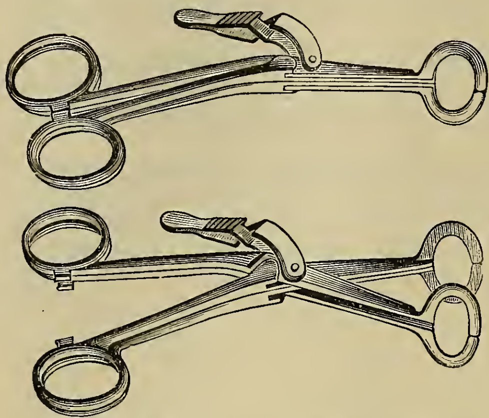

Fig. 701.—Laplace's forceps for intestinal anastomosis.

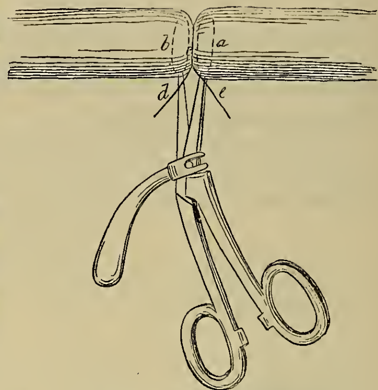

Fig. 702.—End-to-end anastomosis with the aid of Laplace's forceps.

being closed by a stitch (Figs. 701, 702). By aid of Laplace's forceps the operation can be neatly and rapidly performed, but a large diaphragm is formed, a considerable area is exposed to infection, the tissues of the diaphragm are bruised and may slough, the raw ends may grow together and cause obstruction, and it seems probable that considerable contraction will follow. Another objection is that an infected instrument is withdrawn from the bowel and may contaminate the peritoneum.

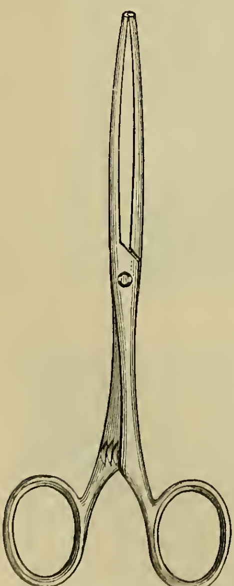

Fig. 703.—O'Hara's anastomosis forceps (about one-third original size).

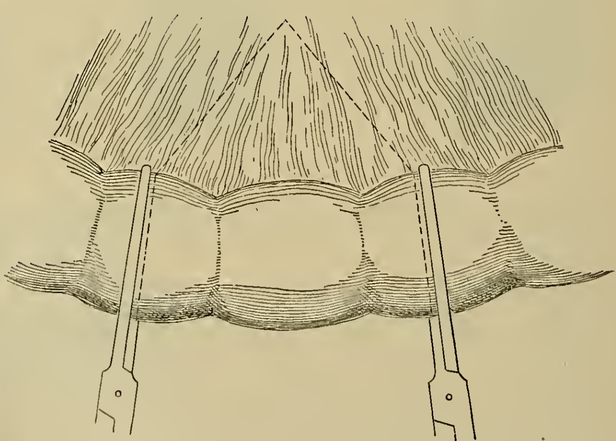

Fig. 704.—Showing the manner of placing forceps in resection of bowel; dotted lines show the incision to be made (O'Hara).

O'Hara's forceps (Fig. 703) permit of rapid and accurate suturing, but possess the same disadvantages as the Laplace forceps. In 1 case within my knowledge absolute obstruction from adhesion of the raw edges of the septum

followed its employment. Figures 704 and 705 show the use of O'Hara's forceps. Of the operations previously set forth, I prefer the clamp and suture as employed by Moynihan, the operation of Halsted by mattress sutures and without mechanical aids, and in some cases the operation with the Murphy button.

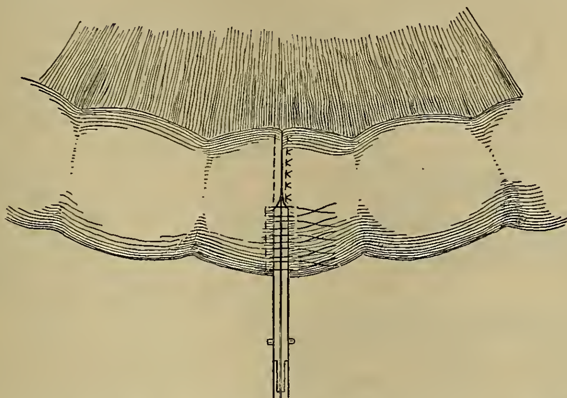

Fig. 705.—End-to-end anastomosis. Forceps brought together and held by serre-fine (not shown); sutures introduced, some of which are tied (O'Hara).

Lateral Intestinal Anastomosis.—Approximation may be effected by other methods than by end-to-end junction or by implantation. In fact, I prefer in most cases of resection to close each end of the divided gut and perform lateral anastomosis. It is a safer operation than end-to-end anastomosis and by it we can obtain as large an opening as we desire. Again, after lateral anastomosis the parts obtain a better blood-supply than after end-to-end suturing, because in the former operation the mesenteric vessels are not interfered with. Further, in lateral anastomosis there is little tendency to cicatricial contraction. Lateral anastomosis may be performed in some cases without a preliminary resection for the purpose of short-circuiting the fecal current, throwing a diseased portion of the bowel out of action, and thus avoiding obstruction (Fig. 706). This operation has the disadvantage that the diseased structure is not removed.

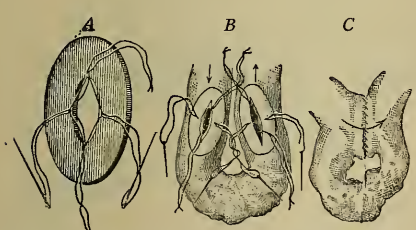

Fig. 706.—Senn's entero-anastomosis: A, Senn's bone plate; B, intestinal anastomosis; C, operation complete.

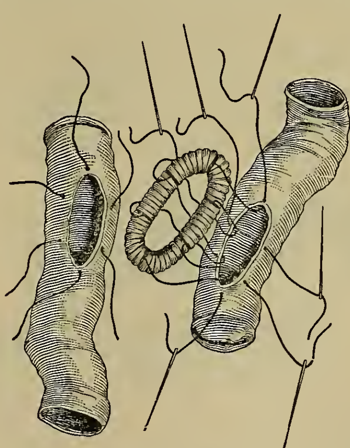

Fig. 707.—Method of passing the silk sutures in inserting the rings of Abbe.

Operation with Rings.—In this operation a portion of bowel above the obstruction and a loop below the obstruction are brought into the wound.

These segments are emptied, and are kept empty by fastening around them rubber tubes or iodoform strips. Two tubes are needed for each loop of bowel. Pack in gauze pads. Make an incision in one loop, in the long axis of the bowel, on the surface away from the mesentery; permit the contents to escape externally; irrigate this segment with saline solution, and introduce the bone plate of Senn (Fig. 706, A) or Abbe's catgut ring (Fig. 707). Calyx-eyed needles are used to pass the silk, and the threads of the ring are carried through the coats of the bowel and are gathered together in the bite of a pair of forceps. The other loop of intestine is treated in a similar manner. The two segments of intestine are so brought together that the two wounds are opposite each other, the posterior sutures being tied first, the upper next, then the lower, and finally the anterior threads. The ends of the threads are cut off, and the entire anastomosis is surrounded by a layer of Lembert or Halsted sutures or is encircled by Cushing's suture. Figure 706, B, shows an intestinal anastomosis partly finished, and Fig. 706, C, shows an anastomosis complete. Figure 707 shows the passing of the sutures when the catgut rings of Abbe are employed. After an intestinal resection each end can be closed and anastomosis effected as described above. Lateral anastomosis can be accomplished with a Murphy button, the intestine being prepared for the button as is shown in Fig. 708.

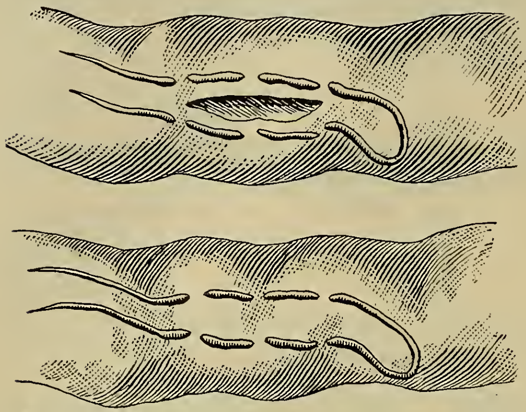

Fig. 708.—Showing relative size of incision and method of introducing sutures in lateral approximation with Murphy's button.

Abbe's method of anastomosis without mechanical aid is as follows: After resecting the bowel and mesentery and closing the ends of the bowel he places

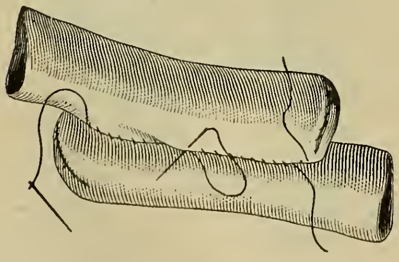

Fig. 709.—Suturing intestines in apposition before incision (Abbe).

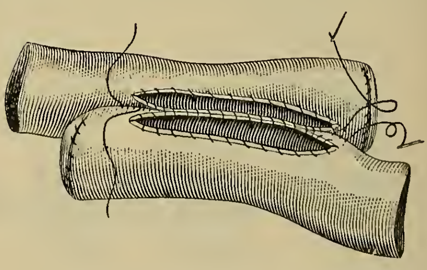

Fig. 710.—Showing the 4-inch incision and sewing of the edges (Abbe).

the extremities side by side and applies two rows of a Dupuytren suture, ¼ inch apart. These rows of sutures are 1 inch longer than the slit in the bowel will be (Fig. 709), the thread at the end of each row being left long. An incision is made in the bowel, ¼ inch from the sutures, both rows of threads being on the same side of the cut. This incision is 4 inches long. The other portion of the bowel is then incised in the same way. The adjacent cut edges are united by a whip-stitch which goes through all the coats, and the free cut edges are

stitched in the same manner (Fig. 710). The surgeon now utilizes the long threads of the first sutures, and brings the serous surfaces of the opposite sides together by means of Dupuytren's suture. Halsted performs anastomosis as follows: He places the two portions of bowel with their mesenteric borders in contact. Six quilted sutures of silk are introduced, tied, and cut off (Fig. 711, *a*). At each end of this row of sutures two quilted sutures are introduced,

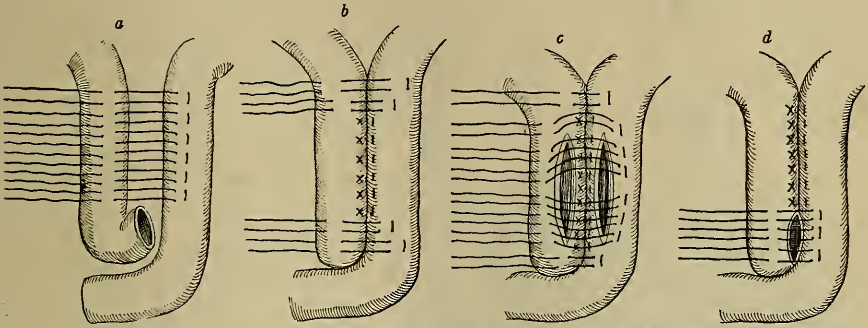

Fig. 711.—Halsted's operation for lateral anastomosis, showing four steps of same (Jessett, from Halsted).

tied, and cut (Fig. 711, *b*). A number of quilted sutures are introduced, as is shown in Fig. 711, *c*. The intestinal openings are made with scissors, and the sutures last introduced are tied and cut off (Fig. 711, *d*).

J. Shelton Horsley has suggested an ingenious method of intestinal anastomosis which secures for the sutured portion a greater diameter than that normal to the intestine.[1] After resection of the intestine and a V-shaped piece of

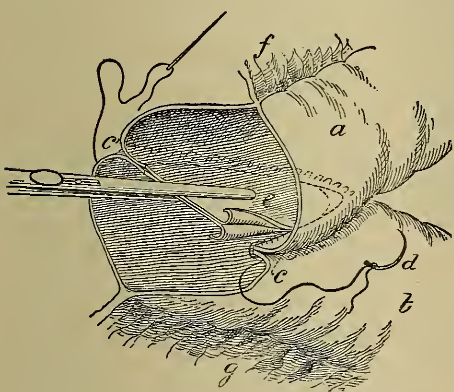

Fig. 712.—Represents the ends of the intestine in position and grasped by the artery forceps. The first row of sutures has been partially applied, the septum partly cut away, and the second row of overhand sutures begun: *a*, *b*, are the two ends of the intestine; *c*, *c'*, the first row of sutures (Cushing); *d*, the second row of sutures (overhand); *e*, the septum; *f* and *g*, the mesentery (J. Shelton Horsley).

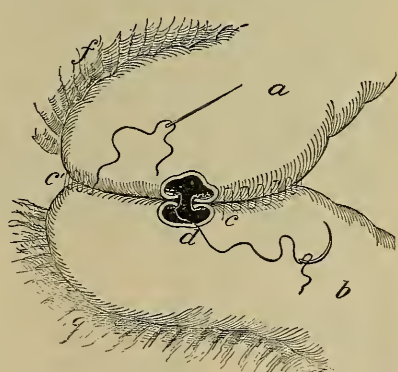

Fig. 713.—Operation nearly completed. The septum has been cut away, and the row of overhand sutures has been brought almost to its point of commencement. The cut also shows the first row of sutures (Cushing) as it should be continued after the overhand sutures are finished (J. Shelton Horsley).

mesentery, the ends of the bowel are placed side by side, the openings being in the same direction, and are clamped in place (Fig. 712). The first stitch approximates the two limbs of the bowel near the mesenteric attachment, is carried obliquely for about 2 inches to the border opposite the mesenteric

[1] "New York Polyclinic."

attachment, and continued over the other side (Fig. 712). The septum is cut away, a margin being left ⅓ inch wide. The edge of the shelf made by cutting the septum is sutured. When the suture reaches the end of the shelf, it is continued by invaginating about the rest of the resected ends (Fig. 713).

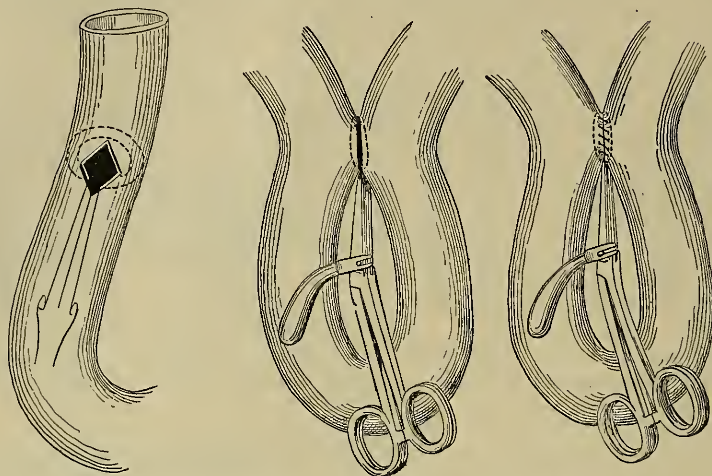

Fig. 714.—Lateral anastomosis with the aid of Laplace's forceps.

Bodine's method of intestinal anastomosis is referred to on page 1122. Laplace, of Philadelphia, has devised an operation in which temporary approximation is effected by means of forceps, the instrument being withdrawn before the abdomen is closed. Junction of two segments of intestine can be quickly and neatly effected by this method and the suture line is even and secure. The objections are that an infected instrument is withdrawn from the bowel and may contaminate the surface; that the septum is tightly squeezed and this septum may slough or may become infected, conditions which will be followed by infection of the suture line; and that contraction of the collar may ensue. The operation is more liable to be followed by leakage or by partial or complete obstruction than is the operation without forceps. Figures 714 and 715 illustrate the use of Laplace's forceps in lateral anastomosis. I usually perform lateral anastomosis with the assistance of Moynihan's clamps, the method being identical with the operation of gastro-enterostomy. Moynihan's operation is shown in Fig. 716.

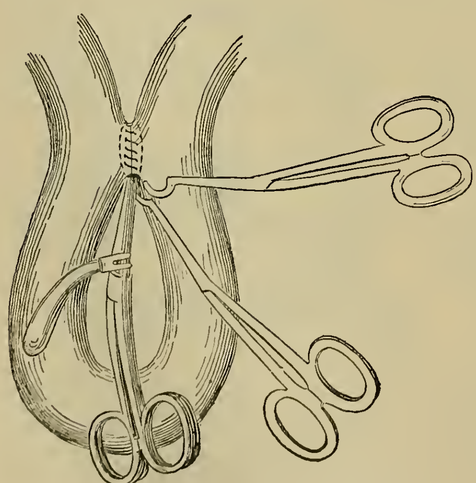

Fig. 715.—Withdrawal of Laplace's forceps.

Consideration of Methods of Intestinal Approximation.—At least 250 methods of uniting a divided intestine have been devised and the best method is a matter of dispute. The essentials of a good method are: rapidity of execu-

tion, the formation of an even and reliable line of junction, and the absence of any considerable permanent septum. The Murphy button can be applied with great rapidity, and rapid operation is of immense importance in intestinal work. The opening left by the Murphy button is small (too small, some surgeons think), but it does not strongly tend in most instances to contract because the tissue-diaphragm is separated by tissue-atrophy and not by inflammatory gangrene. The separation of the diaphragm is a most valuable feature. No other instrument thus cuts away the objectionable septum. Occasionally the opening made by the button contracts and gives trouble; occasionally the lumen of the button blocks with feces; occasionally the button is retained, this latter complication being especially frequent after anterior gastro-enterostomy. If the button is used, liquid food should be given soon after the effect of the anesthetic has passed off, and movement of the bowels should be obtained at an early period after operation and frequent evacuations should be maintained. The button gives better results in end-to-end approximation than in lateral anastomosis. Moynihan's forceps, Laplace's forceps, O'Hara's forceps, the decalcified bone plates of Senn, the catgut rings of Abbe, the segmented ring of Harrington, the catgut strands inside of rubber tubing of Brokaw, Chaput's button, Allingham's bone bobbin, Robson's bone bobbin, Frank's coupler, Clark's bobbin, tubes or plates of potato or carrot, and rings or plates of leather, all have their adherents. Of mechanical appliances, the best are Murphy's button, the bone ring, and Moynihan's forceps. Of recent years many surgeons have abandoned all mechanical aids, and have returned to closure by simple sutures. The ideal operation is without mechanical contrivances. But such devices are time-savers, and to lessen the time of operation will often save life. Further, Moynihan's forceps prevent fecal extravasation and consequent infection. What method to follow must be determined in each particular case by a study of the necessities of the situation. Nevertheless, it may be possible to formulate a few general rules: If the condition of the patient is excellent and the bowel is in a fairly healthy condition, well above and well below the seat of trouble, end-to-end approximation should be performed by circular enterorrhaphy with the aid of Moynihan's clamp, or each end can be closed after resection and a lateral anastomosis be effected with the aid of the clamp. If the condition of the patient is such as to make haste necessary, use a Murphy button. If the bowel below the seat of trouble is much contracted and haste is necessary, do not use a Murphy button, but

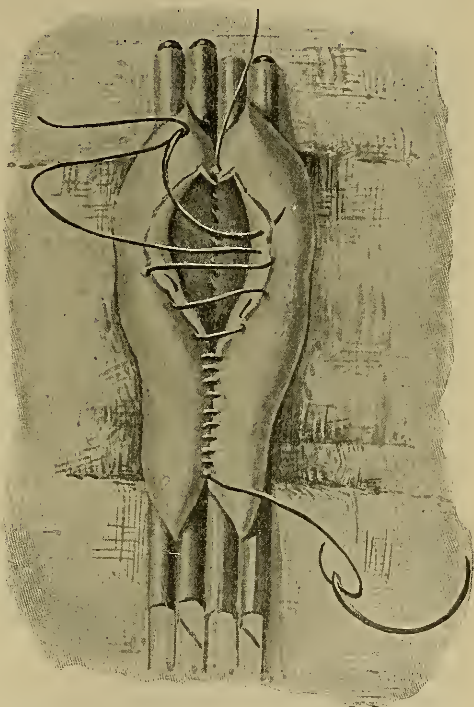

Fig. 716.—Moynihan's inner surfure in lateral anastomosis to show the infolding of the mucosa which results. A loop of the suture lies on the mucous surface (Moynihan).

use Senn's bone plate or Robson's bobbin. If haste is not imperatively necessary, do simple enterorrhaphy. If the surgeon is obliged to join a very much distended bowel to a very much contracted bowel, perform end-to-side approximation (implantation) with the bone plate of Senn or by simple suturing, or else effect side-to-side junction by the method of Abbe or of Moynihan.[1]

Local Intestinal Exclusion.—This operation was introduced by Salzer in 1891. It excludes the fecal current from a portion of the intestine. In complete exclusion the intestine is cut through above and below the diseased portion, and the ends of the healthy gut are united to each other or the end of one portion of gut is implanted into the side of the other. Both ends of the excluded portion may be fastened to the skin, making a double fistula (Von Eiselsberg); the distal end or the proximal end alone may be fastened to the skin, the other end being closed by sutures and replaced within the abdomen. Sometimes each end is closed and dropped back, and a fistula is made in the middle of the excluded portion to permit of drainage. Some operators close each end by suture and drop them back, and do not drain the excluded portion; and others aim at the same end by suturing together the two ends

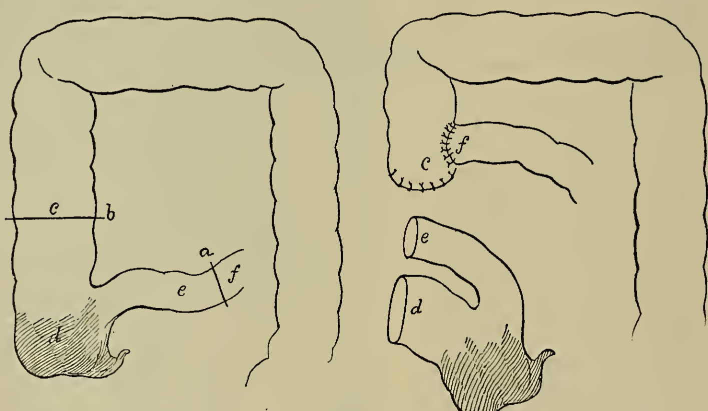

Fig. 717.—Operation of complete exclusion of the cecum: *a* and *b*, Lines of incision; *f* is implanted into *c*; *e* and *d* are sutured to the abdominal wall.

of the excluded part. It seems wisest to suture both ends, or at least one end to the skin (LeDentu, in "Rev. de Gyn. et de Chir.," Jan. and Feb., 1899). It is true this makes a permanent fistula, but if it is not done, the loop may become distended with secretion containing virulent bacteria, a condition which may lead to perforation and death. Exclusion is rarely performed upon the small intestine. It is best suited to the large intestine. If it is done at all, complete exclusion is the best operation (Fig. 717). Partial exclusion is rarely satisfactory. Exclusion has been performed instead of colostomy in cases of intestinal obstruction, but it is best suited to inflammatory areas or tumors, irremovable because of adhesions or some other cause. After the operation the diseased area may improve because of drainage and freedom from irritant fecal matter. In many cases it can be irrigated through the fistula. Sometimes the diseased part improves sufficiently after a time to permit of extirpation.

Surgical Treatment of Ascites Resulting from Hepatic Cirrhosis (Epiplopexy; Talma's Operation).—The portal system communicates with the vena cava by means of a number of small vessels. Normally, only an

[1] See the discussion of this subject by the late J. Greig Smith, in his "Abdominal Surgery."

insignificant amount of portal blood passes by this route to the general circulation. When cirrhosis obstructs the flow of blood through the liver, the radicles of communication between the portal system and the vena cava enlarge and an increased amount of blood is thus sent direct to the systemic circulation. Adhesions develop between the parietal peritoneum and some of the viscera and the collateral circulation is further increased. Thus, Nature seeks to prevent ascites. If, however, the obstruction to the passage of portal blood becomes so great that "the collateral circulation is no longer able to maintain an equilibrium in the blood-pressure in the portal radicles, the pressure thus rises to a point at which transudation takes place and ascites develops" (M. L. Harris, paper read before Chicago Medical Society, Feb., 1902). The theory above set forth is the "mechanical theory"; but, as Harris points out, increased portal tension is not the only factor concerned in the production of ascites, chronic inflammatory changes in the peritoneum being "materially instrumental" in maintaining ascites by lessening the absorbing power of the peritoneum. Influenced by the mechanical theory of causation, Talma, of Utrecht, devised an operation to cure ascites by establishing more free communication between the portal system and the systemic circulation. Drummond and Morison about the same time independently devised a like procedure.[1] This operation is called *epiplopexy*. In some cases the abdomen has been opened and the omentum sutured into the abdominal wound; in others, between the layers of the anterior abdominal wall. The results are slightly better when the omentum is sutured between the layers of the abdominal wall. The gall-bladder may be sutured to the abdominal wall as well as the omentum. The liver and spleen, under surface of the diaphragm, and parietal peritoneum about the liver and spleen are usually rubbed harshly with a piece of gauze. Drainage is not used by most operators. It does not appear to contribute any favorable chances and it exposes the patient to the danger of infection. Morison, however, advocates it, and makes suprapubic drainage, a glass tube being carried into the rectovesical or recto-uterine pouch ("Brit. Med. Jour.," Jan. 20, 1912).

The operation ought to be performed early, before the onset of chronic inflammation of the peritoneum. In a great majority of cases the operation proves futile, and not uncommonly death soon follows from complications or because the disease is very far advanced. In exceptional cases the operation proves of distinct benefit. The operation shows the least mortality and the greatest number of apparent cures when the liver is large; the greatest mortality and the fewest cures when the liver is contracted. The greatly lowered vital resistance of these patients is the imminent danger. Renal disease, cardiac disease, other grave complications, and the absence of sufficient functionating liver substance to maintain life contra-indicate operation (Greenough, in "Am. Jour. Med. Sciences," Dec., 1902).

Harris, in the paper previously quoted, collected 46 cases; 23 of these were instances of alcoholic cirrhosis; 30 per cent. were dead within fourteen days; 52 per cent. were dead within two months; 56 per cent. were dead within six months. Ascites had returned in all of those who died late. At the end of one year or longer 13 per cent. had recovered from ascites. The remaining 30 per cent. were either unimproved or were said to be improved with some ascites.

Of the group of mixed cases constituting the remainder of those Harris collected, 10 per cent. were dead in four days, 25 per cent. were dead in four months. In 40 per cent. no improvement took place. In 10 per cent. the report was too early to give any information. About 15 per cent. were free of ascites after one year or longer, and 5 per cent. were cured of intestinal

[1] "Brit. Med. Jour.," Sept. 19, 1896.

hemorrhage, ascites never having been present. Greenough collected 105 operations: 42 per cent. were improved; 58 per cent. were not improved; 29.5 per cent. died within thirty days. Two years after operation 9 cases were apparently in good health ("Am. Jour. Med. Sciences," Dec., 1902). One of Morison's cases was alive and well eleven years after operation; another was well for six years, when an attack of pneumonia lead to death; another patient remained well for two years, but died after an operation for ventral hernia (Morison, in "Brit. Med. Jour.," Jan. 20, 1912).

Operation for Intussusception.—Air distention and hydrostatic pressure are uncertain; in an advanced case may rupture the gut; even in a recent case may fail or may reduce the bulk of the intussusception, but not its apex. Russell ("Intercolonial Med. Jour. of Australasia," March 20, 1902) alludes to the uncertainty of the method. He used hydrostatic pressure in 5 cases. Two died and 2 recovered. In 1 case the method failed and operation was then performed. It is safer and better to operate early, but if the conservative plan is tried and fails, operation should certainly be done at once, because an early operation enables the surgeon easily to effect reduction, and also because early complications are unusual. The incision is made in the midline above the umbilicus. The surgeon endeavors by manipulation to reduce the intussusception by pushing it back, not by pulling it out. If the intussusception is gangrenous, perform intestinal resection and circular enterorrhaphy. The same rule maintains when malignant disease of the gut exists (D'Arcy Power). It is inadvisable to make an artificial anus. *Maunsell's operation* is suited to cases of irreducible intussusception. It is performed as follows: A longitudinal incision is made in the intussuscipiens. The intussusception is gently pulled upon and is caused to protrude from this opening. Two straight needles threaded with horse-hair are passed so as to transfix the base, and ¼ inch above the needles the intussusception is cut off. The needles are carried completely through, the sutures are hooked up in the middle and cut, and the two ends are tied on each side. These sutures unite the intussusception to the intussuscipiens. The two surfaces are now carefully approximated by sutures. The sutures are cut. The stump is replaced. The longitudinal incision is closed with Lembert sutures.[1]

Russell (Ibid.) reports 16 cases operated upon: 12 recovered and 4 died. In every one of the 4 fatal cases the diagnosis was not made until the disease had lasted several days. In only 2 of the successful cases the diagnosis was made late. If operation is done in the first twelve hours the mortality, even in infants, will probably be comparatively small. If gangrene exists the mortality is enormous (at least 90 per cent.).

Senn's Operation for Fecal Fistula.—Suture the opening transversely with Czerny sutures of silk in order to prevent infection. Cleanse the surface thoroughly. Open the abdomen and separate the edges of the bowel from the parietes. Deliver the portion of bowel which contains the fistula and apply Lembert sutures over the Czerny sutures. Another method is to open the abdomen above the fistula, insert the fingers, cut out the skin and tissues around the fistula in an elliptical course, leaving them attached to the bowel, draw the bowel from the abdomen, pack gauze around, remove the tissues adherent to it, and suture the fistula transversely.

Enterostomy is the making of an artificial anus. If performed in the large bowel, it is called *colostomy*. In some cases of intestinal obstruction it is necessary to open the small intestine, and if this is required, the artificial anus should be made as near as possible to the cecum. The higher above the cecum it is made, the more apt is the patient to die of lack of nourishment. A small intestinal anus may be made in the middle line or in the

[1] T. Pickering Pick, "Quarterly Med. Jour.," Jan., 1897.

right iliac region. The bowel is fixed and opened as directed under Colostomy. In acute intestinal obstruction it may be necessary to open the bowel at once. In such a case Paul's tube (Fig. 718) is very useful. It is made of glass, is bent to a right angle, and has a rim near each end. The large tube is used in the colon, the small tube in the small intestine. A small opening is made in the intestine, the tube is introduced, and is tied in place by a silk suture which surrounds all the coats of the bowel, a gush of feces is caught in a basin, a rubber tube is fastened to the glass tube, and fluid feces are collected in a bottle and beneath an antiseptic fluid.[1] In from three or four days to a week the tube becomes loose and can be removed. Stewart's method of enterostomy was outlined on page 992.

Valvular Cecostomy (Gibson's Operation).—This operation was devised in 1900 by Charles L. Gibson, of New York. It is used in chronic dysentery. It allows us to flush the large intestine and to apply remedies to it. The incision is made over the caput coli, a small puncture is made in it, a soft catheter (No. 30 Fr.) is introduced well into the bowel, and is fixed there as is the tube in Kader's gastrostomy (see page 1087). After ten or twelve days the tube is not kept in place, but is introduced when needed. The fistula closes spontaneously on the discontinuance of introducing the catheter daily. Appendicostomy has, to a great extent, replaced cecostomy, because, as a rule, it is easier and safer. "The appendix may, however, not be of a suitable size or position (retrocecal) to lend itself properly to the procedure" (Gibson, paper read before the Internat. Surg. Assoc. at Brussels, Sept., 1911).

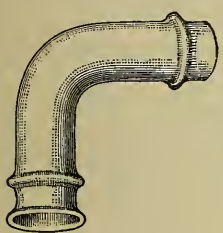

Fig. 718.—Paul's tube.

Fig. 719.—Inguinal colostomy (after Zuckerkandl).

Inguinal Colostomy (Maydl's Operation) (Fig. 719).—In this operation a vertical or oblique incision 4 inches in length is made over the portion of colon to be incised. In all cases when possible do a left inguinal colostomy. In right inguinal colostomy it is more difficult to deliver the bowel than in a left inguinal colostomy, because of shortness or absence of mesocolon at this point of the colon. Right inguinal colostomy has been performed for chronic amebic dysentery. It puts the colon at rest and permits of free irrigation. It is kept open until the dysentery is well. Appendicostomy and valvular cecostomy have replaced it for dysentery. It has also been employed for the treatment of ulceration of the colon. After the incision on the left side the colon usually bulges into the wound, but if it does not, it may easily be found by following with the finger the parietal peritoneum outward, backward, and inward, the first obstruction it encounters being the mesocolon. Draw the colon out of the wound until its mesenteric attachment is level with the abdominal incision. Push a glass bar through a slit in the mesocolon near the bowel, and wrap the ends of the bar with iodoform gauze to prevent slipping. Instead of the bar, a piece of gauze can be employed (Fig. 719), or a bridge

[1] Paul, in "Liverpool Med.-Chir. Jour.," July, 1892.

of skin can be made under the bowel by suturing the two skin edges. In order to make a spur the two parts of the flexure are stitched together by sutures which penetrate to and catch the submucous coat. Stitch the serous coat of the bowel to the parietal peritoneum (Fig. 719). Whenever possible, wait from

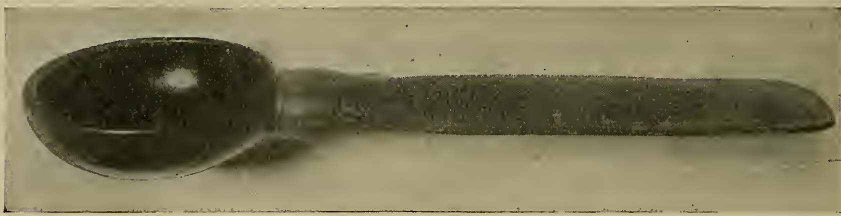

Fig. 720.—Stevenson's bag for inguinal colostomy.

twenty-four to forty-eight hours before opening the gut. The colon is opened by the cautery or by scissors. If the artificial anus is to be permanent, make a transverse incision through the bowel. Cut one-fourth way across the colon when it is first opened, and entirely across at a later period. If the artificial anus is to be temporary, the incision should be longitudinal. Maydl's operation has great advantages: it is quick, certain, reasonably safe, satisfactorily prevents fecal accumulation below the opening, and is rarely followed by absolute fecal incontinence. In many cases the bowels move but two or three times a day. The movements, however, come quickly with but little warning. Sometimes there is no warning. If diarrhea develops, there will be fecal incontinence as long as it lasts. An air-pad covered with gauze may be held in place by a firm belt, or the appliance shown in Figs. 720 and 721 may be worn.

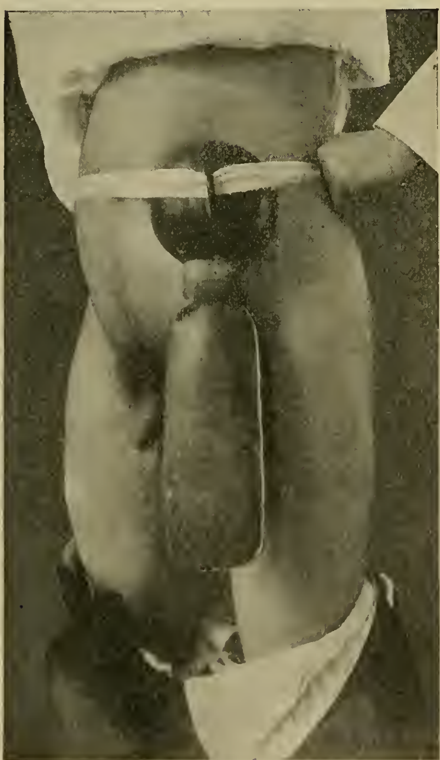

Fig. 721.—Stevenson's bag applied.

Bodine's Operation (Figs. 722, 723).—Bodine's method of colostomy permits of a future restoration of the fecal current by an easily performed anastomosis. This surgeon maintains that the spur after colostomy should reach to and remain at the level of the skin, a condition impossible of attainment by hanging the bowel over a rod or piece of gauze, because a spur thus formed is not thick and rigid and is inevitably dragged below the skin level, and when this dragging has taken place, some fecal matter will pass into the bowel below the artificial anus. Bodine opens the abdomen, sutures the parietal peritoneum to the skin, seeks for the lesion, and draws it with 6 inches of healthy bowel out of the incision. He lays the limbs of the loop side by side. He inserts a silk stitch, beginning at the point where exsection is to be made, and

for 6 inches unites the two segments close to their mesenteric borders. The loop is dropped into the abdomen until the beginning of the suture is on a level with the skin, and at this point it is fastened to the abdominal wound with a continuous catgut suture. The protruding lesion is cut off along the dotted line (Fig. 722). The artificial anus is thus established. When it is desired to close the artificial anus, divide the septum with scissors or a Grant clamp (Fig. 723) and close the abdominal wound.[1]

Lumbar colostomy is a most unsatisfactory operation. It does not completely intercept the fecal current, and it leaves the patient in a condition of wretched discomfort because fecal incontinence is inevitable. A patient who has had lumbar colostomy performed upon him either obtains little benefit, because the feces pass into the bowel below the opening which was made to intercept them or else they pour out of the opening uncontrolled, making the poor unfortunate a living horror to himself and others. It is rarely performed at the present day.

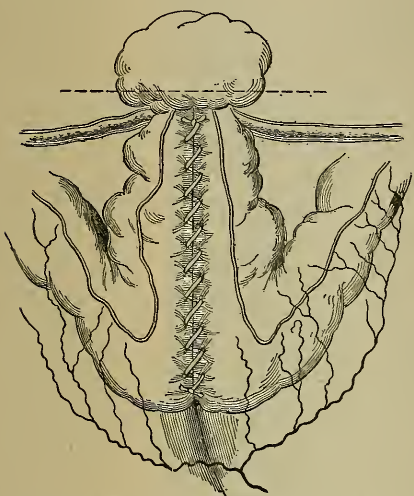

Fig. 722.—Bodine's method of colostomy, showing one side of the loop after it has been sutured, passed back into the cavity and stitched into the abdominal wound. The lesion is left protruding, and the dotted line indicates where the protrusion is to be clipped off.

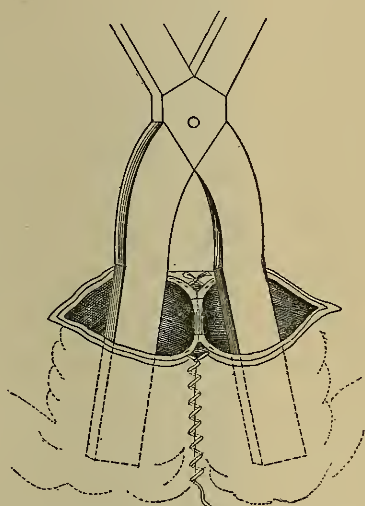

Fig. 723.—Bodine's method of colostomy, showing the septum to be divided in restoring the fecal current; Grant's clamp in position for the division. (In permanent colostomy this septum remains as a rigid and effective spur.)

The **healthy gall-bladder** has a capacity of about 1 oz., and its hue is bluish. If a gall-bladder contains calculi or has contained them, its hue is grayish-white or yellowish (Moynihan).

Congenital Absence of the Gall-bladder.—When the gall-bladder is shrunken and buried in adhesions, it is very difficult to find it at operation. Sometimes it is not found and one may jump to the conclusion that it is congenitally absent. This is occasionally, but very seldom, the case. Gray collected 19 instances of congenital absence of the gall-bladder ("Trans. of Chicago Path. Soc.," 1902). When it is absent the subject seems to have gotten along perfectly well without it.

The Incision for Operations Upon the Gall-bladder and Bile-ducts.—I have employed several methods, and have frequently used Bevan's incision (Fig. 724, B). The primary portion of the incision is shaped like the italic letter *f*. It is by the side of or through the right rectus muscle,

[1] "New York Polyclinic," Feb. 15, 1897.

and is shown by the double line in Fig. 724, B. The primary incision is used for exploration and cholecystotomy. The primary incision is from 3 to 4 inches long, and the extended portions, shown by heavy lines in Fig. 724, B, are added if required (Arthur Dean Bevan, "Annals of Surgery," July, 1899). This incision gives most satisfactory exposure, its edges can be separated without tension, and it injures but few of the nerves of the abdominal walls.

Kocher's incision (Fig. 724, A) gives a very satisfactory exposure. It cuts the two obliques and the transversalis muscle and divides intercostal nerves, but can be sewed up evenly and is seldom followed by hernia. Mayo-Robson's incision (Fig. 724, D) gives an admirable exposure of the common duct, although it damages the right rectus muscle and the nerve-supply of the inner part of the muscle. None of these incisions are entirely satisfactory. Collins's incision (Figs. 724, C, 725) ("Surg., Gynec., and Obstet.," March, 1909) seems to

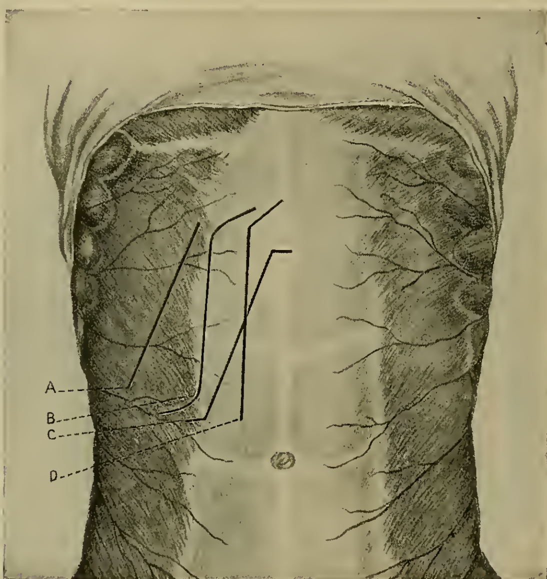

Fig. 724.—Incisions for the surgery of the bile-tracts: A, Kocher's incision; B, Bevan's incision; C, Collins's incision; D, Mayo-Robson's incision (Collins).

largely correct the defects of the previous operations. Collins thus describes his incision:

"The incision for the bile-tracts begins at the inner edge of the right muscle, 1 or 2 inches from the ensiform cartilage, and extends diagonally downward and outward to the outer edge of the right rectus, close to the level of the umbilicus. It cuts through the skin, fat, and anterior wall of the sheath of the rectus (Fig. 725). A short transverse incision about 1 inch in length may be made inward from the upper end of the diagonal incision through the skin, fat, and linea alba; and a similar one through the linea semilunaris at the lower end. In case more room is required the upper transverse incision may be extended further into the anterior and posterior walls of the sheath of the left rectus.

"The rectus muscle is then separated from its sheath. It is easily separated from the posterior portion of its sheath by blunt dissection, but the anterior portion presents some difficulty at the insertion of the linea transversæ, one of which is found about midway between the ensiform cartilage and umbilicus and is crossed by this incision. The attachment of the muscle to

the anterior wall of its sheath is very close at this linea transversa, and requires sharp dissection with knife or scissors.

"When the muscle is thoroughly freed from its sheath except at its outer border, it is easily retracted outward and allows the posterior wall of its sheath and the peritoneum to be incised in the same direction as the skin and anterior wall. The upper end of this diagonal incision through the posterior wall extends into the short, transverse incision across the linea alba. When this last cut is made the incision pulls open and gives ready access to the right upper abdomen." This incision does not damage the intercostal nerves, hence muscular atrophy is avoided. The opening through the different planes of the abdominal wall are not continuous, hence closure will be more

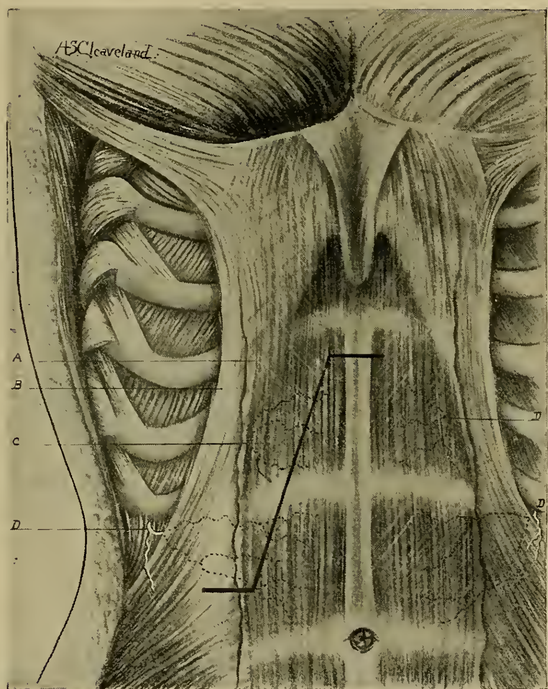

Fig. 725.—A, Anterior wall of sheath of rectus muscle; B, posterior wall of sheath; C, rectus muscle; D, intercostal nerves. The direction of the incision through the skin, fat, and anterior wall of the sheath of the rectus muscle (Collins).

solid. The opening in the posterior portion of the rectus sheath is protected by uninjured muscle.

Cholecystostomy or, as many call it, **cholecystotomy**,[1] is the operation of opening and draining the gall-bladder in order to extract gall-stones or secure the removal of infectious material. - In the hands of the Mayos operations for stone exhibit a mortality of less than 1 per cent.; Kocher's mortality is 2 per cent. When death follows an operation on the gall-bladder or ducts, in about one-half the cases it is due to duct infection and is preceded by grave nervous symptoms (Mayo). Cholecystostomy is performed in cases of acute cholecystitis, in hydrops, and in empyema of the gall-bladder; in gall-stone cases in which jaundice has lasted for four weeks or more, and in colic of the gall-bladder with fever, the colic having recurred a second or third time

[1] First performed by Bobbs, of Indianapolis, in 1867.

(Carl Beck). The operation completed in one stage is performed as follows: The patient is placed recumbent with a sand-pillow beneath the liver and the incision is made. The peritoneum is opened. If the gall-bladder is distended, it is surrounded with pads and aspirated, and is then opened. Gall-stones are removed by forceps, the scoop, or irrigation. The gall-ducts are examined by the fingers external to them before opening the gall-bladder, and are sounded, if possible. If a stone is wedged in the duct, try to manipulate it back into the gall-bladder. If this fails, introduce an instrument from the gall-bladder and break up the stone; if this fails, open the duct, remove the stone, and close the incision in the duct (A. W. Mayo Robson). The only way to be certain that stones have been removed entirely from the cystic duct is to insert a finger and dilate. Sounds are unreliable. After the removal of all stones and fragments pass a rubber tube which has no side perforations into the gall-bladder, purse up the cut in the gall-bladder around the tube by means of a catgut suture, and suture the gall-bladder to the abdominal aponeurosis. If sutured to the skin, a permanent biliary fistula is apt to follow. It will seldom follow if the gall-bladder is sutured to the aponeurosis. A small piece of gauze is retained under the gall-bladder in case there should be a leak into the peritoneum and in case the peritoneum may have been soiled. If gauze causes no trouble it is retained in place from five to eight days. It can then be removed easily and without breaking encompassing adhesions. The drainage-tube, which drains into a bottle outside of the dressings and below the level of the bed, can usually be dispensed with in from one week to ten days. It should not be dispensed with until the bile becomes sterile.

Some surgeons have advocated immediate suture of the gall-bladder after removing a stone (*ideal cholecystotomy*). I believe this is never advisable when the stones are active for harm, because small calculi may be in the ducts and minute fragments of stone are often left in the bladder, and the drainage will remove them. Drainage also relieves the diseased condition of the gall-ducts and bladder. In Kocher's 31 operations by this method, gall-stones re-formed in 3 cases. Further, the operation with immediate suture is decidedly more dangerous when infection exists. The Mayos only employ it in latent cases of gall-stone disease when the existence of stones is discovered during the performance of an abdominal operation.

It is advised by some that the operation of cholecystostomy be performed in *two stages*. First, the bladder is exposed and sutured to the parietal peritoneum. When adhesion takes place, the gall-bladder can be opened without risk of infecting the general peritoneal surface. Riedel advocates operation in two stages, and so did Christian Fenger in certain cases. The two-stage operation is objectionable because it does not permit of satisfactory exploration of the ducts. The *biliary fistula* which is left by cholecystostomy usually closes spontaneously, but may not. If it does not close and the secretion is pure mucus, it is evident that the cystic duct is absolutely blocked and cholecystectomy should be performed.

If the secretion from a persistent fistula is bile and if the common duct is not obstructed, separate the edges of the gall-bladder opening from the parietal peritoneum, endeavoring to avoid entering the abdominal cavity, and close the fistula with Lembert or Halsted sutures. If the secretion is bile and the common duct is obstructed permanently, perform *cholecystenterostomy*. If the secretion does not contain bile and the cystic duct is blocked, remove the gall-bladder. At the end of 1907 Hans Kehr placed his mortality at 2 per cent. ("Jour. de Chir.," Oct., 1908). The report of St. Mary's Hospital, Rochester (the Mayo clinic), for 1912 shows 426 cholecystostomies, with 3 deaths.

The McArthur Drip.—In 1909 Lewis L. McArthur suggested using a biliary fistula as a means for introducing fluid or food into the duodenum. He

proved that if a tube draining bile from the gall-bladder is connected to an irrigator containing salt solution (elevated not more than 20 inches and giving a rate of flow not over 5 or 6 drops a second), there will be a continuous flow of fluid into the duodenum without any discomfort to the patient (McArthur, in "New York Med. Jour.," Jan. 27, 1912). Matas has improved the method by introducing into the duodenum at the time of operation and by way of the common duct a ureteral catheter, through which food, fluid, or medicine can be at any time carried into the duodenum (Rudolph Matas, in "New Orleans Med. and Surg. Jour.," Oct., 1911). The method is used in many cases of obstructive jaundice (after removal of the obstruction). The salt solution relieves thirst, removes toxins, and stimulates the kidneys. It relieves post-operative vomiting, favors intestinal peristalsis, combats flatulent distention, and causes movements of the bowels. Matas points out that liquid food

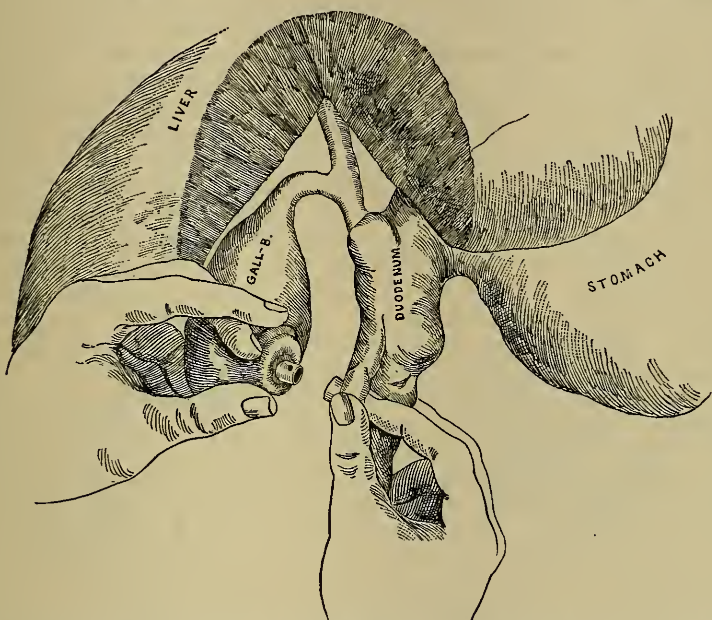

Fig. 726.—Showing method of holding parts while approximating a Murphy button in cholecystenterostomy.

and medicines (strychnin, castor oil, Hunyadi water, etc.) can be given by the biliary route. McArthur believes that the method can be used instead of jejunostomy in certain cases of pyloric obstruction and stomach ulceration.

Cholecystenterostomy[1] consists in making an anastomosis between the gall-bladder and intestine, preferably the duodenum, or, if this cannot be done, the jejunum. It is employed in cases of irremovable obstruction of the common duct. It is done chiefly in cases of malignant obstruction. It is not a suitable operation for gall-stones impacted in the common duct, because it does not remove the cause of trouble, infection of the bile-passages may follow, and the fistula is liable to contract. In those rare cases of common duct obstruction from gall-stones, in which the gall-bladder is distended and the patient is desperately ill, it may be done (Robson). In such a case Robson attaches the gall-bladder to the colon because the operation is easier and because he considers it as useful as the attachment to the duo-

[1] The operation was suggested by Nussbaum, but was first performed by Winiwarter in 1882 ("A Manual of Operative Surgery," by Sir Frederick Treves).

denum. Cholecystenterostomy can be done most rapidly and successfully by means of a small Murphy button. Before the gall-bladder is incised it is aspirated. Murphy's operation is shown in Fig. 726, and is similar in performance to intestinal anastomosis. I believe that Brentano is right and that it is best to do posterior cholecystenterostomy, bringing the jejunum through an opening made in the transverse mesocolon.

Cholecystectomy is the extirpation of the gall-bladder. It was first performed by Langenbuch in 1882. Sometimes primary extirpation is performed; at other times cholecystectomy is performed as a secondary operation, cholecystostomy for drainage having been first performed. Its performance may be demanded by the existence of phlegmonous inflammation or gangrene, ulceration, "in chronic cholecystitis from gall-stones where the gall-bladder is shrunken and too small to safely drain, and where the common duct is free from obstruction" (A. W. Mayo Robson), in empyema with greatly damaged walls, in fistula associated with irremediable obstruction of the cystic duct, the common duct being free, in cancer, and in some wounds of the gall-bladder. Objections to the operation are that drainage can only be obtained by putting a tube into the hepatic or the common duct, and that, should renewed drainage be subsequently required, the necessary operation will prove difficult and dangerous (Maurice H. Richardson, "Medical News," May 2, 1903).

After opening the abdomen the gall-bladder is found and is drawn into the wound. If it is distended and tense or if it is thought "to contain infectious fluid" (Lilienthal), it is packed about with iodoform gauze and emptied by an aspirating trocar. "When the walls are very friable, it is even wise to incise and empty the viscus, closing the opening by ligature or clamp before proceeding with the extirpation. The gall-bladder is usually quite a tough organ, and in the majority of cases it may be grasped with an ovarian ring-clamp applied near its fundus, which at the same time closes the aspiration puncture" (Lilienthal, "Annals of Surgery," July, 1904). The peritoneum which covers the gall-bladder must be divided just below the liver, the gall-bladder is dissected from the liver until the cystic duct is reached, the cystic artery is tied and divided, and if the liver ducts are healthy, the cystic duct is ligated with silk and divided, the stump is touched with pure carbolic acid and is covered with a layer of peritoneum fastened by sutures of fine silk. In cases free from infection it is not necessary to drain the bile-ducts. In cases with cholangitis external drainage is necessary, and it is obtained by incising the hepatic duct and inserting a drainage-tube, or, better, by leaving the stump of the cystic duct open. The report of St. Mary's Hospital, Rochester, Minnesota (the Mayo clinic), shows 255 cases of cholecystectomy with 5 deaths. Howard Lilienthal (Ibid.) reported 42 cases with 1 death. Hans Kehr's mortality at the end of 1907 was 3.6 per cent. ("Jour. de Chir.," Oct., 1908).

Removal of the Mucous Membrane of the Gall-bladder.—Mayo has suggested the removal of the fundus and of all the mucous membrane of the gall-bladder as an occasional substitute for cholecystectomy. By this operation we are enabled to drain the cystic duct and through it the hepatic ducts. A serious objection to the operation is that, as glands pass from the mucous coat to and through the muscular coat, it is impossible absolutely to remove the mucous membrane of the gall-bladder alone (Emil Reis).

Drainage of the Hepatic Duct.—This operation is employed for certain hepatic infections. It was first performed by Cabot in 1892. If the cystic duct is dilated throughout, it may be carried out through that. After opening the gall-bladder a tube is passed through the cystic and into the hepatic duct. It is often done after opening the common duct, a tube being carried up into the hepatic duct. The hepatic duct may be exposed and

right iliac region. The bowel is fixed and opened as directed under Colostomy. In acute intestinal obstruction it may be necessary to open the bowel at once. In such a case Paul's tube (Fig. 718) is very useful. It is made of glass, is bent to a right angle, and has a rim near each end. The large tube is used in the colon, the small tube in the small intestine. A small opening is made in the intestine, the tube is introduced, and is tied in place by a silk suture which surrounds all the coats of the bowel, a gush of feces is caught in a basin, a rubber tube is fastened to the glass tube, and fluid feces are collected in a bottle and beneath an antiseptic fluid.[1] In from three or four days to a week the tube becomes loose and can be removed. Stewart's method of enterostomy was outlined on page 992.

Valvular Cecostomy (Gibson's Operation).—This operation was devised in 1900 by Charles L. Gibson, of New York. It is used in chronic dysentery. It allows us to flush the large intestine and to apply remedies to it. The incision is made over the caput coli, a small puncture is made in it, a soft catheter (No. 30 Fr.) is introduced well into the bowel, and is fixed there as is the tube in Kader's gastrostomy (see page 1087). After ten or twelve days the tube is not kept in place, but is introduced when needed. The fistula closes spontaneously on the discontinuance of introducing the catheter daily. Appendicostomy has, to a great extent, replaced cecostomy, because, as a rule, it is easier and safer. "The appendix may, however, not be of a suitable size or position (retrocecal) to lend itself properly to the procedure" (Gibson, paper read before the Internat. Surg. Assoc. at Brussels, Sept., 1911).

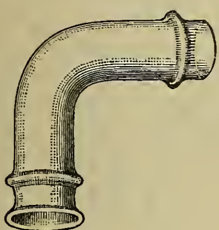

Fig. 718.—Paul's tube.

Fig. 719.—Inguinal colostomy (after Zuckerkandl).

Inguinal Colostomy (Maydl's Operation) (Fig. 719).—In this operation a vertical or oblique incision 4 inches in length is made over the portion of colon to be incised. In all cases when possible do a left inguinal colostomy. In right inguinal colostomy it is more difficult to deliver the bowel than in a left inguinal colostomy, because of shortness or absence of mesocolon at this point of the colon. Right inguinal colostomy has been performed for chronic amebic dysentery. It puts the colon at rest and permits of free irrigation. It is kept open until the dysentery is well. Appendicostomy and valvular cecostomy have replaced it for dysentery. It has also been employed for the treatment of ulceration of the colon. After the incision on the left side the colon usually bulges into the wound, but if it does not, it may easily be found by following with the finger the parietal peritoneum outward, backward, and inward, the first obstruction it encounters being the mesocolon. Draw the colon out of the wound until its mesenteric attachment is level with the abdominal incision. Push a glass bar through a slit in the mesocolon near the bowel, and wrap the ends of the bar with iodoform gauze to prevent slipping. Instead of the bar, a piece of gauze can be employed (Fig. 719), or a bridge

[1] Paul, in "Liverpool Med.-Chir. Jour.," July, 1892.

of skin can be made under the bowel by suturing the two skin edges. In order to make a spur the two parts of the flexure are stitched together by sutures which penetrate to and catch the submucous coat. Stitch the serous coat of the bowel to the parietal peritoneum (Fig. 719). Whenever possible, wait from

Fig. 720.—Stevenson's bag for inguinal colostomy.

twenty-four to forty-eight hours before opening the gut. The colon is opened by the cautery or by scissors. If the artificial anus is to be permanent, make a transverse incision through the bowel. Cut one-fourth way across the colon when it is first opened, and entirely across at a later period. If the artificial anus is to be temporary, the incision should be longitudinal. Maydl's operation has great advantages: it is quick, certain, reasonably safe, satisfactorily prevents fecal accumulation below the opening, and is rarely followed by absolute fecal incontinence. In many cases the bowels move but two or three times a day. The movements, however, come quickly with but little warning. Sometimes there is no warning. If diarrhea develops, there will be fecal incontinence as long as it lasts. An air-pad covered with gauze may be held in place by a firm belt, or the appliance shown in Figs. 720 and 721 may be worn.

Fig. 721.—Stevenson's bag applied.

Bodine's Operation (Figs. 722, 723).—Bodine's method of colostomy permits of a future restoration of the fecal current by an easily performed anastomosis. This surgeon maintains that the spur after colostomy should reach to and remain at the level of the skin, a condition impossible of attainment by hanging the bowel over a rod or piece of gauze, because a spur thus formed is not thick and rigid and is inevitably dragged below the skin level, and when this dragging has taken place, some fecal matter will pass into the bowel below the artificial anus. Bodine opens the abdomen, sutures the parietal peritoneum to the skin, seeks for the lesion, and draws it with 6 inches of healthy bowel out of the incision. He lays the limbs of the loop side by side. He inserts a silk stitch, beginning at the point where exsection is to be made, and

for 6 inches unites the two segments close to their mesenteric borders. The loop is dropped into the abdomen until the beginning of the suture is on a level with the skin, and at this point it is fastened to the abdominal wound with a continuous catgut suture. The protruding lesion is cut off along the dotted line (Fig. 722). The artificial anus is thus established. When it is desired to close the artificial anus, divide the septum with scissors or a Grant clamp (Fig. 723) and close the abdominal wound.[1]

Lumbar colostomy is a most unsatisfactory operation. It does not completely intercept the fecal current, and it leaves the patient in a condition of wretched discomfort because fecal incontinence is inevitable. A patient who has had lumbar colostomy performed upon him either obtains little benefit, because the feces pass into the bowel below the opening which was made to intercept them or else they pour out of the opening uncontrolled, making the poor unfortunate a living horror to himself and others. It is rarely performed at the present day.

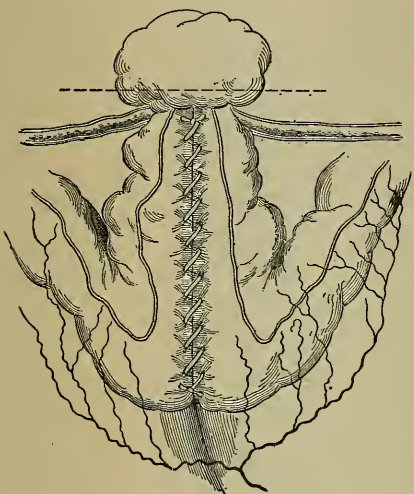

Fig. 722.—Bodine's method of colostomy, showing one side of the loop after it has been sutured, passed back into the cavity and stitched into the abdominal wound. The lesion is left protruding, and the dotted line indicates where the protrusion is to be clipped off.

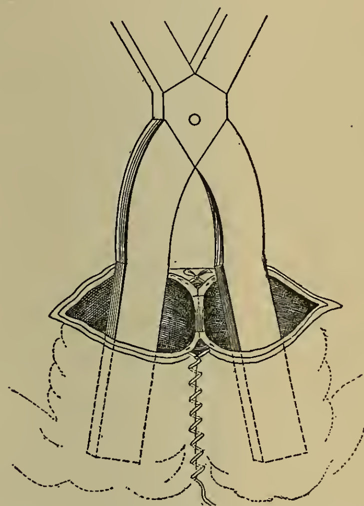

Fig. 723.—Bodine's method of colostomy, showing the septum to be divided in restoring the fecal current; Grant's clamp in position for the division. (In permanent colostomy this septum remains as a rigid and effective spur.)

The **healthy gall-bladder** has a capacity of about 1 oz., and its hue is bluish. If a gall-bladder contains calculi or has contained them, its hue is grayish-white or yellowish (Moynihan).

Congenital Absence of the Gall-bladder.—When the gall-bladder is shrunken and buried in adhesions, it is very difficult to find it at operation. Sometimes it is not found and one may jump to the conclusion that it is congenitally absent. This is occasionally, but very seldom, the case. Gray collected 19 instances of congenital absence of the gall-bladder ("Trans. of Chicago Path. Soc.," 1902). When it is absent the subject seems to have gotten along perfectly well without it.

The Incision for Operations Upon the Gall-bladder and Bile-ducts.—I have employed several methods, and have frequently used Bevan's incision (Fig. 724, B). The primary portion of the incision is shaped like the italic letter *f*. It is by the side of or through the right rectus muscle,

[1] "New York Polyclinic," Feb. 15, 1897.

and is shown by the double line in Fig. 724, B. The primary incision is used for exploration and cholecystotomy. The primary incision is from 3 to 4 inches long, and the extended portions, shown by heavy lines in Fig. 724, B, are added if required (Arthur Dean Bevan, "Annals of Surgery," July, 1899). This incision gives most satisfactory exposure, its edges can be separated without tension, and it injures but few of the nerves of the abdominal walls.

Kocher's incision (Fig. 724, A) gives a very satisfactory exposure. It cuts the two obliques and the transversalis muscle and divides intercostal nerves, but can be sewed up evenly and is seldom followed by hernia. Mayo-Robson's incision (Fig. 724, D) gives an admirable exposure of the common duct, although it damages the right rectus muscle and the nerve-supply of the inner part of the muscle. None of these incisions are entirely satisfactory. Collins's incision (Figs. 724, C, 725) ("Surg., Gynec., and Obstet.," March, 1909) seems to

largely correct the defects of the previous operations. Collins thus describes his incision:

"The incision for the bile-tracts begins at the inner edge of the right muscle, 1 or 2 inches from the ensiform cartilage, and extends diagonally downward and outward to the outer edge of the right rectus, close to the level of the umbilicus. It cuts through the skin, fat, and anterior wall of the sheath of the rectus (Fig. 725). A short transverse incision about 1 inch in length may be made inward from the upper end of the diagonal incision through the skin, fat, and linea alba; and a similar one through the linea semilunaris at the lower end. In case more room is required the upper transverse incision may be extended further into the anterior and posterior walls of the sheath of the left rectus.

"The rectus muscle is then separated from its sheath. It is easily separated from the posterior portion of its sheath by blunt dissection, but the anterior portion presents some difficulty at the insertion of the linea transversæ, one of which is found about midway between the ensiform cartilage and umbilicus and is crossed by this incision. The attachment of the muscle to

the anterior wall of its sheath is very close at this linea transversa, and requires sharp dissection with knife or scissors.

"When the muscle is thoroughly freed from its sheath except at its outer border, it is easily retracted outward and allows the posterior wall of its sheath and the peritoneum to be incised in the same direction as the skin and anterior wall. The upper end of this diagonal incision through the posterior wall extends into the short, transverse incision across the linea alba. When this last cut is made the incision pulls open and gives ready access to the right upper abdomen." This incision does not damage the intercostal nerves, hence muscular atrophy is avoided. The opening through the different planes of the abdominal wall are not continuous, hence closure will be more

solid. The opening in the posterior portion of the rectus sheath is protected by uninjured muscle.

Cholecystostomy or, as many call it, **cholecystotomy**,[1] is the operation of opening and draining the gall-bladder in order to extract gall-stones or secure the removal of infectious material. In the hands of the Mayos operations for stone exhibit a mortality of less than 1 per cent.; Kocher's mortality is 2 per cent. When death follows an operation on the gall-bladder or ducts, in about one-half the cases it is due to duct infection and is preceded by grave nervous symptoms (Mayo). Cholecystostomy is performed in cases of acute cholecystitis, in hydrops, and in empyema of the gall-bladder; in gall-stone cases in which jaundice has lasted for four weeks or more, and in colic of the gall-bladder with fever, the colic having recurred a second or third time

[1] First performed by Bobbs, of Indianapolis, in 1867.

(Carl Beck). The operation completed in one stage is performed as follows: The patient is placed recumbent with a sand-pillow beneath the liver and the incision is made. The peritoneum is opened. If the gall-bladder is distended, it is surrounded with pads and aspirated, and is then opened. Gall-stones are removed by forceps, the scoop, or irrigation. The gall-ducts are examined by the fingers external to them before opening the gall-bladder, and are sounded, if possible. If a stone is wedged in the duct, try to manipulate it back into the gall-bladder. If this fails, introduce an instrument from the gall-bladder and break up the stone; if this fails, open the duct, remove the stone, and close the incision in the duct (A. W. Mayo Robson). The only way to be certain that stones have been removed entirely from the cystic duct is to insert a finger and dilate. Sounds are unreliable. After the removal of all stones and fragments pass a rubber tube which has no side perforations into the gall-bladder, purse up the cut in the gall-bladder around the tube by means of a catgut suture, and suture the gall-bladder to the abdominal aponeurosis. If sutured to the skin, a permanent biliary fistula is apt to follow. It will seldom follow if the gall-bladder is sutured to the aponeurosis. A small piece of gauze is retained under the gall-bladder in case there should be a leak into the peritoneum and in case the peritoneum may have been soiled. If gauze causes no trouble it is retained in place from five to eight days. It can then be removed easily and without breaking encompassing adhesions. The drainage-tube, which drains into a bottle outside of the dressings and below the level of the bed, can usually be dispensed with in from one week to ten days. It should not be dispensed with until the bile becomes sterile.
